THE writings of Lord Bacon, and especially the "Novum Organum," possess a fourfold interest. They have a direct bearing upon the history of philosophy, literature, logic, and physical science; and whatever estimate we may form of their influence upon each of these branches of knowledge, we think that few will fail to admit that Bacon threw a bridge over that vast and deep gulf which separates the ancient from the modern modes of thought, and directly opened a way to our present philosophy and science. Those who would make him the Founder of a sect, the Inventor of induction, or the Father of experimental philosophy, know nothing of his writings. Many had written against Aristotle before his time, many had advocated the collection of positive facts, and the application of a just induction, but they had offered on their part no system which could replace that of Aristotle. When the Scholastics began to abandon their leader, some took refuge in the meagre philosophies of Ramus, of Telesius, of Aconcio, of Nizolius, of Campanella, and of minor men. But when Bacon gave to the world a vast and definite system, and for the first time pointed out the fallacies of the old methods, and suggested new means of interrogating Nature, the scattered refugees from Scholasticism were glad to unite their forces under his banner.

We must bear in mind at the outset that Prof. Fowler approaches the editorship of the "Novum Organum," from the logical and philosophical, rather than from the scientific side. It is improbable that any one man could combine the very exhaustive knowledge of logic, literature, philosophy, and science, necessary for the complete and thorough editing of the work. The main object on the part of our author has been to show that the "Novum Organum" marks an epoch in the history of logic. At the same time he has by no means neglected the other aspects of the work. He has added copious notes, which from every point of view are admirable. It is only here and there that one detects that some of the notes relating to the scientific matters so largely discussed in the second book, were not written by a man of science. Playfair and Whewell are quoted among the older authorities, while Prof. H. G. S. Smith, Mr. Kitchin, and Prof. Clifton, have lent a willing hand in the elucidation of the more knotty points. The most recent ideas on scientific subjects are introduced: such as the kinetic theory of heat, and the conservation of energy. The liquefaction of oxygen and hydrogen is noticed, although much of the work must have been in type when these discoveries were made. Altogether we have no fault to find with the treatment of the work from a scientific point of view.

There have been wide differences of opinion concerning Bacon's influence on the rise and progress of physical science. While Voltaire and the Encyclopedists on the

one side call Bacon "the father of experimental philosophy," Sir D. Brewster asserts that he had no influence whatsoever on the development of our modern experimental method. As to the most recent attacks—those of Liebig and Tchihatchef—they are based on such a very shallow acquaintance with Bacon's works, and are couched in such a pitiful and contemptible spirit, that they are quite unworthy of notice. The true estimate of Bacon's influence on modern science is no doubt to be found between the extremes of the Encyclopedists on the one hand, and of Brewster on the other. Bacon certainly was not the father of experimental philosophy, but most surely he had much to do with our modern scientific method.

Prof. Fowler discusses the nature of Bacon's influence on the progress of science, under nine separate headings. (1) "He called men, as with a voice of a herald, to lay themselves alongside of nature, to study her ways, and imitate her processes. . . . In one word he popularised science." (2) "He insisted, both by example and precept, on the importance of experiment as well as observation." (3) He thus recalled men to the study of facts; and (4) in order to do this it was necessary to free them from the subjection to authority, to which they had so long submitted. "Nor can I doubt," says our author, "that his utterances on this subject had far more influence in producing the intellectual revolution which followed than the utterances of any one of his predecessors, or perhaps than those of all taken together." (5) "The emancipation of reason from the bewitching enchantments of imagination," which he effected (6) by asserting the claims of "a logic of induction which shall do for the premisses, what the old logic, the logic of deduction, does for the conclusions." (7) "The manner in which he insisted on the subordination of scientific inquiries to practical aims, the furtherance of man's estate, and the increase of his command over the comforts and conveniences of life." (8) The "hopefulness" of Bacon, as regards the future of the human race; and finally (9) "the marvellous language in which Bacon often clothes his thoughts."

Taken in connection with all this, the charges which have been brought against Bacon, as a man of science, appear very trivial. It is urged against him that he did not accept the Copernican theory, and that it was fully accepted more than fifty years before the "Novum Organum" was written; but we must remember that the system was by no means firmly established before the discovery of the satellites of Jupiter in 1609. Prof. Fowler remarks that "it is possible to draw up a long list of eminent men, astronomers and others, anterior to, or contemporary with, Bacon, who adopted and taught the Copernican theory; but we believe there were only ten Copernicans in the world, when the "Novum Organum" began to be written. Moreover, we must remember that the anti-Copernicans could boast the great name of Tycho Brahé, while Riccioli, five-and-twenty years after Bacon's death, pretended in his "Almagestum Novum" to refute fifty-seven arguments in favour of the theory. It has also been urged that Bacon did not fully recognise the value of the discoveries of Galileo. Liebig boldly tells us that he was ignorant of the discoveries of Jupiter's satellites, of the ring of Saturn, of mountains in the moon, of the law of the motion of planets, and of the spots of the sun, while in the 39th Aphorism of Book 2 of the "Novum Organum," we read "Secundi generis sunt illa altera perspicilla quæ memorabili conatu adinvenit Galilæus; quorum ope, tanquam perscaphas aut naviculas aperiri et exerceri possint propiora cum cælestibus commercia. Hinc enim constat, galaxiam esse nodum sine coacerrationum stellarum parvarum, plane numeratarum et distinctarum; de qua re apud antiquos tantum suspicio fuit. Hinc demonstrare videtur, quod spatia orbium (quos vocant) planetarum non sint plane vacua aliis stellis, sed quod cœlum incipiat stellescere antequam ad cœlum ipsum stellarum ventum sit; licet stellis minoribus quam ut sine perspicillis istis conspici possint. Hinc choreas illas stellarum parvarum circa planetam Jovis (unde conjici possit esse in motibus stellarum plura centra) intueri licet. Hinc inæqualitates luminosi et opaci in luna distinctius cernuntur et locantur; adeo ut fieri possit quædam seleno-graphia. Hinc maculæ in sole, et id genus: omnia certe inventa nobilia, quatenus fides hujusmodi demonstrationibus tuto adhiberi possit."

If we compare Bacon's writings solely as regards their scientific aspect with those of the greater number of his contemporaries, we find a decided balance in favour of the former; at the same time it must be admitted that men like Gilbert and Galileo were far in advance of our philosopher, both as experimentalists and as discoverers Among Bacon's experimental achievements we may mention, however, the experiment which simultaneously proved the slight compressibility of water, and the porosity of the densest solids, usually alluded to as "the celebrated experiment of the Florentine academicians." Bacon made use of a sphere of lead filled with water, while the Florentines employed a sphere of silver, but this was the only difference. Bacon's experiment was tried more than thirty years before the establishment of the Accademia del Cimento, and was published ("Nov. Org.," lib. ii. aph. 45) nearly fifty years before Megalotti, the secretary of the Academy, made it known in the "Saggi di Esperienze." Mr. Ellis speaks of this as "perhaps the most remarkable of Bacon's experiments."

We may also mention that Bacon endeavoured (we believe for the first time) to determine the relationship between the volume of a vapour and that of the liquid producing it ("Nov. Org.," lib. 2, aph. 40; also the tractate, "Phenomena Universi"). Furthermore, he determined the specific gravity of seventy-three substances, taking gold as the standard. It is true that the method was clumsy, but the table was, at least, far more extensive than that of any previous writer.

In the "Historia Soni et Auditus" Bacon suggests the method for determining the velocity of sound which was employed with so much success by the French nearly two centuries later; and in the same treatise he compares "visibles and audibles" with great acuteness. Again, in the second book of the "Novum Organum," the inquiry into the nature of heat often displays, not only great observational powers, but an elegant application of logical inference.

All this, and much more, Prof. Fowler has pointed out in his exhaustive notes. His work has been, to a great extent, a labour of love; he has bestowed upon it an infinite amount of care and pains, and he has been unwearied in his endeavours to sift everything to the

bottom, and in giving an opinion to act as a just judge; moreover, he has brought to bear upon every part of it his own logical habit of mind. It will be welcomed as a valuable addition to Baconian literature, and to the history alike of philosophy, literature, logic, and science.

G. F. RODWELL

THE AMERICAN CYCLOPÆDIA

The American Cyclopædia: a Popular Dictionary of General Knowledge. Edited by George Ripley and Charles A. Dana. 17 vols. (New York and London: Appleton and Co., 1873-1878.)

IT was not to be expected that so eminently practical a nation as the United States would be long behind the stereotyped peoples of Europe in so indispensable an article as an encyclopædia. It is indeed many years since such a work was published in the States, and that so recently completed by the enterprising firm of Appleton is really a new edition of what some of our readers may remember as "The New American Cyclopædia." On the very surface the present issue is a vast improvement on the old, with its black funereal covers and unpleasant type. Indeed, the present edition may be regarded as really a new work, brought up to date in all departments. Ten years had elapsed between the completion of the old edition and the commencement of the new, and between 1863 and 1873, advances of vast importance had been made in nearly all departments of science. That Messrs. Appleton made competent provision to take account of these advances is evident from the list of men whose services they were able to obtain in bringing out the new edition. Besides the editors-in-chief, Messrs. Ripley and Dana, and four "associate editors," there was a large staff or "revisers," and a "corps" of contributors containing most of the well-known scientific workers of the States. The organisation of the work of the new edition appears to have been excellent, and from a description of the extensive premises devoted to the staff, it seems to have been a British Museum in miniature, with greatly improved arrangements.

The "American Cyclopædia" can scarcely be compared with any existing Cyclopædia in this country. It is not on so extensive a scale as the "Britannica," but is considerably larger than "Chambers'." It is indeed a kind of compromise between these two well-known works of reference; the information is not so conglomerated into huge articles as in the former, nor is it quite so subdivided as the latter—a feature which renders the latter so satisfactory from a purely "reference" standpoint. The "American" has, however, on the whole, stronger affinities with "Chambers'" than with any other; for while there are longish articles on some of the leading departments, still as a rule the great subjects are broken up into their subdivisions. Thus the article "NATURAL PHILOSOPHY" is little more than a reference to the various departments included under the wide term; under "CHEMISTRY" some of the main principles and data of the science are given, with copious references to subordinate heads. Some of these latter, in the two great divisions of physical science, are treated at considerable length, as AFFINITY, ATOMIC THEORY, HEAT, LIGHT, MAGNETISM, and so on, the last-mentioned having been written by the late Joseph Henry. GEOLOGY is a moderate-sized article by Sterry Hunt, and BOTANY is rather short, with, however, a good bibliography appended; the author's name is not given. Prof. Cleveland Abbe contributes a model article on METEOROLOGY, and many kindred subjects are written by the same able hand. One feature which the "American" has in common with "Chambers'" is the giving biographies of living men, a feature the advisability of which we do not care to discuss. Happily the "American" confines itself mainly to a statement of facts in the life and work of living men; eminence in any direction is sufficient to gain admission to these pages, and all sorts of names will be found therein, from "Boss" Tweed to Charles Darwin.

The geography in this new edition is specially well done, one of the largest and best articles in the work being that on the United States. Japan is well done by Prof. Griffis of Tokio, the language being by Dr. Hepburn, of Tokio, and the literature by Mr. Satow, our Secretary of Legation there. We are glad to find that in most cases where it is desirable, satisfactory bibliographies are appended to the articles. Perhaps one of the most distinctive features of the Cyclopædia is the copious index, occupying the whole of the seventeenth volume, which has been prepared for the whole work. This, indeed, doubles the value of the Cyclopædia as a book of reference. Although, as we have said, the great subjects are, as a rule, subdivided into their leading branches, still, throughout the greater number of articles are incidental references containing scraps of valuable information which can find no place of their own. In this way much useful knowledge would be buried but for a good index, and the index prepared for the "American" by Dr. Conant, is one of the most thorough and best planned we have seen. It covers 800 pages, is simple in its method, easily consulted, and admirably adapted not only to bring out all that is in the work, but to enable any one who might desire it, to follow out any subject to completeness. The bold clear type in which the index is printed adds greatly to its usefulness, and, altogether, it is a feature which those who are in the habit of consulting cyclopædias in earnest will know how to value.

The maps and illustrations in the "American" are, on the whole, faithful and good, and ample in quantity, and the type and paper are excellent. In short, in all the features distinctive of a cyclopædia the "American" will hold its own with any in the Old World. It would no doubt be possible to pick faults in plan and criticise some of the particular articles, but this we are not disposed to do where the work as a whole is so eminently satisfactory. The only objection we feel inclined to make is to the price. The volumes are almost the same size as those of "Chambers'," but each is more than double in price, and not very much less than the price of a volume of the "Britannica." This may have been rendered necessary by the great expenses of preparation, but we doubt if at such a price it would command any great sale here. We are surprised to find that the work is sold, not through the regular "trade," but by what is known here as the "canvassing" system. We should have thought that so high-class a work would not have had to depend on any such system for sale. Of course the articles are mainly

written from the American point of view; but to an English reader this adds little that seems peculiar, and were it not for the price of the work, it might very well be put into the English market. Altogether it is highly creditable to publishers and editors, as well as to American enterprise.

OUR BOOK SHELF

The Fairy-Land of Science. By Arabella B. Buckley. (London: Stanford, 1878.)

THE modest preface which Miss Buckley has prefixed to her attractive-looking volume almost disarms criticism, her desire being, she states, simply to awaken a love of nature and of science, while giving pleasure to young people. In this aim Miss Buckley will, we have no doubt, fully succeed.

The substance of this volume was given as a series of lectures to children last spring, at St. John's Wood, and it is at the request of friends who were then present, that the lectures have been printed. We could wish that there were some one in every town equally gifted in rendering science attractive to young people and thus inciting them to a farther and deeper study of natural knowledge.

It would be easy to find fault with some things in this book if we simply regarded it from the narrow standpoint of the scientific critic, without taking into consideration the aim of the author; but as a reading-book to inspire children with a love for nature, which is all the author claims for it, we do not know of a more interesting nor useful gateway to science. The really admirable illustrations with which the book abounds and the pleasant, light manner in which the author carries her readers along from one subject to another will make the "Fairy-Land of Science" a welcome and useful addition to juvenile literature.

In the opening lecture Miss Buckley introduces us to her fairies, showing how things far more wonderful than those related in fairy-tales are daily happening around us, and also how this fairy-land of science may be entered by any one with eyes and with a wish to use these eyes.

In concluding the series of lectures, after showing how it is but the outskirts of this fairy domain which has been touched, the results of a study of science are thus summed up:—

"Pleasant and happy thoughts may thus be conjured up at any time, wherever we find ourselves, by simply calling upon nature's fairies and asking them to speak to us. Is it not strange, then, that people should pass them by so often without a thought, and be content to grow up ignorant of all the wonderful powers ever active in the world around them?

"Neither is it pleasure alone which we gain by a study of nature. We cannot examine even a tiny sunbeam, and picture the minute waves of which it is composed, travelling incessantly from the sun, without being filled with wonder and awe at the marvellous activity and power displayed in the infinitely small as well as in the infinitely great things of the universe. We cannot become familiar with the facts of gravitation, cohesion, or crystallisation without realising that the laws of nature are fixed, orderly, and constant, and will repay us with failure or success according as we act ignorantly or wisely; and thus we shall begin to be afraid of leading careless, useless, and idle lives. We cannot watch the working of the fairy 'life' in the primrose or the bee, without learning that living beings as well as inanimate things are governed by these same laws of nature; nor can we contemplate the mutual adaptation of bees and flowers without acknowledging that it teaches the truth that those succeed best in life who, whether consciously or unconsciously, do their best for others."

This extract will be sufficient to show the happy way in which Miss Buckley addresses her young hearers and readers. At the same time the author would, in our opinion, have done better had she not attempted to travel over so wide a range of subjects as is embraced in her lectures, for we skip from chemistry to physics, then to meteorology, physical geography, and geology, thence to the life of a primrose, afterwards to coal, then to bees, and finally to the fertilisation of plants. This discursiveness leads to occasional looseness of statement, as, for example, employing the terms positive and negative to express the poles of a magnet; it also causes a slurring over difficulties, as in the attempt to explain the measurement of the wave-lengths of light which, with the subject of diffraction, had better have been omitted in a child's book like the one before us.

More durable and equally interesting information might have been given by selecting some one branch of science, examining carefully a few simple phenomena, and regarding them under various aspects; Faraday's juvenile lectures at the Royal Institution—his lectures on a candle, for instance—are the best illustrations of what we mean.

In the study of nature there are very many statements which a child must take simply on the assertion of his or her teacher, with the explanation that their verification is only possible when the child has grown older and wiser; regions are thus opened up beyond its present powers, and the first lesson in education has been learnt—the consciousness of ignorance. We have no doubt, however, that this lesson Miss Buckley would wish to convey as much as we ourselves.

New Commercial Plants, with Directions for their Growth and Utilisation. By Thos. Christy, F.L.S. (London: Christy and Co., 1878.)

THIS is the second of what is evidently intended to form a series of pamphlets on plants either of entirely new economic interest or those whose uses have been extended or developed or are capable of being developed. It is a matter of notoriety that numerous products of the vegetable kingdom require only to be more generally or better known to become more largely used. New products which reach our markets often fall entirely through, simply for the want of a proper appreciation of their value or of some one to take them up and properly test them. This task Mr. Christy seems to have set himself to do, for in his preface he asks for information upon new drugs or plants, such as notes bearing upon their properties and uses, and what is a very valuable point indeed, he appeals to residents in tropical countries for flowers, leaves, and fruits of any useful plant, all of which can be sent any distance in perfect condition in jars or bottles filled with salt and water. This advice is well worthy of consideration by those in distant lands who have opportunities for sending home such specimens, for it often happens that much time, trouble, and expense are thrown away by sending home specimens in such a manner that they rot on the voyage.

As an illustration of what is a "new commercial" product so far as this country is concerned, but which has been known and used in India for a long time, we may mention the Chaulmugra (*Gynocardia odorata*), a full description of which, accompanied by a figure, is given by Mr. Christy. It is not a little remarkable the rapidity with which the oil from the seed of this tree has become adopted by the medical profession in this country for consumptive and cutaneous diseases. Amongst the other plants treated of in the pamphlet under review are *Urostigma vogelii*, Miq., a new source of india-rubber from West Africa, the Mahwa tree (*Bassia latifolia*, Roxb.), a native of the East Indies, the flowers of which are produced very abundantly and yield a large quantity of spirit.

A glance through the pamphlet will give an idea of what kind of products different parts of the world are yet capable of supplying.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

American Weather

I INCLOSE you a cutting from the *Manitoba Weekly Free Press* of December 14, 1878, containing a record of what I cannot but think is a phenomenon unsurpassed in the annals of meteorology. For a month to exceed its average temperature by the amount of twenty-five degrees is scarcely credible even in such a continental climate as that of Manitoba. An editorial paragraph from the same paper which I also inclose will show that the fact has not been overlooked by the Manitobans, and that their attention has also been drawn to the occurrence of the reverse characteristics in the weather over here. Surely the moral of all this is universal synoptic weather charts. The whole thing at present is worked on far too small a scale. The daily papers contain a weather chart which comprises scarcely a quarter of Europe, and of what goes on outside the limits of this we are practically ignorant, unless we hunt up reports when the atmospheric conditions they refer to are long past. Even granting the impossibility of drawing the daily isobars over the North Atlantic, except hypothetically, would it not probably have thrown much light on the proximate causes of, and probable duration of, our recent cold weather here, had we been able to secure a daily synoptic chart of the isobars over America, as well as those over our own islands and the countries immediately adjacent? Surely the valuable results which would follow such an extension of our present system would quite compensate for the extra outlay incurred.

E. D. ARCHIBALD

January 11

"*Weather Record for November*

"The following is Mr. Stewart's monthly record of the weather:—

"The highest reading of the barometer in the month was 29·650 at 7 A.M. on the 7th; the lowest reading was 28·643 on the 26th, showing a monthly range of 1·007 inches. The mean barometrical pressure for the month was 29·1377 inches. The highest temperature in the month was 53·3 on the 17th; the lowest temperature was 10·3 on the 30th; the warmest day was the 17th, the mean temperature being 44·10; the coldest day was the 29th, the mean temperature being 18·25. The mean temperature of the month was 30·75, being 25·73 *higher than the average of the month for the past seven years.* The mean monthly pressure of aqueous vapour was 0·148, and the mean humidity of the month was 83. The mean amount of sky clouded was 0·45. The highest wind in the month occurred at 8 A.M., on the 14th, the force being at the rate of 24 miles per hour. The most windy day in the month was the 14th, the average daily force being 15·92 miles per hour; the least windy day was the 7th, the average daily force being 2·42 miles per hour; the mean monthly velocity was 7·89 miles per hour. The prevailing direction of the wind was south. The total amount of rain that fell during the month was 0·070 inches; total amount of snow, 1·45. Total precipitation of rain and melted snow, 0·220 inches. The Red River opened again on the 18th. On the same day the steamboat *Lady Ellen* arrived from Lake Winnipeg; on the 23rd the steamer *Cheyenne* arrived from Pembina. The Red River was finally frozen over on the 27th. Two auroras and two lunar coronas were seen in the month."

The following is the editorial comment referred to:—

"The peculiar freaks of the weather during the last year or wo have defied the most ingenious efforts of the weather prophets to foreshadow its complexion with any degree of truthfulness. It is a comparatively easy task to depict the general characteristics of a season under ordinary circumstances, when the seasons for a number of years have shown no marked deviation from their usual regularity, but the abnormal nature of the weather of late has set the prophets completely at sea. The predictions of those wise-acres who, a month or two ago, told us the present season was to be excessively severe, and cited the musk-rats, the beavers, and the cornshucks, to support the prognosis, have not been verified up to the present, and without attempting the prophecy business ourselves, we would remark that the indications are against any unusual severity this season. *November has been mild to a marked degree*, and indeed the whole fall, which has just passed into winter, has been exceptionally pleasant. There has been severe weather both in Europe and Asia, and heavy frosts have fallen in England, Austria and Italy—and it has been remarked that when the winters in the Old World are very cold, they are very moderate in America."

The Microphone

IN a recent letter (NATURE, vol. xix. p. 221) Dr. Bleekrode mentions the fact that a microphone through which a strong current is sent emits an audible sound; the electro-dynamical action of the current on its movable part is considered the origin of it.

The experiment is a very interesting one, and is nearly related to the facts I published in NATURE, vol. xviii. p. 642. But I cannot agree with Dr. Bleekrode in the interpretation. It is my opinion that no electro-dynamical action is in play, but only a dilatation at the points of contact.

In a circuit were placed a battery, a tangent-galvanometer, and two pieces of carbon, which supported a third one. A sound was heard and sparks were seen. The galvanometer showed that the intensity of the current increased, the deflection increasing from five to ten degrees. This proves the influence of the clouds formed at the points of contact.

The pieces of carbon were then inclosed in very flat sheets of platinum, and the experiment repeated. No sound was heard; the deflection of the galvanometer rose to 28°. When a rough sheet of platinum was taken the intensity of the current fell again, sparks were seen, and a sound was heard.

Dr. Bleekrode believes that, the coefficient of dilatation of carbon being small, the sound cannot be caused by dilatation at the points of contact. But the temperature of those points is very high, a great part of the heat generated in the circuit being produced here.

I cannot see that his experiment is a true demonstration of the repulsive action between the subsequent parts of a current. In my opinion the experiments of von Ettingshausen (*Sitzungsberichte der Wiener Akademie*, lxxvii. p. 109) are considerably more convincing. Von Ettingshausen found that, with a current which was somewhat stronger than the one I made use of, the influence of the earth-magnetism was almost as great as that of the electro-dynamical action. Moreover, this action depends upon the relative position of the movable part and the other parts of the circuit. Now I have not been able to detect the slightest variations in the sound by changing the position of the movable piece of carbon in relation to the direction of the dipping needle, or in relation to the other parts of the circuit.

I therefore hold to the explanation of the acting of the microphone as a receiver, which I believe I was the first to propose. In my opinion it depends upon the varying dilatation at the points of contact by the varying intensity of the current.

V. A. JULIUS

The Formation of Mountains

THE quotation given by Mr. Wallace from the English Cyclopædia affords a sufficient basis to prove "the more rapid [present] cooling of the interior of the globe than of the crust." I will add a passage from Sir W. Thomson's "Secular Cooling of the Earth," of a like tendency: "I think it cannot be denied that a large mass of melted rock, exposed freely to our air and sky, will, after it once becomes crusted over, present in a few hours or a few days, or at most a few weeks, a surface so cool that it can be walked over with impunity. Hence, after 10,000 years, or, indeed, I may say a single year, its condition will be sensibly the same as if the actual lowering of temperature experienced by the surface had been produced in an instant, and maintained constant ever after." [1]

[1] *Trans.* R.S. Edin., 1862; also Thomson and Tait's "Nat. Phil.," App. D.

This constant temperature of the surface having been once established, the internal parts would be hotter than the crust, and their heat must then necessarily, by the law of conduction, pass from the hotter to the cooler region, and so into and through the crust, and be radiated away from the surface into space, the kind of action which I illustrated in my former letter by the dispersion of a crowd. Thus the interior would tend to fall to the already established temperature of the surface, and thenceforth tend to cool more rapidly than the "crust." For the nearer a stratum lies to the surface, the less cooling will be requisite to bring it down to the temperature of the surface. To take the extreme case; after the lapse of an infinite time the whole globe would eventually become of the temperature which the surface assumed at that already far-distant epoch, and has maintained ever since.

When the superficial strata had early assumed their nearly permanent temperature, they will concomitantly have attained a corresponding permanent volume, which will afterwards have proved too large for the cooling interior, so that they must, in subsiding, have become wrinkled. To this extent, then, I think Mr. Wallace's objections are untenable. Here, however, enters the question, so difficult to answer in nearly all geological problems, of "How much?" For my part, I think I have proved that the mere cooling, though a *vera causa*, would not be of itself a sufficient cause to account for the inequalities existing now, at what must be, judging by the enormous store of heat still within the earth, a comparatively early stage of the cooling.[1] O. FISHER

Harlton, Cambridge, January 18

Leibnitz's Mathematics

IN NATURE, vol. xix. p. 196, I see there is a letter respecting the claims of Newton and Leibnitz to the discovery of the differential calculus. In view of any future discussion of this matter it seems to me that the following extract from a letter of Leibnitz to James Bernoulli is worth the consideration of the advocates of both claimants:—

"Ego qui semper hoc habui eximium, ut essem mortalium docillimus, sæpeque luce ex unius magni viri verbis pauculis hausta innumera mea meditata nondum matura delevi; statim arripere monita summi mathematici."—Ex epistola Leibnitii ad Jac. Bernoullium, April, 1703, data.

The sense of this passage may, I think, be fairly rendered into English as follows:—

"I [am one] who ever regarded this as most important, that I should be most apt of mortals to receive instruction, and frequently light having been drawn from a very few words of a great man, my countless meditations not yet ripened I have blotted out forthwith to seize upon the hints of the most eminent mathematician." JAMES BOTTOMLEY

Lower Broughton, near Manchester, January 13

I HOLD myself prepared to make good my own assertions, and to respond to Mr. A. B. Nelson's call as soon as I know whether Prof. Tait has abandoned his position, or, if not, what he has to say in justification of his proceeding in denying Leibnitz to be a mathematician and affirming him to be a thief.

I am sure the editor will allow me to reply to his postscript. It is certainly not to be presumed, as a matter of course, that when Prof. Tait "lets pass such a challenge he has given up his point." But I do insist upon it that this "hard-worked scientist" had no right to pass it by after having provoked it. He put himself in the wrong, and I left him there.

But as to this being a question of merely "antiquarian interest," I take leave to deny it. I revere the name and intellect of Leibnitz, and I, for one, have a human interest in clearing that name from a foul slander. Nor should we pass by the main issue to discuss the collateral question which the editor raises in respect of Gregory's series. C. M. INGLEBY

German Degrees

IT having come to the certain knowledge of the Faculty of Philosophy in the University of Erlangen that a fraudulent trade is carried on in England under a pretence of procuring doctor diplomas of the said Faculty, I consider it in the interest of the public hereby to make it known that promotions *in absentia* are not conferred in that faculty, and that no one in England, or elsewhere, is, or has ever been, authorised to confer or negotiate for the conferring of such diplomas.

E. LOMMEL,
Dean of the Faculty of Philosophy,
University of Erlangen, Bavaria

Feeding a Python

THE following details of a recent attempt to feed a python now at the Raffles Museum, Singapore, may be of interest as upsetting previous ideas as to the certainty of that reptile's attack:—

The python in question is a fine specimen caught on the island, for the sake of the reward given by the police in such cases, and measures about 22 feet in length. It has been in my charge for about two and a half months, during which time it has not been fed. About ten days since it commenced casting its skin, and, as is usual after that proceeding, was unusually lively, snapping at a stick put into the cage, and in one or two instances narrowly missing the attendant's hand. The reptile, I should mention, escaped from its cage just before casting, but having taken refuge beneath some odds and ends of timber near the museum, was recaptured without difficulty, and was then placed in a cage about 5 feet square every way.

A pariah dog having been obtained, it was introduced, muzzled, into the cage, the muzzle being then slipped. While entering, the snake struck twice at the dog's hind-quarters, but without seizing it. The dog crept into a corner and sat down. Two or three more blows were then made by the snake, but, as before, without gripping, and the dog was then seen to have been struck by the teeth on the fore-quarters, the punctures slightly bleeding. *For nine successive times* the snake struck at the dog with the same ill-success, and as it was then growing dark, the shutter of the cage was closed. Early next morning the snake was found coiled round the dog, which it had killed and commenced to swallow; but a Malay attendant having touched the python with a rod, it untwined itself and retreated to a corner of the cage, refusing to again touch its prey.

I may be misinformed, but have always understood that snakes of the python or boa tribe seldom renew their attacks if the first fails; and I shall be glad if you can direct me to any published experience on the subject. The python in question is a male.

Singapore, November 25, 1878 N. B. D.

Shakespeare's Colour Names

I FEAR it would be somewhat rash to convict Shakespeare of colour-blindness, or even vagueness in the use of colour-names, solely on the evidence of the Nurse in "Romeo and Juliet"—a lady who is the Mrs. Malaprop of the play, and whose extraordinary faculty for the confusion of terms may perhaps have contributed somewhat to the "merriness" with which she credited her husband. It is possible that the Nurse—in the passage quoted by Mr. J. J. Murphy (NATURE, vol. xix. p. 197)—meant to convey the idea of a *hazel* eye, which would not be far removed in colour from that of an eagle, but also often has a slight tendency to a greenish hue. The nurse, not being particular as to the precision of her descriptions in general, refers to it as green.

It is likely besides that Shakespeare deliberately intended the incongruity, just as in the "Midsummer Night's Dream" he makes the bumpkin who acts Thisbe in that piece of "very tragical mirth," *Pyramus and Thisbe*, lament

"Those lily brows,
This cherry nose,
These yellow cowslip cheeks,
. . . . .
His eyes were green as leeks."

This passage indeed shows that Shakespeare knew perfectly well the chromatic meaning of green.

A very cursory glance through Shakespeare will show innumerable lines where colours are referred to in their true and exact sense.

Here are a few passages selected with special reference to the colours green and blue.

Prospero's description of the witch Sycorax:—

"This blue-eyed hag."—*Tempest*, i. sc. 2.

(The ideal Scandinavian witch.)

"... white and azure, laced
With blue of heaven's own tint."
Cymbeline, ii. sc. 2.

"Whose ranks of blue veins."—*Lucrece.*

"Those blue-veined violets."—*Venus and Adonis.*

"Where fires thou find'st unraked, and hearths unswept
There pinch the maids as blue as bilberry."
Merry Wives of Windsor, v. sc. 5.

"And *Hony soit qui mal y pense* write
In emerald tufts, flowers purple, blue, and white,
Like sapphire, pearl, and rich embroidery."—*Ibid.*, v. sc. 5.

Here there is no confusion. The comparisons are exact and beautiful. Again we have—

"When wheat is green, when hawthorn buds appear."
Midsummer Night's Dream, i. sc. 1.

The season indicated shows there was no confusion between green and *brown.*

We must not forget the well-known song—

"When daisies pied and violets blue,
And lady-smocks all silver white,
And cuckoo-buds of yellow hue
Do paint the meadows with delight."
Love's Labour Lost, v. sc. 2.

And to conclude our comparisons of green and blue—

"... I will rob Tellus of her weeds
To strew thy green with flowers: the yellows, blues,
The purple violets, and marigolds,
Shall as a chaplet hang upon thy grave."
Pericles, iv. sc. 1.

Returning to the colour of eyes. Shakespeare not only knew a blue eye, but could discriminate, and appreciate the beauty of a grey eye—a shade which often does duty for blue. The lovely rivals Julia and Sylvia are so endowed—

"Her eyes are grey as glass—and so are mine."
Two Gentlemen of Verona, iv. sc. 4.

"... Thisbe, a grey eye or so."
Romeo and Juliet, ii. sc. 4.

I think the above quotations afford good proof of the poet's correctness of colouring with regard to green and blue. It is true that he occasionally uses a small degree of licence with purple and blue, in the case of violets; but clearly not from unconsciousness of the difference. I cannot remember any instance where he confuses green with blue except purposely and humorously.

In the use of other colours Shakespeare is in most instances I am acquainted with equally true to nature. To give examples would occupy too much space; but if there are exceptions I have no doubt that your correspondents—now that the matter is broached—will be able to furnish them.

Sligo, January 10 EDWARD T. HARDMAN

Intellect in Brutes

THE following incident may interest some of the readers of NATURE, as affording evidence of the possession and exercise of reasoning power by a brute. During the present frost the window-sills of my drawing-room are supplied with bread for the benefit of the birds, who, finding food there, are constantly fluttering about the windows. One day a large water-rat was seen on the window-sill, helping himself to the bread. In order to reach the window he had to climb to a height of about thirteen feet: this he did by the help of a shrub trained against the wall. Neither instinct nor experience will easily account for his conduct: since he never found food there before. If neither experience nor instinct, what save reason led him? His action seems to have been the result of no small observation and reasoning. He seems to have said to himself—I observe the birds are thronging that window all day; they would not be there for nought; it may be they find there something to eat: if so, perhaps I too might find there something which I should like. I shall try.

Bardsea EDWARD GEOGHEGAN

OUR ASTRONOMICAL COLUMN

OLBERS' COMET OF 1815.—On March 6, 1815, Olbers discovered a small comet at Bremen, in about 49° right ascension, and 32° north declination, or between Perseus and Musca; it had an ill-defined nucleus and was not visible without telescopic aid. The first parabolic elements were calculated by Olbers himself, and he was followed by Bessel, Gauss, Triesnecker and others in the determination of similar orbits. Ephemerides founded upon them showed that the comet would be observable for a considerable period, and as the result proved observers were not negligent of this circumstance. Gauss, writing to Bode on April 24, alludes to the long visibility of the comet, and the probability that elliptical elements would be found, but this remark apparently was merely intended to imply that the grasp which a long course of observation would afford upon the orbit, might lead to an ellipse, not that Gauss had remarked any sensible deviation from parabolic motion; indeed he mentions that he had not then reduced his April observations. The first detection of the inadequacy of the parabola to represent accurately the comet's course, is due to Bessel: he had calculated parabolic elements from observations on March 11, April 11, and May 20, which, while agreeing well with the positions employed, gave the right ascensions sensibly too small from March 11 to April 11, and between April 11 and May 20, as decidedly too great, even to as much as 4′, and on May 26, the calculation was again many minutes in defect; these differences naturally induced Bessel to relinquish the parabolic hypothesis, and after some disappointment from the failure of the first method he employed, he communicated to Olbers on June 23 the elements of an elliptical orbit, in which the period of revolution was a little over 73 years. At the end of June Gauss deduced an ellipse with a period of 77 years, and soon afterwards Nicolai, then assistant to von Lindenau at Gotha, added a further confirmation of the elliptical character of the orbit, assigning a revolution of 72½ years. On July 22, being in possession of observations to the middle of the month, Bessel improved upon his first calculation, and now found an ellipse with a period of 73·8968 years, which was made the foundation for his subsequent investigations, of which we have presently to speak. Thus was the periodicity of the comet established, and Bessel, after remarking upon the importance of the addition to the system (at that time Halley's comet was the only one that could be considered certainly periodical) he proposed that it should bear the name of its discoverer—Olbers.

Besides a long series of observations taken by Olbers himself, the comet was observed by Gauss at Göttingen, Bessel at Königsberg, Triesnecker at Vienna, Struve at Dorpat, Oriani at Milan, Lindenau at Gotha, Maskelyne at Greenwich, and Bouvard at Paris. Its distance from the earth continued pretty nearly constant (about 1·45) during the greater portion of the time it was visible, and at no period was it a conspicuous object; its nucleus was pretty bright at the beginning of May, and it then had a tail about 1° in length.

On the disappearance of the comet Bessel collected the observations which extended to August 25, the last having been made by Gauss at Göttingen; indeed, he was the only observer after July 25. He then commenced the work which is incorporated in his great memoir upon this comet, published in "Abhandlungen der königlichen Akademie der Wissenschaften in Berlin, 1812–13," a volume which was not published until 1816. He formed ten normal positions, in which all the observations appear to be brought to bear, excepting those at Greenwich and Paris, which were doubtless unknown to him. He corrects these normals for the effect of perturbations from the action of Venus, the Earth, Mars, Jupiter, and Saturn, during the comet's visibility, and by a fine series of observations of the sun at Königsberg between March 8 and August 29, 1815, he applies corrections to the sun's places obtained from Carlini's first tables. Equations of condition were then formed and solved on the method of least squares, and thus the following definitive elements of the comet's orbit in 1815 were obtained:—

Perihelion Passage, April 25·99867, M.T. at Paris.

Longitude of the perihelion	149° 1′ 55″·9	1815·0
,, ,, ascending node	83 28 33·6	1815·0
Inclination of the orbit to ecliptic... ...	44 29 54·6	1815·0
Excentricity	0·93121968	
Semi-axis major	17·63383	
Logarithm of perihelion distance	0·0838109	
Period of revolution	74·04913 years.	

Motion—direct.

These elements represent the normals upon which they are founded very closely, considering that observations of comets in 1815 did not pretend to the degree of precision which is now sought to be attained, and, moreover, were subject in the reductions to errors in the places of the comparison stars.

But Bessel's labours did not stop here. With a special interest in the comet of 1815, not, it may be presumed, alone due to its exceptional character, but in no small degree to the circumstance of its having been detected by his most intimate and revered friend, Olbers, Bessel undertook, and in the year of its appearance accomplished, the laborious task of computing the perturbations of the planets Jupiter, Saturn, and Uranus upon the motion of the comet during the present revolution, and so determining the epoch of the next perihelion passage. The principal details of this work are comprised in the memoir to which we have already referred. The masses of Jupiter and Uranus were Laplace's, while the mass of Saturn was taken from Bouvard's tables. The whole period is divided into three sections, the first extending from August 4, 1815, to July 30, 1833; the second from the latter date, with new values of the semi-axis and excentricity to July 21, 1869, and the second from July 21, 1869, to the next perihelion passage. The action of each of the three planets tends to accelerate the comet's return, that of Jupiter by upwards of two years; the final result indicating an acceleration of 824·51 days, with reference to the period belonging to Bessel's definitive ellipse for 1815; it was thus found that the duration of the actual revolution would extend to 26222·4 days, and consequently the next perihelion passage is fixed to February 9·4, 1887. This conclusion will be affected not only by the imperfect values of the planetary masses which were available when Bessel undertook the investigation, but in a greater degree by the uncertainty which still remained as to the precise length of the revolution at the last appearance; this Bessel found to extend to ± 0·27657 of a year, or 101 days.

With such an amount of probable error attaching to Bessel's result it must soon be a matter for the consideration of the astronomer, whether a nearer approximation may not be yet attained. We have much more accurate values of the masses of Jupiter, Saturn, and Uranus than Bessel possessed, and are able to take into account the influence of Neptune, though this is not likely to be very material. Fortunately, in several series of observations, the observed differences of right ascension and declination between the comet and the comparison stars are preserved to us, and thus we can reduce the observations anew, with much improved positions of many of the stars and with modern elements of reduction. The series of observations thus available include the long one of Olbers (*Berliner astronomisches Jahrbuch*, 1818), and those of Greenwich, Paris, and Dorpat. It is a work which, together with the recalculation of the perturbations to the next perihelion passage, may perhaps be made the subject of a prize by one or other of our scientific academies; on the last return of Halley's comet, the first approximation to the epoch of arrival at perihelion was due to action of this kind on the part of the Academy of Turin, and though a much higher degree of interest attached to the reappearance of that famous body, we do not despair to see Olbers' comet deemed worthy of a new and more refined calculation.

If these cometary bodies wandering into the confines of the solar system from the stellar spaces are fixed therein by the action of one or other of the planets, it will have been owing to a very close approach to the planet Mars that Olbers' comet presented itself in 1815, moving in an ellipse of moderate dimensions. The nearest approach of the two orbits in that year was 0·07 in 86°·4 heliocentric longitude, but this distance must have varied in successive revolutions through the perturbations of the other planets, and at some past time there may have been an intersection of the orbits and a close encounter of the two bodies.

METEOROLOGICAL NOTES

BEFORE the commencement of the summer rains this year Mr. Eliot, the officiating meteorological reporter to the Government of India was called upon for a report on the prospects of the season. His reply, to which we have already referred in the "Notes," consisted of a short *résumé* of the most important characteristics of the southwest monsoons of recent years, from which the following conclusions were deduced:—"1. The persistent excessive pressure over Northern India at the present time (June, 1878), tends to diminish the baric gradient between Southern Asia and the Mid-Indian Ocean, and if this is not compensated by increased pressure over the sea area to the South of India, the monsoon current will be below its average strength. 2. There appear to be no strongly-marked abnormal variations of pressure over Northern India. It is therefore probable that the rainfall will be much more equally distributed than last year. 3. Comparing the present year with 1865, it is probable that the heavy rainfall during the cold weather, and more especially in May, will slightly retard the advent of the monsoon in Upper India. 4. The probable effect of the low pressure along the Bombay coast cannot be determined except by comparison with last year. It appears to promise fairly abundant rain over that portion of the country." These conclusions have now been subjected to the test of experience and are found to have been verified in almost every particular. The southerly current from the Indian Ocean has been decidedly below its normal strength; the rains set in from a fortnight to a month after the usual time; every district in the country has received a moderate supply of rain, though the average rainfall for the whole country has been less than usual, and over the Bombay Presidency, from Belgarum to Kurrachee, the rainfall has been in excess of the average for previous years. The only peculiarity of the monsoon of 1878, that was not predicted, was the frequent recurrence of heavy falls of rain over a few small and well-defined areas; but this would seem to be the character of the rainfall of every year in which the monsoon current is of less than the usual strength. The percentage of verifications reached by Mr. Eliot has thus been as great as that attained by the American observers, and the predictions in his case were made months, not days or hours, in advance. The same meteorologist has recently made a discovery which promises to be of the greatest possible value in connection with the system of storm-warnings to the ports round the Bay of Bengal. It is that a cyclonic vortex, when generated in the middle of the Bay, always travels towards that part of the coast where the wind velocity for the time being is least in comparison with the average velocity for the same place and time of year. This law has been verified by almost all the cyclonic disturbances that have occurred in the Bay since a chain of meteorological observatories was established round it, and it lends a great deal of support to the theory that a cyclonic vortex is developed through the accumulation, concentration, and condensation of aqueous vapour over a region of comparative calm. All that appears now wanted to

render cyclone prognostications for the Bay of Bengal almost absolutely certain is a submarine cable to the Andaman and Nicobar Islands, by which the meteorological stations on these islands, near the place of origin of all the great cyclones of the Bay, would be brought into telegraphic communication with the rest of the empire.

IN his "Tenth Contribution to Meteorology," which appears in the *American Journal of Science and Arts* for the present month, Prof. Loomis gives the results of an examination he has made as to the course of seventy-seven storms after leaving the eastern coast of the United States, these storms having occurred from March, 1874, to November, 1875. Of these seventy-seven storms he was able to follow thirty-six of them entirely across the Atlantic Ocean, eight of them, however, becoming merged in other storms before reaching Europe. The annual average of storms which are found to cross the Atlantic from the United States to Europe is eighteen, and nearly all of these storms pursued a course north of east, passing in their eastward course considerably to the north of Scotland; indeed, in only four of the storms did the centre pass as far south as the north of England. Prof. Loomis concludes that, when a storm with a centre depression at least below 29·5 inches leaves the coast of the United States, the probability that it will pass over any part of England is only one in nine; that it will occasion a gale anywhere near the English coast, one in six; and that it will give rise to a fresh breeze, one in two. A characteristic feature of these storms is the slow rate of their onward progress in crossing the ocean, as compared with their rate over the United States—a feature of the utmost possible importance in attempting to predict the time of their descent on the shores of Europe of those American storms which cross the Atlantic. About half of the whole number of the storms originated in the neighbourhood of the Rocky Mountains, five in or near Texas, and four were distinctly traced to the Pacific coast. Of six West India cyclones which occurred in the same time only two could be traced across the Atlantic, and even one of these became blended with another storm. The rest of the paper is taken up with a discussion of the fluctuations of the barometer on Mount Washington, 6,285 feet, and Pike's Peak, 13,960 feet, as compared with what takes place on the level ground at the base of these mountains. As regards Mount Washington, the valuable result is arrived at that the diurnal maxima and minima of the barometer occur more than three hours later at the summit than at the base, showing an average retardation of one hour for each 900 feet of elevation. In the case of Pike's Peak, the rate of retardation is one hour for an elevation of 1,380 feet. It is evident from these figures that the law of the rate of retardation is yet to be sought, one of the most important factors, in all probability, being the absence or presence of high plateaux and their extent near the high station, to which must be added the latitude of the place. Observations of the wind at these high levels show, just as at places near sea-level, a circulation about a low centre, the movement of the wind being approximately at right angles to the direction of the low centre; and further, that at the height of Mount Washington, the low centre of storms sometimes lags behind the low centre at the surface of the earth as much as 200 miles. This last result is so vital in the theory of storms as to demand a much more extended examination, the most special care being taken that the retardation of the time of occurrence of the diurnal barometric minima be allowed for in the discussion.

IT is with extreme satisfaction we learn that at a recent meeting of the Council of the Scientific Association of France, M. Mascart, Director of the Meteorological Department, submitted a proposal from the Departmental Commission of Vaucluse, for the establishment of an observatory on the top of Ventoux, situated to the north-east of Carpentras, and rising above all the surrounding summits to a height of 6,300 feet above the sea. This observatory in the south of France, along with the observatories of Puy de Dôme in the north, and of Pic du Midi in the south-west, may be regarded as furnishing France with an enviable system of elevated observatories for meteorological observations such as no other country possesses, thus putting French physicists in possession of the essential data whence the more difficult meteorological problems may be attacked, and the systems of weather-warnings for navigation and agriculture more rapidly developed and improved. It is estimated that 150,000 francs will be required to establish the station, of which sum there are already subscribed by M. R. Bischoffsheim 10,000 francs, by the Commune of Bédoin, situated at the foot of Mt. Ventoux, 10,000 francs, the Council of the Scientific Association 500; and as the Meteorological Commission of Vaucluse has opened a subscription-list, the General Council of the Department has promised to aid in forming the roadway up the mountain, and a subsidy is looked for from the Minister of Public Instruction, the establishment of this important observatory will doubtless soon become an accomplished fact.

GEOGRAPHICAL NOTES

WITH reference to the reports that Prof. Nordenskjöld's vessel had got shut in by the ice near East Cape, in Behring Strait, the Committee for Promoting Russian Trade and Industry have resolved to apply to the Governor-General of Eastern Siberia, requesting him to assist in instituting a search for Prof. Nordenskjöld, and in obtaining more certain information as to the situation of the expedition. Mr. W. H. Dall, the well known U.S. Alaska explorer, has written a letter to an acquaintance in Stockholm, mentioning the previously-reported statement of whalers, from which it is supposed that the *Vega*, has been stopped by ice east of Cape East. Should this be the case, Mr. Dall entertains no fears for the fate of the expedition. If these suppositions be correct, he says, "the breaking up of the ice next July will leave open water for the *Vega* to proceed to Behring Strait. Vessels pass to westward of East Cape every year. There is a creek there. (The letter here gives a sketch map describing a bay, with a small island in the middle of it, and an anchorage inside.) A river with fresh water runs into the bay, and on the coast is a native village. This is not marked in the ordinary maps and charts, and it is just here that the vessel, according to the repots of the natives, must be lying. She can safely winter there. There is a large village, inhabited by Tchuktchees, who would be able to supply fresh meat. This place is situate not more than 200 English miles from the white men's trading station at Plover Bay. If the *Vega* is lying there, the success of the operation is practically achieved, because, as I said, the bay is open every year, and does not get closed by ice until October. Vessels sail there, and carry on trade every summer."

THE last number of the *Isvestia* of the Russian Geographical Society contains an interesting paper by M. Grigorieff, on the temperature and density of water in the Arctic Ocean, along the coast of Russian Lapland, and in the White Sea, being the result of observations carefully made on board the schooner *Samoyede*, by means of good instruments. As to the Arctic Ocean, M. Grigorieff confirms the existence of a warm branch of the Gulf Stream which flows along the coast as far as Gavrilovskiye Islands, and thence turns due east to the Kanin Peninsula and Kolgueff Island, and further, to the Moller Bay on Novaya Zemlya. Beneath this warm current there is a cold one flowing in an opposite direction at some depth. When it meets with a rising bottom, and especially with the deep bank of less than 100

fathoms under 71° N. lat., this denser and cold current is compelled to change its direction, and makes its way between the Gulf Stream and the shore; hence the low temperatures and great density of water at the Lapland coast, in the space between Svyatoy Nos and the Seven Islands. The density of the eastern (North Cape) branch of the Gulf Stream (1·025 to 1·026, figures which correspond to a percentage of salt of from 3·28 to 3·41), seems to be smaller than that of the Spitzbergen branch, where Nordenskjöld has found a percentage of salt as high as 3·625. As to the White Sea, M. Grigorieff denies the entrance of a branch of the Gulf Stream into that sea, as was supposed some years ago by Prof. Middendorff; the Gulf Stream does not penetrate further than the Gulf of Mezen, and the warm temperatures observed by Middendorff are due to purely local causes. On the contrary, a cold polar current enters the White Sea along the Tersky coast, whilst the current which flows out of the sea into the ocean, follows the Winter and Kanin Coasts. The water of the White Sea on the whole has a very low temperature, especially in the deeper parts; on depths more than 100 fathoms the temperature is always below 32° Fahr., and this, because of the great loss of heat during the long winter. Altogether, the observations having been made and computed very carefully, and published *in extenso* in the *Isvestia*, are a real acquisition to science.

TWO new expeditions to Central Asia are planned in Russia for the next spring. The first, by Col. Prjvalsky, to Hlassa in Thibet, and thence to Afghanistan; and the other, by M. Blumenfeld, a German *savant* who has studied in Russia, for botanical and geological explorations; M. Blumenfeld will follow nearly the same route as that proposed by M. Prjvalsky.

UNDER the title of "D'Orenbourg à Samarkand" Madame de Ujfalvy has commenced in the *Tour du Monde* an illustrated account of her travels in Ferghanah and Western Siberia. Leroux, of Paris, has just brought out the first volume of M. de Ujfalvy's account of the results obtained during his mission. These results are mainly ethnological, and contain many observations and careful and detailed measurements of a large number of individuals representing the various races of that part of Central Asia visited by the traveller and his wife.

DURING the year 1878 the following accounts of Russian exploration were published in Russia: that of Col. Prjvalsky to Lob-Nor, now translated into English; of M. Wojeikoff in India and Japan; rather literary than scientific is that of M. Minayeff on his journey to India, which contains very interesting observations on Buddhism; of M. Ogorodnikoff to Persia, giving among other data an account of the trade-routes to Persia and Afghanistan; and of M. Skalkofsky to Eastern Asia and California.

AS Sir H. Rawlinson has announced his intention of delivering an address at the next meeting of the Geographical Society, on the road to Merv from the Caspian, it will not be without interest to note some particulars respecting the earlier part of the route, as far as the Tekké fort of Kizil Arvad, from an account lately furnished to the *Moscow Gazette* by a writer who appears to have been attached to General Llamakin's staff. The party were obliged to strike eastwards from the Chikishliar littoral by a road which has never yet been described, but which is the most practicable route to the Attrek, the bank of that river, from its mouth at Hassan-Kuli Bay almost to Balt Adji, being bordered by inapproachable morasses. The ground traversed was at first covered with shells, but soon presented the appearance of a salt marsh petrified by the sun; then, after a stretch of sand, firmer soil was met with. No water was found until the wells of Karadji-Batyr were reached. About twelve versts from the wells the party arrived at the gates, as it were, of an enormous wall, which bore a greater resemblance to an artificial structure than to a natural conformation of the soil. Three versts further on the valley of the Attrek appeared in sight, with the river itself winding between high and verdant banks. Here is Bayat-Adji, a name which is also applied to the whole of the surrounding country. From this spot the party proceeded up the Attrek to Chat or Chad, following an excellent road. About ten versts before reaching Chat the road turned to the left, leaving the Attrek at a point where there are large *auls*, or settlements of the Atabai tribe. At length Chat was reached, and it is described as the most repulsive place along the whole Attrek, although from a strategical point of view the most important, because it is here that the River Sumbar (which Capt. Napier calls the Sunt) flows into the Attrek, and the delta might be made an impregnable position. Fifty versts above Chat two enormous rocks rise out of the Attrek, forming a sharp delimitation of the geological structure of the country. This place is called Su-Sium; after this point the road is impassable for camels, and 10 versts further on is difficult even for horses; 100 versts beyond Chat the course of the Attrek can only be followed on foot, and it would take three months to make the road practicable. In consequence of the difficulties mentioned, the party was obliged to abandon the course of the Attrek at Su-Sium, and to strike a new road. After making the necessary surveys they turned to the left at a place called Alun-Yak, and proceeded over the high Sugundag chain. The ascent and descent of the Sugundag extends over a distance of 16 versts, the descent terminating at the small River Chandyr, which falls into the Sumbar. Twenty-five versts from Chat the party crossed the Sumbar, and marching between that river and the Chandyr, reached an elevated mountain called Bek-Tépé, belonging to the spurs of the Kurindag. Leaving the Sumbar they proceeded through the waterless defiles of the Ters Akon, and through the Morgo defile (belonging to the Kaplandag range), and reached the ruins of Hadjan-Kala, near the Tekké fort of Kizil Arvad. The road through the defiles presents many difficulties, and only two horses can proceed along it abreast, but it is thought that a good road could be made without much trouble or expense.

THE Society for Promoting Christian Knowledge publishes a very excellent small wall-map of Africa, by Stanford, containing all the most recent discoveries and useful both for teaching and general purposes.

ON January 25 the Geographical Society of Paris will hold a public reception in the large hall of the Sorbonne, in honour of MM. de Brazza and Ballay, the two French Ogowé explorers. The great medal for 1879 will be delivered on this occasion by Admiral La Roncière le Nourry, the president of the Society.

NO. 78 of the *Zeitschrift* of the Berlin Geographical Society contains a careful geographical and statistical study on the Brazilian province of Rio Grande do Sul, by M. Bescharn. Botanical students will be interested in Dr. Klunzinger's elaborate paper on "The Vegetation of the Arabian Desert near Koseir." This number contains a carefully arranged, most complete, and valuable bibliography of geographical literature and cartography for the year from November, 1877, to November, 1878.

NO. 3 of *Globus* of this year contains a fine illustration of the wonderful reclining statuary figure of Chac-Mool, unearthed in Yucatan some time ago by M. le Plongeon. The same number contains the sixth contribution of Herr Zehme to a *résumé* of recent exploration in Arabia.

THE GEOLOGICAL HISTORY OF THE COLORADO RIVER AND PLATEAUS[1]

II.

IN the Pliocene period the climate of the region gradually experienced a great change. Miocene times were characterised by a moist and ordinary sub-tropical climate; the Pliocene by developing an arid one, like that which now prevails there. Let us look at the causes which make this climate what it is. In whatever rectilinear direction we may undertake to pass from the Pliocene Country to the ocean we shall be compelled to cross some of the loftiest barriers of the Continent. It is hemmed in by range after range of high mountains. The winds laden with moisture are wrung dry long before they reach the plateaux in the heart of the province. The prevailing wind throughout the year is from the westward, and must cross the Sierra Nevada. Sweeping across the great basin it blows over many ranges, and at last strikes the Wasatch and the chain of high Plateaux which form the

Fig. 3.—Grand Cañon, from the Middle Terrace.

western wall of the Plateau Province. Here it is suddenly projected upward more than a mile and flings down moderately copious rains. Descending into the Cliff and Cañon Country, its humidity is so much exhausted that it can yield but the scantiest pittance of snow and showers. Thus the country is a desert. Now the strange forms impressed upon this land—its cliffs and cañons, with their myriads of wonderful shapes and their astounding architecture—are due, as we shall presently find, in great part to the aridity. The aridity is due to the great barriers which surround it, and above all to that great barrier of high plateaux which lies upon its western verge. Here, then, we may look for another key which may unlock another door within the vestibule. The search will not be fruitless.

The district of the high plateaux has been during the last four years a field of special study by myself, and has

[1] By Capt. C. E. Dutton, U.S. Army, Assistant-Geologist U.S. Survey of the Rocky Mountain Region, under Prof. J. W. Powell, in charge. Continued from p. 252.

been investigated as thoroughly as circumstances and my very limited qualifications would admit. Its original attraction consisted in the enormous displays of volcanic energy there in former times, to which I cannot here venture to allude any further. The structure of the district is also otherwise very interesting, and has been worked out with much care and patience, and in great minuteness of detail. It will be possible at present to give nothing more than a categorical statement of certain results. To master the evidence would require the handling of a large amount of detail, and unwarrantably protract discussion.

The structure of these plateaux is identical with what Prof. Powell has described as Kaibab structure, being in fact a northward continuation of the same belt which he has described and delineated in his well-known section of the Grand Cañon which cuts across this series of displacements at a right angle. The faults which have blocked out the plateaux and intervening valleys are of prodigious length, and the amounts of dislocation are very great—greater in the high plateaux than in the Kaibabs. The age of these displacements is an important landmark in the history of the country, and that age can be fixed with confidence as late Pliocene, and continuing into the Quarternary, and probably down to the present time.

With this fact in our possession as a datum we come now to the history of the cañons. The Grand Cañon first makes its appearance in the epoch of the faults. It suddenly bursts into view as a less than half-formed thing, with walls ranging from 2,000 to 2,700 feet high, late in Pliocene times. But it presents itself under somewhat unexpected circumstances, for it had been in the condition in which we first find it for a considerable period. The work of vertical erosion had long been suspended, the channels had ceased to grow deeper, and the energies of the river had for an unknown period been employed in another kind of occupation to which rivers have been frequently known to betake themselves under certain common conditions. It was widening its cañon and making a flood plain in which to meander. This any river will inevitably do when it has sunk its channel to the limiting depth which local circumstances prescribe for it. When that limit is reached it will attack its own banks whether they be walls of rock or nothing but gravel and loess, and will thereafter meander or squirm from side to side. There are numerous places along the Upper Colorado and its tributaries where this is abundantly exemplified. From local causes the fall of the river has for a space been diminished, the flow has been sluggish, sediment has been deposited, the river has ceased to erode its bottom, it has attacked its walls, and the cañon has been widened.

If now the reader will look at the section of the Grand Cañon (Fig. 3) he will perceive that it is a cañon within a cañon. The walls are in two leaps with an intermediate terrace. The upper or outer cañon is usually from three to six miles wide, and the inner cañon meanders within the upper, sometimes close to one upper wall, sometimes to the other, but usually with a middle terrace on both sides. The inner and the outer cañon represent two periods, the outer one of course being formed first—formed no doubt originally as a narrow gorge—which was widened while the river was unable to cut vertically. The middle terrace is the final flood plane of the old cañon. And now the faults come to our assistance in determining the two periods. The outer cañon is older than the faults; the inner one is coeval with them. The reasoning by which we determine this is of the simplest order. If we were to see a fault cutting a particular stratum we should know that the stratum was older than the fault. By parity of reasoning we know that the outer cañon is older than the faults because they cut its trough and dislocate its floor transversely. If the faults were older the river would have

FIG. 4.—Pa-ru-nu-Weep Cañon, Virgin River, a tributary of the Colorado.

planed an even grade across them regardless of the dips of the strata just as it is doing to-day 3,000 feet below. As it is—if the side gorges would permit us to travel along the middle terrace—we should be compelled every time we crossed a fault to clamber up or down its face.

Thus, then, as we draw near the close of the Pliocene

period only the outer cañon was completed. When was it commenced? At present we cannot give an answer, though I hope we may soon be able to do so; but I should be surprised to find its commencement dating beyond Pliocene time. The best conjecture which I am at present able to frame would place the birth of the Grand Cañon since the middle of that epoch. The commencement of the cutting of the inner cañon was contemporary with the commencement of a new uplifting of the Kaibabs—an uplifting which extended as far north as the Wasatch, and southward to unknown regions in Arizona, through a belt having its maximum width just where the Grand Cañon crosses it. The amount of this uplifting was very variable, ranging from 2,000 to 4,000 feet. It was during this period of elevation that the faulting took place. The level of the river's bed was at once disturbed; its old energies were reawakened, and its ancient labours resumed. From that epoch to the present day the river grinding like "the mills of God" has slowly but resistlessly sunk itself to solemn depths in the earth.

Wonderful and impressive as are the great cañons, they are no more so than some other features. Chief among the objects of special interest is the vast array of colossal cliffs, which stretch across the country with seemingly interminable length in a grouping which is half order half disorder. The number is indeed very great, their altitudes generally impressive—1,500 feet being common, and 2,000 feet not very uncommon, while the distant view of cliff rising above cliff, one beyond another, yet seeming to be united, is often seen. Each stratigraphical series has a series of cliffs, planned, sculptured, and painted in a style peculiarly its own, and the several styles differ, as decidedly and constantly as human architecture among distinct races of men. These distinguishing characters developed under one homogeneous process can be traced to the lithological composition and texture of the rocks which are powerfully contrasted between any two series. The constancy of result in any given series may also be traced to the constancy with which that series preserves one set of characters over a great extent of country. I may be mistaken—perhaps from the circumstances it is more apparent than real—but I imagine no region in the world hitherto explored exhibits rocks where the texture and lithological characters are so strongly pronounced, so strongly contrasted among themselves, and yet where there is so little horizontal variation in the characters of each group over vast areas.

In the Plateau Country we have to do with an arid region, and the aridity tends to reduce the amount of disintegration. On the other hand it is a lofty country giving a rapid descent to all its waterways, and their transporting power is of a very high order—the rocks are swept bare of *débris* and kept naked to the attacks of the elements. This tends powerfully to quicken the disintegration. The number of inches of annual rain is less than one-sixth the number in the Mississippi valley, but every inch in the plateaux may do sextuple work. Probably, however, the rate in the plateaus is on the whole slower, but the disproportion is much less than might have been anticipated if we had considered the rainfall alone.

To comprehend the origin and perpetuation of cliffs it is necessary to expand these general relations into some detail. I have stated that the attack of erosion is directed against the edges of the strata and but slightly against the horizontal surfaces. These surfaces being but little inclined, water has but little energy, as it courses over them, either to erode or to transport. But in the myriads of gulches the steepness of their sides enables the water to keep the edges of the strata naked, and the water is assisted powerfully by the aridity of the climate and the absence of vegetation. Now when the edges of a thick series of vertically heterogeneous strata are exposed, there will always be some stratum softer or more readily disintegrated than the others. The elements attack it, and soon a long under-cut is formed, and the rocks above robbed of a part of their support, cleave off vertically, and a great slab falls in ruins. The fallen fragments and rubble form a talus, but being now in a comminuted state, they become a much easier prey to dissolution than when in the solid wall, and they gradually moulder away. All that is necessary is that the talus should dissolve fast enough to keep the perishable stratum exposed to attack, and this is almost universally the case. The great cliffs are massive beds of sandstone and limestone, resting upon perishable calcareous and gypsiferous shales. The rapidity with which the cliff wastes away and recedes by erosion is measured by the power of resistance to weathering in the shales below and not by the massive beds on its face. By further analysing the details of erosive action, we have no difficulty in explaining the origin and causes of the different styles of architecture, the sculpture of the repetitive forms, and all their train of phenomena, both normal and abnormal.

And now a few words about the cause of cañons. This problem has been so admirably and satisfactorily solved by Messrs. Powell and Gilbert that I have no better excuse for saying anything about it than a desire to fill what would otherwise be a serious gap in the discussion.

The fall of the Colorado through the cañons is between seven and eight feet per mile—nearly twenty times as great as that of the Ohio and Mississippi and nearly seven times as great as that of the Missouri below the Yellowstone. It is a fierce torrent—a series of quickly-recurring rapids. Its lateral gorges have usually a greater descent. The tools with which the river works are sand and gravel held in suspension by the water, hurled along at race-horse speed, and scouring like a sand-blast machine the naked rocks of its bed. But there is one thing more, and it is a crucial point. The Platte has about the same fall through the plains as the Colorado through the cañons; it has its sources high up in the same mountains; it flows through a desert; it carries a huge load of sand, but from Denver to Plattesmouth has not the semblance of a cañon. The trouble with the Platte is that it carries *too much* sand. A river of given volume and velocity can carry in suspension only a definite load of sediment of given coarseness. When that limit is exceeded the excess will be precipitated upon the bottom protecting it from the scour of the gritty particles which are carried in suspension. But if the supply of sand be not in excess of the power of the current to keep it in suspension, none will be deposited except locally, and the bed-rock will experience the full attrition of the sand-blast. The Platte is the case of an overloaded stream while the Colorado is slightly underloaded and in a condition to produce the maximum erosion.

The study of the Plateau Country has during the last nine years been the work of the Survey under Prof. J. W. Powell. Comparatively little has been published about it because it has been felt by him that until the subject could be presented in systematic and thoroughly intelligible form it would be a mistake to accumulate fragmentary literature and encumber a splendid subject with a chaos of unconnected observations. But the work approaches completion and has developed into form in the minds of the workers, and it is hoped that the results will soon be before the world. If the geology of the Plateau Country shall therein be set forth in a manner commensurate with its importance, and full justice done to the revelations it affords, I believe that physical geology will have received important additions. I cannot close without paying a just tribute to Prof. Powell, the director of their work. His direction of the Survey has not been limited to the perfunctory duties of an administrative officer. On the contrary he has furnished those whom he has called to his assistance with methods of

observation and principles which have worked like a master-key in opening to our understanding the meaning of this wonderful region. Without those methods and principles it would have been of comparatively little utility to attempt to solve the problems of such a region. Those whose privilege it has been to carry them into practice will ever be glad to acknowledge how great is their indebtedness.

INCLINATION OF THE AXES OF CYCLONES AND ANTICYCLONES

I HAVE during the last seven years endeavoured, though apparently without much effect, to direct the attention of meteorologists to a law which I conceive to be of very high importance in relation to the theory of the movements of the atmosphere. The law to which I refer is this:—The movements of the upper-currents prove that the axis of a progressive cyclonic circulation is commonly inclined, so that the extremity nearest to the earth's surface is considerably in advance of that in the higher regions of the atmosphere. A barometric minimum consequently occurs at any locality on the earth's surface some hours before the corresponding minimum in the higher regions passes over the same spot ("Laws of the Winds Prevailing in Western Europe," pp. 156 to 162, 1872; *Meteorological Magazine*, vol. x. pp. 92 to 93, 1875; *Quarterly Journal of the Meteorological Society*, October, 1877, pp. 440 to 445). I have also pointed out that the axis of an anticyclonic circulation has, at least in some instances, a similar inclination; a point which will be discussed more fully in a future paper.

I hope that the results, strongly confirmatory of this law, which Prof. Loomis has recently derived from his examination of the wind and barometer reports from Mount Washington, Mount Mitchell, and Pike's Peak, will attract more attention than my own deductions from upper-current observations have done. In his tenth paper of "Contributions to Meteorology" (*American Journal of Science and Arts*, January, 1879), Prof. Loomis shows that with very few exceptions the barometric minima occur at the base of a mountain considerably earlier than at the summit, the retardation amounting to about one hour for an elevation of from 900 to 1,300 feet, and that the maxima appear to follow the same law.

Other points of agreement between the results of cloud observations in Europe, and those obtained from the reports of the mountain observatories in America, seem to me to be of great interest. I would especially call attention to the substantial coincidence of these results as regards, first, the rarity of easterly upper-currents, as compared with easterly surface-winds; and secondly, the higher, and also less variable, value of the angle made by the northerly, than that made by the westerly upper-currents, with the direction of the centre of lowest pressure at the earth's surface. W. CLEMENT LEY

BARTOLOMEO GASTALDI

SINCE the last anniversary of the Geological Society many distinguished men among its members, both in this and foreign countries, have been removed by death. We regret to have to add to the sad list the name of Prof. Gastaldi, the well-known head of the Italian Geological Survey.

Bartolomeo Gastaldi was born at Turin, in the year 1818, and was originally destined by his father for a legal career; his fondness for geological studies, however, proved too strong to be repressed, and he was eventually entered as a student at the École des Mines at Paris. Here, and throughout his subsequent career, he enjoyed the friendship of Quintino Sella, who afterwards became so distinguished alike in Italian scientific and political circles.

Gastaldi had reached the age of twenty-eight before his first scientific memoir was published, and his earliest essays in this direction were devoted to anatomical and palæontological questions. Before long, however, he seems to have discovered that the true bent of his genius was towards physical geology. In his studies in this department of science he was greatly aided by his powers as a pedestrian, and he soon made himself familiar with all the southern spurs of the Alpine chain. In company with his friend Sella he founded the Italian Alpine Club, of which he was the second president.

He succeeded Sella as Professor of Geology at the Engineering School of Turin, and subsequently became Professor also at the University. During the later years of his life the work of the Geological Survey, of which he was made director by the Italian Government, occupied much of his attention, and to his energy and capacity much of the success which has already attended that important work is due.

No less than thirty papers on various branches of geological science have proceeded from Gastaldi's pen. He was an advocate, during his later years, of extreme views upon glacial subjects, and many of the views which he propounded on this and on other questions of Alpine geology have not been generally accepted by the geologists of other countries. In some of his speculations, indeed, his boldness seems to have outrun his caution. Those who had the happiness of a personal acquaintanceship with Gastaldi describe him as a most sanguine and earnest student and a warm-hearted friend.

Prof. Gastaldi was a Corresponding Member of the Geological Society of London, and received similar honours from the academies of many other foreign countries. In Turin, where he spent the greater part of his life, and where he occupied the position of a Common Councillor, he was very greatly respected and beloved; this fact is testified to by the circumstance that at his funeral more than three thousand people followed his remains to the cemetery.

ON THE DETERMINATION OF ABSOLUTE PITCH BY THE COMMON HARMONIUM[1]

THE methods described depend upon the principle that the absolute frequencies of vibration of two musical notes can be deduced from the *interval* between them, *i.e.*, the *ratio* of their frequencies, and the number of beats which they occasion in a given time when sounded together. For example, if x and y denote the frequencies of two notes whose interval is an equal temperament major third, we know that $y = 1{\cdot}25992\,x$. At the same time the number of beats heard in a second, depending upon the deviation of the third from true intonation, is $4y - 5x$. In the case of the harmonium these beats are readily counted with the aid of a resonator tuned to the common over-tone, and thus are obtained two equations from which the absolute values of x and y may be found by the simplest arithmetic.

Of course, in practice, the truth of an equal temperament third could not be taken for granted, but the difficulty thence arising would be easily met by including in the counting all the three major thirds which together make up an octave. Suppose, for example, that the frequencies of c, e, $g\sharp$, c' are respectively $x, y, z, 2x$, and that the beats per second between x and y are a, between y and z are b, and between z and $2x$ are c. Then,

$$4y - 5x = a,$$
$$4z - 5y = b,$$
$$8x - 5z = c,$$

from which

$$x = \tfrac{1}{3}(25a + 20b + 16c),$$
$$y = \tfrac{1}{3}(32a + 25b + 20c),$$
$$z = \tfrac{1}{3}(40a + 32b + 25c).$$

[1] Abstract of a paper read before the Musical Association, December 2 1878, by Lord Rayleigh, F.R.S.

In the above statements the octave $c-c'$ is for simplicity supposed to be true. The actual error could be readily allowed for, if required; but in practice it is not necessary to use c' at all, inasmuch as the third set of beats can be counted equally well between $g\sharp$ and c.

Although at first sight the method just sketched looks satisfactory, it is not practical in the case of the harmonium, in consequence of the pitch of the various notes not being sufficiently constant for the purpose, even when the blowing is carefully conducted with the aid of a pressure-gauge. A small variation in the absolute pitch of a chord when sounded under slightly varying pressures, would not be of much importance, but the slightest change of *interval* is fatal to the success of the method, and such a change actually occurs.

In order, therefore, to apply the fundamental principle with success, it is necessary to be able to check the accuracy of the interval which is supposed to be known, at the same time that the beats are being counted. If the interval be a major tone (9 : 8), its exactness is proved by the absence of beats between the ninth component of the lower, and the eighth component of the higher note, and a counting of the beats between the tenth component of the lower and the ninth of the higher note completes the necessary data for determining the absolute pitch.

The equal temperament whole tone (1·12246) is intermediate between the minor tone (1·11111) and the major tone (1·12500), but lies much nearer to the latter. Regarded as a disturbed major tone, it gives slow beats, and regarded as a disturbed minor tone it gives comparatively quick ones. Both sets of beats can be heard at the same time, and when counted give the means of calculating the absolute pitch of both notes. If x and y be the frequencies of the two notes, a and b the frequencies of the slow and quick beats respectively,

$$9x - 8y = a$$
$$9y - 10x = b,$$

whence

$$x = 9a + 8b$$
$$y = 10a + 9b.$$

The application of this method in no way assumes the truth of the equal temperament whole tone, and in fact it is advantageous to flatten the interval somewhat by loading the upper reed with a minute fragment of soft wax, so as to make it lie more nearly midway between the major and the minor tone. In this way the rapidity of the quicker beats is diminished, which facilitates the counting.

It is impossible, of course, for the same observer to count both sets of beats, and the counting of even one set without the aid of resonators would present difficulties to most unpractised persons. Great assistance may be obtained by the choice of a suitable position. A room in which a pure tone is sounded is traversed by surfaces at which the intensity of sound is very much reduced in consequence of the superposition of vibrations reflected from the walls and ceiling. By choosing as the place of observation a position where the intensity of the beats which are not to be counted is a minimum, and with the aid of a resonator tuned to the pitch of the beats which are to be counted, the listener is able to work with ease and certainty.

The course of an experiment is then as follows:—The notes *C* and *D* are sounded, and the listeners begin counting the beats at a given signal, whose pitch is about d'' and e'' respectively. At the expiration of a measured interval of time a second signal is given, and the number of both sets of beats is recorded.

In my experiments the interval of time was ten minutes (in one case eleven minutes), and the rapidity of the beats was about four a second. The listeners counted up to ten only, after each set of ten making a stroke with a pencil on a piece of paper. The number of strokes was afterwards counted, multiplied by ten, and added to the number which the listener was saying at the instant of the second signal. The following are the details of the actual observations:—

September 16, 1878.—Period of observation ten minutes. Numbers of beats 2392 and 2341.

$$a=\frac{2392}{600},\ b=\frac{2341}{600},\ \text{giving } x=\frac{9\times2392+8\times2341}{600}=67{\cdot}09,$$

for the frequency of the lower note C.

September 17.—Period of observation ten minutes.

$$a=\frac{2423}{600},\quad b=\frac{2302}{600},\ \text{giving } x=67{\cdot}04.$$

September 18.—Period of observation ten minutes.

$$a=\frac{2476}{600},\quad b=\frac{2261}{600},\ \text{giving } x=67{\cdot}29.$$

September 19.—Period of observation eleven minutes.

$$a=\frac{2663}{600},\quad b=\frac{2547}{600},\ \text{giving } x=67{\cdot}19.$$

The discrepancies are hardly greater than may be attributed to errors in giving the signals, by which the intervals may have been unduly lengthened or shortened by about a second. On each day after the counting of the beats between C and D, the harmonium was compared with a Kœnig fork whose nominal frequency was 64. In order to obviate any objection arising from a mutual influence of the notes of the harmonium, *both* C and D were sounded at the same time as the fork. The beats between C and the fork were counted for about ninety seconds, during which time the fork was not bowed. In this way the pitch of the fork came out on the four days respectively as 64·06, 64·07, 64·17, 63·98, that is somewhat sharper than its nominal pitch, a result in agreement with that obtained by other methods.

The object of the experiments referred to was rather to prove the practicability of a method so unusually independent of special apparatus, than to obtain a result competing in point of accuracy with those of Prof. Macleod and other experimenters on this subject. Nevertheless it is believed that very accurate results might be obtained by the introduction of certain modifications. Ten minutes is near the limit of time over which beats can be conveniently counted by a single listener, but experiment proved that it is perfectly possible for one listener to relieve another without any break in the regularity of the counting. Even without an extension of time a more accurate result would be obtained if the listeners were able to fix the time for themselves, as they might do for example if they could conveniently observe the swinging of a clock pendulum. In this way the error in the time interval might be reduced to $\frac{1}{4}$ second, which would amount to but one part in 2400 in the case of a ten minutes' observation. In consequence, however, of the imperfect constancy of the pitch of the harmonium notes, even when the blower is assisted by a pressure-gauge, further attempts at accuracy would be useless unless the comparison with the fork were simultaneous with the other observations. In that case the result would be entirely independent of variations in the harmonium notes, and no difficulty would be experienced in carrying out the method excepting the necessity for more observers.

THE FISSURES OF THE CEREBRAL HEMISPHERES IN UNGULATA

An important memoir by Dr. Krueg on the cerebral hemispheres of Ungulata has recently appeared in the *Zeitsch. wiss. Zool.* After a review of the previous papers that have appeared on this subject—but few in number—Dr. Krueg describes his method of investigation.

He made drawings of the hemisphere of each species; compared, first, line for line the hemispheres of different individuals of the *same* species, and then took as characteristic of that species every sulcus that was constantly present in all the individual hemispheres.

The different species in a genus and the different genera in the order were compared in the same way, so that by elimination he at last obtained a schematic drawing of the sulci constant throughout the order. In his drawings he represents those sulci peculiar to the individual, species, &c., by variously dotted lines, those running through the whole order by thick black lines.

Since the most constant or chief sulci are the first to appear in the course of development, he gives drawings of fœtal brains of the sheep, cow, and pig. With regard to these fœtal brains, it is highly important to note that in no instance were transitory or temporary sulcus markings met with; Meckel himself admits that he did not find these temporary sulci in brains of other animals, though he described them in the human fœtus. Dr. Krueg regards them as entirely artificial. The following, then, are the chief fissures or sulci (*Hauptfurchen*) constant throughout the Ungulata, and of these the first six are the most important in relation to those of the Carnivora:—

1. Fissura sylvii; ant., post., processus acuminis.
2. ,, splenialis.
3. ,, supra-sylvia, ant., post., supr.
4. ,, coronalis.
5. ,, præsylvia.
6. ,, lateralis.
7. ,, diagonalis.
8. ,, postica.
9. ,, genualis.
10. ,, rostralis.

h. ,, hippocampi.
rh. ,, rhinalis.
C.ca. Corpus callosum.

The earliest fœtus he possesses shows two fissures, namely, F. sylvii and F. splenialis. The sylvian fissure develops radially, just as Ecker has shown in the human fœtus, and since in the latter, the parieto-occipital fissure appears almost contemporaneously with the sylvian fissure, he considers the Fissura splenialis of Ungulates to be the homologue of the human parieto-occipital. This view derives some strength from the fact that as development proceeds, the anterior extremity of the Fissura splenialis turns upwards and gains the median border. Moreover, here it is opposite to the processus acuminis Sylvii, which is homologous with the posterior or horizontal ramus of the human Sylvian fissure.

The positions of the fissures are shown in the accompanying diagrams. As regards the fœtal forms it is noteworthy that in the Suillidæ, from its earliest appearance the posterior process of the F. supra-Sylvia is directed downwards as well as backwards; this we shall find is a family characteristic of importance.

Before enumerating the slighter distinctive characters of the families, or comparing the Ungulata with the Carnivora, it will be well to mention the results which are of more general importance. Dr. Krueg believes that he has established the following propositions:—

1. That the forerunners of the adult fissures are never transitory radial markings, but always present (though incompletely) the adult form.

2. That the two important fissures (F. hippocampi and F. rhinalis) common to all mammals, are the first to appear, and that next those characteristic of the Ungulata commence.

It is remarkable that the fissures peculiar to the individual, may appear contemporaneously with, or even precede, the last few of the chief fissures. This fact of itself would cast some doubt on the morphological value of these later chief fissures, and comparison with the Carnivora also diminishes their importance as diagnostic marks.

3. On no occasion was a fissure once formed ever broken up by a bridging convolution. The reverse of this may and often does occur, viz., that two originally distinct fissures may, by extension of their neighbouring extremities, so mingle as to form one large fissure. From this fact he concludes that when in adult brains we meet with a well-known fissure bridged over, originally this fissure was developed as two distinct ones. This would certainly explain the remarkable cases lately published by

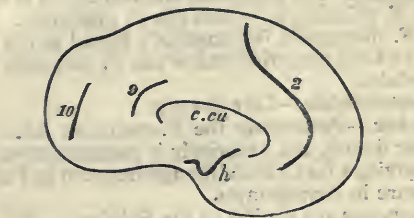

Fig. 1.—Median surface of typical hemisphere.

Henschel, in which the fissure of Rolando was bridged over, and such a state of things would be due to atavism.

4. The influence of the size of the animal on the shape of the hemisphere and its details is very important, and may be regarded as threefold.

(*a*) The number of accessory fissures increases with the size of the brain and the size of the animal.

(*b*) The shape of the hemisphere differs. Thus, in the larger animals it is broader, and more rounded, whereas, in the smaller animals it is distinctly narrower, and tapers more to a point anteriorly.

(*c*) In the smaller animals it is noticed at once that fissures (such as the splenialis), which in the schematic brain are situated on the median surface, in these smaller individuals, often appear on the upper. Such a condition may be supposed to result from a rotation of the upper or median border around the Island of Reil as a centre. This rotation Dr. Krueg has named "supination," and that in the opposite direction and occurring in the larger animals "pronation." The posterior extremity of the F. coronalis almost always presents a "horn" (Bügel) directed inwards. This branch becomes of importance, as it often joins the F. splenialis, and offers a homology with the fissura cruciata of the Carnivora.

The following are the main family characteristics:—

Tragulidæ.—Supination marked. F. coronalis communicates with the processus anterior supra-Sylvii. The Tragulidæ (like the antelopes) present strong elephantine characters as regards their fissures.

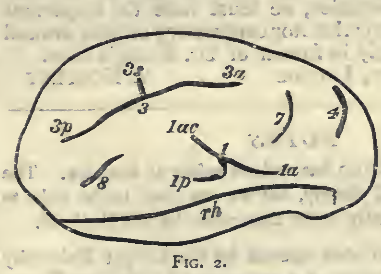

Fig. 2.

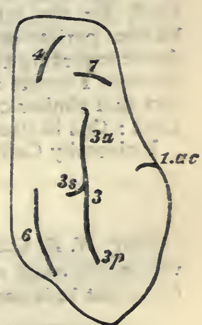

Fig 3.

Fig. 2.—Lateral outer surface of typical hemisphere. Fig. 3.—Upper surface of typical hemisphere.

Elephants.—F. coronalis communicates with the processus anterior supra-Sylvii, and also either with the F. splenialis or ends just behind it.

The *Giraffes* present no generic characters.

Cavicornidæ.—In the majority the F. coronalis does *not* communicate with the F. supra sylvii, the exception being *Bos taurus.* The processus acuminis Sylvii is broken

by "individual" fissures, and, moreover, the angle formed between its anterior and posterior extremities is raised, and into this space a small accessory branch from the Fissura rhinalis is directed.

Tylopoda.—Pronation is so marked that the F. lateralis is actually situated on the median surface. The F. coronalis is directed from the middle line forwards and outwards.

Suillidæ present several characters in common with the Carnivora. The processus anterior Sylvii is continued into the F. rhinalis, as is also the F. præsylvia.

The F. diagonalis is constantly joined to the F. supra Sylvia, and the posterior end of the F. coronalis joins the F. splenialis.

Hippopotamidæ.—Like the pig.

Tapiridæ.—Posteriorly the F. coronalis does not join any other fissure, but anteriorly it communicates with the F. præsylvia, a fact which, though frequent in Perissodactyls, is rare in Artiodactyls.

Nasicornidæ are similar to the Solidungulates.

Solidungulata.—The peculiarities are very constant. Thus there are cross-fissures between F. Sylvii and F. supra Sylvii. Further, there is an accessory longitudinal and parallel fissure on either side of the F. lateralis. Pronation is marked. The F. coronalis is united to the F. supra Sylvii, and the posterior "horn" of the F. coronalis is not united to that fissure, but commencing behind and above the anterior end of F. splenialis, runs forwards and outwards, ending before reaching F. coronalis.

Comparison of the convolutions of the Ungulata with those of the Carnivora shows that in the latter order the first six chief sulci of the Ungulata have undoubtedly their homologues. The question as to whether a F. diagonalis can be said to exist must still be left open, and the remaining three certainly do not always exist in the brain of the Carnivora, and when present are accessory only.

Dr. Krueg thinks that possibly the posterior "horn" (Bügel) of the Fissura coronalis is homologous with the Fissura cruciata in the Carnivora, but this is very uncertain, for it is questionable whether in the Cavicornia the posterior limb of the F. coronalis is homologous with the distinct one described above in the Equidæ. Certainly that of the Perissodactyl is very similar to the Fissura cruciata as regards its relation to the F. coronalis; but while in the Perissodactyl the posterior extremity begins *above* the F. splenialis, in all Carnivora it begins *below*. Further, the anterior end of the F. splenialis turning up to the median border has a plausible homology itself with the Fissura cruciata. It would be very interesting to have the time of appearance of the Fissura cruciata fixed, for the latter theory would compare it to the human parieto-occipital fissure. As confirmatory evidence regarding the homology of the Ungulate and Carnivorate Fissuræ coronales, we must note the important fact that similar cortical motor centres are situate around them: this is strongly in favour of Dr. Krueg's view.

University College, London V. HORSLEY

NOTES

PROF. W. K. CLIFFORD has arrived safely at Madeira. The voyage was rough and stormy, but we are glad to be able to report that he is markedly better than when he left England.

A SUBSCRIPTION has been opened by the Dorpat University for the erection at Dorpat of a monument to the late K. von Baer.

ON January 10 the Imperial Russian Academy of Sciences at St. Petersburg held its annual meeting, which was largely attended this year. The meeting was opened with the reading of the long list of deaths of members, foreign and Russian, during last year, and among whom we notice Regnault, Claude Bernard, Granville, and Bienaimé, at Paris; Hugo Hildebrandt, of Jena; Friis, of Upsala; Tornberg, of Lund; Lers, of Königsberg; and the well-known Russian archæologist Polyenoff; Kovalsky and Khanykoff, orientalists; and Davydoff, mathematician. Count Orloff-Davydoff, Baron Bühler, and Col. Prjvalsky were elected honorary members; and General Maiefsky, mathematician; General Stebnitzky, geodesist at Tiflis; Mr. Hind (as noted last week), Dr. John Muir (Edinburgh), Clausius (Bonn), Boisier (Geneva), Lavrofsky and Veselago were elected correspondent members of the Academy. The report on the museums of the Academy showed several most important acquisitions, among which we notice the immense and very rich collections of birds, fishes, and reptiles brought in from Central Asia by Col. Prjvalsky, during his second journey; a collection of skulls and bones of Steller's sea-cow, which inhabited, during the last century, the shores of the White Sea, but is now extinct, the collection being made by M. Phillipens on the shores of Behring Strait; and a complete skull of an Elasmotherium, presented by M. Knoblauch. There were, until now, only some teeth of this immense quaternary horse-like rhinoceros at the museum of the Academy, and a part of a skull at the British Museum, which had offered, we are told, a large sum of money to M. Knoblauch for the rarity. The skull was found close by Sarepta, on the banks of the Volga River. The Academy proposes to open next year for the public a large anthropological museum, the materials for which are already in the hands of the Academy; we heartily commend this step, as the museums of the Academy, when open to the public each Monday, are visited by masses of people (as many as 12,000 persons daily on holidays). The report on the works of the philological and historical branch of the Academy was presented by Prof. Suklomlinoff, who dwelt at length on the works of Prince Vyazemsky; and a very interesting paper on the correspondence between Catherine II. and Grimm was read by Prof. Groth. In this branch we notice a great undertaking by the Academy for the next year, being a dictionary of the Kurd language. This language has been very well studied, but there are no dictionaries of it. Now, the Academy will publish a complete one, the materials for it being given by the French orientalist, M. Szabo, and completed by M. Yulpi, who will be intrusted with this important publication.

WE notice an interesting work, just issued in Russia, by Prof. Rumishevich at Kieff, being a complete catalogue of all the medicinal and veterinary literature published in Russia during 1876.

WE learn that the St. Petersburg Academy of Sciences has intrusted M. Keppen with the publication of a complete catalogue of animals living in European Russia.

LORD DUFFERIN, Lord Rosse, and Prof. Roscoe received the degree of LL.D. from Trinity College, Dublin, on Tuesday.

THE "Telectroscope" is the name of a new apparatus, the plan of which was, *Les Mondes* states, recently submitted to MM. du Moncel and Hallez d'Arros by M. Senlecq, intended to reproduce telegraphically at a distance the images obtained in the camera obscura. This apparatus is based on the well-known sensitiveness of selenium to various shades of light.

PROF. EDWARD S. MORSE, we learn from the New York *Nation*, has written an interesting paper on the "Traces of an Early Race in Japan," which throws light on a subject hitherto wholly obscure. A race of men called Ainos are believed to have come down from Kamtchatka and to have taken possession of Japan, which they held until displaced in their turn by the Japanese from the south. Of the two races, the Ainos and the Japanese, authentic records exist, but nothing has been known concerning the ancient people whose territory was appropriated

by the Ainos. The only knowledge obtained of them has been ingeniously acquired by Mr. Morse by a careful study of "shell-heaps" in all respects similar to those found along the shores of Denmark, New England, and Florida. The deposit discovered by Mr. Morse near Tokio contained pottery and broken bones, many of which were human. It is generally admitted by ethnologists that a people that has once acquired the art of pottery will always retain it; but as neither the Esquimaux, the Kamtchatdales, nor the Ainos are essentially earthen-pot-makers, these remains naturally point to the former existence of a race in Japan who preceded the Ainos. Again, both the human and the deer bones found in this shell-heap were broken in a manner to facilitate the extraction of the marrow or to enable them to be placed in a cooking-pot, a circumstance which points to the existence of cannibalism among the people by whom the shell-heaps were made. On consulting Japanese scholars and archæologists Mr. Morse learned that the Ainos were not only not cannibals, but were of an especially gentle disposition. The existence of an ancient race of cannibals in Japan, before the occupation of that country by the Ainos, is therefore made very probable. We hope to see another paper before long containing an account of Prof. Morse's later researches.

PROF. HUMPHRY, F.R.S., of Cambridge, will deliver the biennial oration in memory of John Hunter in the theatre of the Royal College of Surgeons on the 14th proximo.

MR. THOMAS SOPWITH, M.A., F.R.S., F.G.S., who died at Westminster, on Thursday last, was born in 1803, at Newcastle-on-Tyne. He was for nearly fifty years extensively engaged as a civil engineer in mining, railway, and other works, both in this country and on the Continent, and was the author of several works on architecture, isometrical drawing, and mining. In 1838 he was appointed Commissioner for the Crown under the Dean Forest Mining Act, and in the same year a communication made by him to the British Association led to the establishment of the Mining Record Office. He was a member of many of the leading scientific societies, and one of the early members of the Institution of Civil Engineers.

IN connection with our article last week on a proposed Scottish observatory, it may be interesting to state that one day last August Mr. Milne Home, chairman of the Meteorological Society for Scotland, accompanied by Mr. Colin Livingston, headmaster, Public School, Fort William; Mr. Thompson, student; and Mr. David Doig, contractor, ascended Ben Nevis and made several observations with the view of erecting a station on the summit. They found the top enveloped in a mantle of snow—a circumstance which rendered it an extremely difficult task to select suitable spots for the erection of a dwelling-house and observatory. After a careful survey Mr. Home came to the conclusion that the plateau immediately beyond the spring affords the best site. The recommendation this spot has is its contiguity to the water-supply. But it might be questioned whether, as accurate observation is the thing required, it would not be better to erect the observatory on the plateau on the very summit, as there must, no doubt, be a difference between the temperature of the two places, the first-mentioned plateau being 350 feet lower. It is proposed to construct the buildings after the following plan: first, a wall of stone with an inside lining of wood and an inner coating of felting, and the outside of the wall to be covered with corrugated iron. An external wall of stone would also be erected to serve as a protection from the blast. The estimated cost of the structure is 500*l*.

WE learn from the *Colonies and India* that rich discoveries of copper have been made at Howe Sound, a few miles from New Westminster in British Columbia, and that the ore resembles that of the famous Australian Burra Burra mine.

THE Royal Society of Arts and Sciences of Mauritius has recently lost its secretary, Mr. L. S. Bouton, the only surviving founding member of the Society. This society was founded on August 24, 1829, under the name of Société d'Histoire Naturelle de l'Ile Maurice, by a few lovers of science; its first secretary was Julius Desjardins, who contributed many papers on the fauna of Mauritius, and also formed a good collection of specimens, which were afterwards given up to Government by his heirs, and became the nucleus of the present museum. The volumes published by the Société during a period of ten or fifteen years contain much interesting information on the natural history of Mauritius. On Desjardins' death in 1840, Mr. Bouton was appointed secretary, and kept up the post till his death; during that long period he chiefly applied himself to the investigation of the flora of Mauritius, and though he never published any complete works he contributed specimens and notes to Prof. Decandolle for the Prodromus, and to Kew, for the Flora of Mauritius by Baker. He wrote a paper on the medicinal plants of Mauritius, and a very interesting paper on the forests of Mauritius, besides a great quantity of notes in the Society's *Transactions*, and in the newspapers of the colony. In 1846 the Society was allowed by Government an annual subsidy of 200*l*., which has been continued up to this day. Mr. Bouton was also curator of the Museum, but he was, we believe, though completely devoted to his duties of secretary, a rather bad curator. The Museum, although containing some very interesting specimens of the natural history of Madagascar, and of the extinct fauna of Mauritius, was allow to decay rapidly. No exchanges were carried on to increase the collections, and the space being too limited, the existing specimens are so crowded as to be of no use whatever to the public. The subject attracted the attention of the late much-esteemed governor, Sir Arthur Phayre, and he applied for a Report from the Council of the Society, and on its recommendation the following decisions have been come to by the Council of Government:—That a proper building be provided for the transfer of the Museum now heaped up in a room at the Royal College; that the funds allowed by Government each year be applied to the formation of a local museum, fully illustrating the fauna and flora of the Mascarene Islands, Madagascar, and the islands along the east coast of Africa; that a general collection, of which the present museum should be the nucleus, be gradually formed by means of exchanges to illustrate only the principal genera in each branch of natural history, and give to the public a general view of the natural world; that on vacancy (which is now come) a competent curator be provided from home, who will be at the same time Professor of Natural History at the Royal College, receiving a salary of Rs. 5,000 per annum; that the staff of the Museum be composed of an assistant, who will be also a collecting n^ uralist, sent round every year to Madagascar or some other place, receiving a salary of Rs. 2,000 and his travelling expenses, a taxidermist, a clerk, and servants; that, as a good taxidermist does not now exist in Mauritius, the services of a proper person be secured from home for two years, to instruct people in stuffing and set up the first collection, receiving Rs. 2,000 and passage-money. We hope that these changes will be insisted upon and that competent men will apply for the vacant posts to the Government at home, and give them a better opportunity of making a good choice. Mauritius is an admirable place for studying the riches of the sea, and a sort of zoological station, like the one at Naples would make many interesting discoveries. Prof. Möbius, of Kiel, who spent some months at Mauritius, said that several years would be necessary for him and many assistants to work up the collections from these seas. Evidently a good opportunity is presented for the promotion of important departments of natural history, and we trust all concerned will seek only to advance the interests o science and the true interests of the colony.

THE Commission of the Municipal Council of Paris has drawn up a report on the working of the electric light, which has been printed, and was discussed on the 14th instant. A certain number of important facts are stated. A Jablochkoff lamp may be said to give a quantity of light equal to eleven gas lamps, consuming each 140 litres per hour. The quantity of gas consumed to produce the same quantity of illumination would be 1,540 litres per hour. The price paid by the city to the gas company for 1,000 litres being 0 fr. 15c., the expense would be of 0 fr. 23 c. The expenses of each Jablochkoff lamp are officially stated as follows, for 62 candles per hour of light, 77 horse-power:—Machinery, 3 fr. 20 c.; coals for working the several steam engines used, 6 fr. 64 c.; oil for lubricating, 1 fr. 23 c.; pay of men for changing candles and superintending illumination, 3 fr. 20 c.; expenses of 62 candles at 0 fr. 50 c. each, supposed to last during an hour, 31 fr. Total, 45 fr. 27 c., or 73 c. for each candle. The Commission proposes to pay to the Jablochkoff company—which accepts 0 fr. 30 c. per candle during one year—for 62 candles at the Avenue de l'Opéra, 15 on the Place de la Bastille, and 6 in a pavilion of the Halles Centrales: in all 83. The total number of burning hours is estimated at 2,073 for each of the street candles, and 4,000 for each of the pavilion candles: altogether, 55,000. The expense paid to the gas company for illuminating the same places is 21,041 fr. The excess of expense for the city will be 34,044 fr. But this credit is asked for in the interest of science. It is hoped that during one year the Jablochkoff company will realise material improvements, and it is supposed that other electric light companies will tender some fresh propositions for comparison. In the meantime, the Commission proposes to accept a tender made by the gas company to improve the illumination of the Rue du Quatre Septembre, Place du Château d'Eau, and a pavilion of the Halles Centrales, with an excess of consumption of 260,000 cubic metres. At the sitting of the 14th, the gas company refusing to accept the price offered to them as a compensation for their expenses, proposed to supply the gas gratis, which was agreed to. Consequently a regular competition will be carried on between gas and electricity before the Parisian public during one year, on a grand scale, at the expense of only 34,044 fr.

IT was recently affirmed in the French Academy that chromic acid might be substituted for vanadic acid in the manufacture of aniline black. An industrial chemist of Rouen, M. Witz, now points out to the Academy (by recommendation of Prof. Girardin) that this is an illusion, and that vanadium is absolutely necessary. Chromium gives a greenish product quite different. M. Witz insists on the small quantity of vanadium which suffices to develop the reaction. It appears that the black is produced in presence of a weight of vanadic acid equal to only the *hundred millionth* part of the weight of the aniline employed. In practice, a thousandth of this weight is quite sufficient, and it will be seen that notwithstanding the high price of vanadium, the use of it in such small quantities is quite practicable for manufacture.

THE Anthropological Exhibition which will be held at Moscow next summer promises to be a highly interesting one. A large series of graphic illustrations of the life of prehistoric man will be supplemented by numerous models of caves, skeletons, and other prehistoric objects. So-called "kurgane" (prehistoric tombs) will be represented containing models of the skeletons and other objects found in them, their various positions being exactly reproduced. Prehistoric skulls will form a separate department of the Exhibition.

WE have received the *Proceedings* of the Cleveland Institution of Engineers, containing the address of the president, Mr. John Gjers, at the annual meeting of November 11. The address refers to various topics of much interest to engineers and even to men of science. Among other things Mr. Gjers, speaking of the variation in the production of the soil, gives it as his opinion that it is undoubtedly connected with the variation in the number of sun-spots. The December number of the *Transactions* of the Institution of Engineers and Shipbuilders in Scotland contains a paper by Mr. James Howden, "On the Action of the Screw Propeller," followed by a long discussion, and another by Mr. W. G. Jenkins, "On the Scientific Form of Harbours as applied to the Port of Melbourne."

A FOREIGNER, who fears the disappearance of bears in the Alps, the killing of these animals being largely paid for in Switzerland by the State and by the communes, and several wild animals having already disappeared in Switzerland in this way, proposes to form a society which will pay for each disaster caused by bears, and prohibit the hunting of them.

THE additions to the Zoological Society's Gardens during the past week include a Macaque Monkey (*Macacus cynomolgus*) from India, presented by Mr. D. Orpen; a Black-faced Spider Monkey (*Ateles ater*) from South America, presented by Earl Brownlow, F.Z.S; a Common Seal (*Phoca vitulina*) from Scotland, presented by the Earl of Hopetown; a Dufresne's Amazon (*Chrysotis dufresniana*), a Yellow-Fronted Amazon (*Chrysotis ochrocephala*) from South America, presented by Mrs. T. Smith; a Noddy Tern (*Anous stolidus*) from Ascension Island, presented by Morris H. Smyth Long, Lieut. R.N.; a Tuberculated Lizard (*Iguana tuberculata*) from the West Indies, presented by Dr. Stradling; a Superb Tanager (*Calliste fastuosa*), a Yellow-winged Blue Creeper (*Cœreba cyanea*) from South America, two Merrem's Snakes (*Liophis merremi*) from Monte Video, deposited; two Cuming's Octodons (*Octodon cumingi*), born in the Gardens.

ON THE LAVAS OF HEKLA, AND ON THE SUBLIMATIONS PRODUCED DURING THE ERUPTION OF FEBRUARY 27, 1878

BUNSEN in a Memoir "On the Processes which have taken place during the Formation of the Volcanic Rocks of Iceland," published in Poggendorff's *Annalen* in 1851, classifies the rocks of the island into two principal groups, which he calls respectively the *normal trachytic*, and the *normal pyroxenic*. The one possesses the largest proportion of acid, and the other of base, and their composition may be approximately stated in the following analyses:—

	Normal trachytic Composition.	Normal pyroxenic Composition.
Silica	76·67	48·47
Alumina and protoxide of iron	14·23	30·16
Lime	1·44	11·87
Magnesia	0·28	6·89
Potash	3·20	0·65
Soda	4·18	1·96
	100·00	100·00

The trachytic rocks represent a mixture of bisilicates of alumina and of the alkalies potash and soda, while protoxide of iron, lime, and magnesia are almost wanting. On the other hand, the pyroxenic rocks are basic silicates of alumina and protoxide of iron, in combination with lime and magnesia, and insignificant quantities of potash and soda. In the trachytic rocks the percentage of alumina is from 10 to 12, and that of protoxide of iron from 2 to 4; while in the pyroxenic rocks the percentage of alumina is from 10 to 18, and that of protoxide of iron from 12 to 20. Normal trachytic rocks are found in great abundance on the banks of the Laxá, at Laugarfjall, near the great geyser, and at Krafla in the north-east of Iceland. The normal pyroxenic rocks are found on and around Hekla, on the banks of the Thjórsá, and at Thingvellir. Bunsen by an admirable induction, supported by a number of analyses, has proved that the rocks of Iceland which do not closely approximate in composition either to the normal trachytic or the normal pyroxenic, are intimate mixtures of these two classes of rocks,

and that hence in all probability there are but two separate volcanic foci.

Dr. Genth examined the various lavas from the western slope of Hekla, among them the lava erupted in 1845, which was found to contain—

Silica	56·76
Alumina and protoxide of iron	27·47
Lime	6·75
Magnesia	4·04
Potash...	2·63
Soda	2·35
	100·00

The lavas of Hekla are trachytic rather than pyroxenic. In the geological map of Iceland which appears in von Leonhard's *Vulkanen Atlas*, a broad strip, including more than half the area of the island, is designated trachyte. It is inclosed by lines running approximately north-east by south-west,—that on the west from Skjalfandik to Reykjavik, and that on the east from Héraðfloi, to the Orœfa Jökull.

I was surprised when I visited the scene of the eruption of February 27, 1878 (*vide* NATURE, vol. xviii. p. 596), to find how precisely the lava of this eruption resembled a very old lava in close contiguity to it, but flowing from a distant crater. Moreover the lava of 1845, on the other side of the mountain, and more than four miles from the craters of 1878, was observed to be quite the same in character as the most recent lava, which undoubtedly possesses a composition differing but little from that of the analysis given above.

The most notable feature of the last eruption appears to be the quantity of hydrochloric acid evolved from the beds of lava, and the considerable sublimations of sesquichloride of iron. Bunsen asserts that hydrochloric acid plays a less important part in the volcanic phenomena of Iceland than at Vesuvius and Etna.

"The hydrochloric acid fumaroles," he writes, "which not unfrequently occur on a large scale near the Italian volcanoes, and are then generally accompanied by a very considerable sublimation of chloride of sodium, appear to be of less importance in Iceland. I was only able to detect traces of hydrochloric acid in a free state in the crater fumaroles a few months old, which owed their origin to the last eruption of Hekla" (in 1845), "as well as in the exhalations of vapour from the lava which was then erupted."

For the future we must recognize hydrochloric acid as one of the products of the volcanic action of Hekla. During the last eruption it was produced in considerable quantity.

I had not proceeded far by the side of the lava of 1878, erupted five months previously, before I saw patches of brilliant red and yellow sublimations on the lava. These I naturally mistook for sulphur, but on a closer approach, warm vapours of hydrochloric acid were found to be issuing from the lava, and the sublimations when removed from the lava speedily deliquesced, forming an intensely acid and corrosive solution of sesquichloride of iron. I only succeeded in bringing one specimen of this sublimate to England, and this can scarcely be wondered at, when we remember that it had to be carried over 150 miles of very rough and pathless country before reaching the sea-coast. Moreover, as ill-luck would have it, the pony which was carrying my minerals, took fright during the last hour of a journey of many days, and within a few miles of Reykjavik our final destination; the box containing the specimens was broken to pieces, and they were scattered on the ground, but fortunately without much injury.

The specimen of chloride of iron sublimate has been qualitatively analysed in our school laboratory, by H. M. Elder, who finds it to contain in addition to sesquichloride of iron and free hydrochloric acid, chloride of aluminium, and very small quantities of the chlorides of ammonium, sodium, and calcium.

During our journey to the scene of the eruption of 1878, we frequently saw large patches of this sublimate, and near one of the new craters, in an inaccessible portion of the lava field, an area of several hundred square yards was covered with it. Most clearly therefore a notable feature of the eruption of 1878 has been the emission of large quantities of hydrochloric acid.

The formation of this substance during the eruption is easy to account for. Sublimations of a white substance were frequently visible in the crevices of the new lava. These, according to Herr Nielssens of Eyrabakki, consist of chloride of sodium, not of chloride of ammonium. Professor Silvestri found in different sublimations in the lava of Etna, erupted in 1865, quantities of chloride of sodium which varied from 50 to 90 per cent. (*I Fenomeni vulcanici presentati dall'Etna nel* 1863-6, page 139-142). Chloride of sodium, if it be heated in contact with silica and steam, undergoes decomposition, silicate of sodium and hydrochloric acid being formed. Bunsen has pointed out the fact that hydrochloric acid fumaroles can only exist when the high degree of temperature necessary for the decomposition of the chloride of sodium, has not receded far below the surface. For if it has so receded, the hydrochloric acid before reaching the surface will necessarily act upon the contiguous rocks, with the formation of chlorides which do not possess a sufficient degree of volatility to be brought to the surface. In the case of the sublimations in the lava of 1878, I noticed both free hydrochloric acid and sublimated chlorides, but the former was small in quantity, and no doubt the sublimations are receding deeper into the mass as the lava cools, and the next observer may find no trace either of the hydrochloric acid, or the sublimate of sesquichloride of iron.

G. F. RODWELL

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

IN addition to the regular course of instruction in the principles and practice of weaving at the Weaving Branch of the Glasgow Technical College, the Directors have made arrangements for three special courses of lectures which are now in course of delivery. These comprise a series on the history and development of the power loom, by Mr. John Watson, author of a "Treatise on Weaving"; another on Dyeing, by Mr. Noble; and a third series on Vegetable Fibres, by Mr. James Paton, F.L.S., Curator of Kelvingrove Museum.

THE Government of St. Petersburg, as we learn from the annual report just issued, had on December 1, 1878 (exclusive of the capital) 53 primary schools of the Ministry of Public Instruction, with 2,262 boys and 1,022 girls; 295 schools depending upon the School Boards, with 10,023 boys and 3,519 girls, and 21,975*l.* yearly expenses; and about 30 schools of separate institutions, with 1,380 boys and 1,533 girls.

WE learn that a Russian lady, Mme. Berladskaya, has just received the degree of Doctor of Medicine at the University of Paris, after having defended at a public meeting her thesis, "On the Structure of Arteries." This paper was spoken of in the highest terms by Prof. Charcot. Mme. Berladskaya is the second lady who has received the degree of Doctor of Medicine at Paris, the first having been Mme. Goncharoff.

SCIENTIFIC SERIALS

THE *Proceedings of the Linnean Society of New South Wales*. Vol. ii. part 4, and vol. iii. part 1. Part 4, vol. ii. contains: Prof. R. Tate, descriptions of three new species of helix from South Australia; Rev. J. E. Tenison-Woods, on the extra-tropical corals of Australia, three plates; the same, on the Echini of Australia, supplementary; W. Macleay, on the fishes of Port Darwin, four plates; John Brazier, on the mollusca of the Chevert expedition; the same, on some recently-found mollusca from Port Jackson and New Caledonia; E. P. Ramsay, on a new species of Rhipidura and of Eopsaltria from the Rockingham district, with remarks on some rare Queensland birds; the same, on a specimen of *Arses telescophthalmus*, on *Arses kaupi*, and on the young of *Cracticus quoyi;* the same, note on *Casuarius australis*, one plate; W. Stephens, the President, the annual address. Part 1, vol. iii. contains: E. P. Ramsay, on a new species of Ptilotis from Torres Straits; on a species of Myolestes from Fiji; notes on list of Australian birds; and descriptions of five new species of birds from Torres Straits and New Guinea; Rev. J. E. Tenison-Woods, on an Australian variety of *Neritina pulligera;* on a new genus (Arachnopora) of Milleporidæ; on a new species of Passamoseris; on a new species of Desmophyllum, and on a young stage of *Cycloseris sinensis;* on some Australian Littorinidæ; W. Macleay, note on a species of Therapon found in a dam at Warialda; on some new fishes from Port Jackson and King George's Sound; on a new species of Hoplocephalus; on the powers of locomotion in the Tunicata; C. Jenkins, on the geology of Yass Plains; Count de Castelnau, on the fishes of the Norman River.

SOCIETIES AND ACADEMIES

London

Royal Society, January 9.—"On the Electromagnetic Theory of the Reflection and Refraction of Light," by George Francis Fitzgerald, M.A., Fellow of Trinity College, Dublin. Communicated by G. J. Stoney, M.A., F.R.S., Secretary of the Queen's University, Ireland.

I have thrown the expressions for the electrostatic and electrokinetic energy of a medium given by Prof. J. Clerk-Maxwell in his "Electricity and Magnetism," vol. ii. part iv. chap. 11., into the same forms as M'Cullagh assumed to represent the potential and kinetic energy of the ether, in "An Essay towards a Dynamical Theory of Crystalline Reflection and Refraction," published in vol. xxi. of the *Transactions* of the Royal Irish Academy. Following a slightly different line from his, I obtain, by a quaternion and accompanying Cartesian analysis, the same results as to wave propagation, reflection, and refraction, as those obtained by M'Cullagh, and which he developed into the beautiful theorem of the polar plane. Of course, the resulting laws of wave propagation agree with those obtained by Prof. Maxwell from the same equations by a somewhat different method. For isotropic media, the ordinary laws of reflection and refraction are obtained, and the well-known expressions for the amplitudes of the reflected and refracted rays.

In the second part of the paper I consider the case of reflection at the surface of a magnetised medium, adopting the expressions Prof. J. Clerk Maxwell has assumed in "Electricity and Magnetism," vol. ii. part iv. § 824, to express the kinetic energy of such a medium.

I show that the method adopted in my former paper on Magnetic Reflection in the *Proceedings* of the Royal Society for 1876, No. 176, is justified, and that it is legitimate to consider an incident plane polarised ray as composed of two oppositely circularly polarised rays, each of which is reflected according to its own laws. I consider next the cases of the magnetisation being all normal to the surface, and all in the surface and the plane of incidence, and obtain the following result: When the incident ray is plane polarised, and the plane of polarisation is either in or perpendicular to the plane of incidence, the effect of magnetisation is to introduce a component into the reflected ray perpendicular to the original plane of polarisation, which vanishes at the grazing and normal incidences, and, in the case of iron, attains a maximum at about the angle of incidence $i = 63° 20'$.

I do not obtain any change of phase by reflection in any case; and this is to be expected, as this change of phase probably depends on the nature of the change from one medium to another, which, following M'Cullagh, I have uniformly assumed to be abrupt. Apart from this question of change of phase, my results conform completely to Mr. Kerr's beautiful experiments on the reflection of light from the pole of a magnet, as published in the Philosophical Magazines for May, 1877, and March, 1878.

"On Dry Fog," by E. Frankland, D.C.L., F.R.S., Professor of Chemistry in the Royal School of Mines.

January 16.—"Concluding Observations on the Locomotor System of Medusæ," by George J. Romanes, M.A., F.L.S. Communicated by Prof. Huxley, Sec. R.S.

The principal bulk of the paper is devoted to a full consideration of numerous facts and inferences relating to the phenomena of what the author terms "artificial rhythm." Some of these facts have already been published in abstract in the *Proceedings* of the Royal Society" (vol. xxv.), and to explain those which have not been published would involve more space than it is here desirable to allow. The tendency of the whole research on artificial rhythm, as produced in various species of Medusæ, is to show that the natural rhythm of these animals (and so probably of ganglio-muscular tissues in general) is due, not exclusively to the intermittent nature of the ganglionic discharge, but also in large measure to an alternate process of exhaustion and restoration of excitability on the part of the responding tissues—the ganglionic period coinciding with that during which the process of restoration lasts, and the ganglionic discharge being thus always thrown in at the moment when the excitability of the responding tissues is at its climax.

Light has been found to stimulate the lithocysts of covered-eyed Medusæ into increased activity, thus proving that these organs, like the marginal bodies of the naked-eyed Medusæ, are rudimentary organs of vision.

The polypite of *Aurelia aurita* has been proved to execute movements of localisation of stimuli somewhat similar to those which the author has already described as being performed by the polypite of *Tiaropsis indicans*.

Alternating the direction of the constant current in the muscular tissues of the Medusæ has the effect of maintaining the make and break stimulations at their maximum value; but the value of these stimulations rapidly declines if they are successively repeated with the current passing in the same direction.

In the sub-umbrella of the Medusæ waves of nervous excitation are sometimes able to pass when waves of muscular contraction have become blocked by the severity of overlapping sections.

Exhaustion of the sub-umbrella tissues—especially in narrow connecting isthmuses of tissue—may have the effect of blocking the passage of contractile waves.

Lithocysts have been proved sometimes to exert their ganglionic influence at comparatively great distances from their own seats—contractile waves, originating at points in the sub-umbrella tissue remote from a lithocyst, and ceasing to originate at that point when the lithocyst is removed. A nervous connection of this kind may be maintained between a lithocyst and the point at which the waves of contraction originate even after severe forms of section have been interposed between the lithocyst and that point.

When the sub-umbrella tissue of *Aurelia* is cut throughout its whole diameter, the incision will again heal up, sufficiently to restore physiological continuity, in from four to eight hours.

Chemical Society, January 16.—Dr. Gladstone, president, in the chair.—The following papers were read: On the action of isobutyric anhydride on the aromatic aldehydes, by W. H. Perkin. The author has studied the action of isobutyric anhydride on cuminic aldehyde, hydride of benzoyl, cinnamic aldehyde paroxybenzoic and anisic aldehydes. The bodies formed are respectively β isopropylbutenylbenzene, β butenylbenzene, butenylcinnamene, parabutenylphenol, and β parabutenylanisoïl.—On two new methods for the estimation of minute quantities of carbon and their application to water-analysis, by Drs. Dupré and Hake. The first consists in burning the substance in a current of oxygen in a combustion tube with oxide of copper, absorbing the carbonic acid in a Pettenkofer tube with baryta water, filtering off the barium carbonate with great care, converting it into chloride, then into sulphate, and weighing; in the second, the carbonic acid passes into a 2 per cent. solntion of basic acetate of lead, and the turbidity compared with that produced by a solution of carbon of known strength in a Mills colorimeter.—On stannic ethide, by Dr. Frankland and Mr. A. Lawrance. By treating zinc ethyl with successive quantities of fused stannous chloride, the authors have prepared stannic ethide with great facility, they have also examined its properties, and specially investigated the action of sulphurous acid.—On aurin, by R. S. Dale and C. Schorlemmer. The authors have prepared pure aurin with great care, and confirmed the formula which they have already assigned to it. They have also studied ammonia aurin, tetrabromaurin, and the compounds formed by aurin with acetic, sulphuric, hydrochloric, and nitric acids.—On the derivatives of diisobutyl, by W. Carleton Williams.—On the action of chlorine upon iodine, by J. B. Hannay. The author confirms his previous conclusion, viz., that a body containing one atom of iodine and four atoms of chlorine does not exist.

Geological Society, January 8.—Henry Clifton Sorby, F.R.S., president, in the chair.—Charles Barrington Brown, Carl Fischer, M.D., F.L.S., William Coles Paget Medlycot, were elected Fellows; and Dr. F. V. Hayden, Washington, and M. Jules Marcou, Salins, Foreign Members of the Society.—The following communications were read:—On some tin-deposits of the Malayan Peninsula, by Patrick Doyle, C.E. (Communicated by the Rev. T. Wiltshire, F.L.S.) The tin-ore of the Malayan Peninsula is obtained from "stream-works" in an alluvial plain extending between a range of granitic mountains and the sea. The author describes the mines of the district of Larut Perak. The ore is got in open workings at an average depth of about 10 feet. The tin-bearing stratum has an average thickness of 4·87 feet; it is overlain by stratified sand and clay, and rests upon either porcelain clay or, sometimes, a sandstone. The ore varies from a fine sand, near the sea, to a coarse gravel, near the mountains, and is mixed with quartz, felspar, mica, and schorl. The author is of opinion that the stratum of ore has been derived from the granite of the mountain range, in which it still occurs in veins,

by denudation, and under conditions which still exist, though in a modified form.—Description of fragmentary indications of a huge kind of Theriodont reptile (*Titanosuchus ferox*, Owen), from Beaufort West, Gough Tract, Cape of Good Hope, by Prof. R. Owen, C.B., F.R.S. The author stated that among the fossils recently sent to the British Museum from the Cape of Good Hope by Mr. T. Bain, there were two boxes containing specimens of a most unpromising character, there being in them no entire bones, but only numerous more or less water-worn fragments. Among these was found a portion of a maxillary showing some traces of teeth; and sections having been made of this bone, the remains of several teeth were displayed, including a canine, the preserved portion of the socket of which was 4½ inches long. From the number and mode of implantation of the teeth, the author concluded that the animal to which they belonged resembled the Theriodont genera *Galesaurus* and *Galenops*. The anterior portion of the left ramus of the lower jaw, measuring 7½ inches in length, showed teeth presenting close analogies with those of Theriodonts, and this alliance was confirmed by the study of other fragments. Some of the characters presented by these remains seem to suggest affinities with the carnivorous mammalia, such as have been already indicated by the humeri of Theriodonts and Carnivores. The canine tooth of the new South-African reptile, which the author proposes to name *Titanosuchus ferox*, was six times as long as that of the allied form *Lycosaurus*; and we have in *Titanosuchus* evidence of a carnivorous reptile of more carnassial type than *Machairodus* and other felines. The author suggests that *Titanosuchus* found its prey in the contemporary *Pareiosauri*, Oudenodonts, and Tapinocephalans of the same locality.—Notes on the consolidated beach at Pernambuco, by J. C. Hawkshaw, M.A., F.G.S. The consolidated beach at Pernambuco, which has already attracted considerable notice, is a ridge of sandstone from 25 to 75 yards wide, and, as shown by borings made under the author's direction, from 10 to 13 feet thick. The landward or higher edge is nearly at the spring-tide high-water level, and it slopes seaward; the river (with a depth of 28 feet at low water 60 feet from the rock) flowing along the former face. The rise and fall of spring tides is 7 feet. Beneath the above rock is a stratum of sand with shells and stones about 8 feet thick, and then a second layer of sandstone rock. The consolidated beach is cemented by carbonate of lime, which the author considers to have been deposited by the action of water percolating through the rock, probably when the level of the land differed somewhat from what it is at present. He thinks it possible that this and other similar beaches on the Brazilian coast may mark periods of repose in the slow vertical movements which the coast has undergone.

Zoological Society, January 14.—Prof. Newton, F.R.S., vice-president, in the chair.—Dr. Traquair, F.R.S.E., exhibited a specimen of the Hackled Pigeon (*Alectorœnas nitidissima*) recognised, last September in the Museum of Science and Art in Edinburgh, by Prof. Newton, F.R.S., M.A., who made some remarks on the species showing (1) that it was peculiar to Mauritius, (2) that it is now wholly extinct, and (3) that only three specimens of it are known to have been preserved.—The Secretary read an extract from a letter received from Commander Hoskins, R.N., of H.M.S. *Wolverine*, on the subject of the range of the Mooruk, stating that no traces of the existence of this bird could be found in New Ireland.—An extract was read from a letter addressed to the secretary by the Rev. George Brown, giving additional particulars on the same subject.—The Secretary read an extract from a letter addressed to him by Mr. R. Trimen, F.Z.S., of Cape Town, on the subject of the true locality of the Black Spurwinged Goose (*Plectropterus niger*), which he had ascertained had been brought to Cape Town from Zanzibar.—A communication was read from Dr. Morrison Watson and Dr. Alfred H. Young, on the anatomy of the Spotted Hyæna (*Hyæna crocuta*).—A communication was read from Mr. A. D. Bartlett, giving an account of the habits and changes of plumage of Humboldt's Penguin, as observed in a specimen which had been recently living in the Society's Gardens.—A communication was read from Dr. O. Finsch, C.M.Z.S., containing an account of a collection of birds made by Mr. Huebner, on Duke of York Island and New Britain.—A communication was read from Mr. Edward J. Miers, F.Z.S., describing a collection of crustacea, made by Capt. H. C. St. John, R.N., in the Corean and Japanese Seas. The present paper related to the Podophthalmia of the collection, of which groups twenty-six species were described as apparently new to science.—A communication was read from Count T. Salvadori, C.M.Z.S., containing critical remarks on Mr. Elliot's paper on the Fruit-pigeons of the genus *Ptilopus*, lately published in the Society's *Proceedings*.—A communication was read from the late Marquis of Tweeddale, F.R.S., containing the twelfth of a series of contributions to the ornithology of the Philippines. The present paper gave an account of the collection made by Mr. A. H. Everett in the Island of Basilan.—Dr. A. Günther, F.R.S., gave an account of the mammals, reptiles, batrachians recently collected by Mr. Everett in the Philippine Islands, and called special attention to a new form of snakes of the family Calamariidæ, of which one example had been obtained. This snake, which was remarkable as possessing no external rudiments of eyes, was proposed to be called *Typhlogeophis brevis*.

Mineralogical Society of Great Britain and Ireland, January 7.—General Meeting.—Mr. H. C. Sorby, F.R.S., president, in the chair.—The following papers were read or taken as read:—On pilolite, an unrecognised species, by Prof. M. F. Heddle, M.D.—On so-called green garnets from the Urals, by Prof. A. H. Church, M.A.—On the magnetism of rocks and minerals, by J. B. Hannay, F.C.S.—On the celestine and baryto-celestine of Clifton, by J. N. Collie, communicated by W. W. Stoddart, F.G.S.—On some silicates of copper, by Wm. Semmons, president of the Liverpool Geological Society.—Contributions towards a history of British meteorites, by T. M. Hall, F.G.S.—Notes on some crystals of iron, by Amos Beardsley, F.G.S.—Notes on massive and crystallised cronstedite from Wheal Jane, by A. K. Barnett, F.G.S.—A large number of Members and Associates were elected by the Council previous to the meeting.

EDINBURGH

Royal Society, January 6.—Prof. Kelland, president, in the chair.—Mr. James Blyth gave notes on some experiments with the telephone. When the ends of two wires attached to the telephone were rubbed against one another and kept at a high temperature a grating sound was heard in the telephone, which diminished as the temperature was lowered. The sound, however, did not quite cease when the ends of both wires were cold. In this case the sound was louder and more distinct when the wires were attached to two files which were rubbed against each other. The experiment was modified by attaching one wire to the file and the other to a vice. Different substances—brass, carbon, zinc, iron, steel—were then screwed into the vice and rubbed by the file, but not much difference was observed between the effects produced. Another modification consisted in attaching the second wire to the axle of the fly-wheel of a lathe. In the last case the sound was very loud and distinct when the file attached to the other wire was held hard against the wheel as it revolved. A sound was also heard in the telephone when a hammer was made to strike a body—the hammer and the body being each connected to one of the telephonic wires. The sound was distinct but not so loud as with the rubbing. The sound was very loud when a large toothed wheel driven fast was used, and against which a strong spring struck, the one wire being attached to the wheel the other to the spring. Here there is a combination of striking and friction. Mr. Blyth suggested that these currents might be due to thermo-electric action or might be the electricity which Sir Wm. Thomson considers as the probable cause of friction.[1] The experiment was again varied by connecting one wire to the style of a phonograph and the other with the screw; there were two Bunsen cells in the circuit, which was completed by the style and cylinder. When the phonograph was spoken into, a person in a distant room could hear by means of the telephone. This seemed to show that the style presses unequally on the tinfoil and hence that although magnified copies of the curve on the tinfoil may be obtained by multiplying levers, these copies do not necessarily represent the motion of the style.—Prof. Tait gave a note on the measurement of beknottedness. The former measure was the smallest number of crossings whose signs must be changed to take off all the knotting. An objection to this was that these seemed to have no direct connection with the electro-magnetic measurement. The new method consists in drawing the knot in two parallel curvilinear lines easily distinguishable from each other by colour or formation, the one knot being thus wholly within the other. A knot is cut across through the symmetrical angle, and the ends joined again.—Prof. Tait gave a preliminary note describing some experiments

[1] Bakerian Lecture, 1856, *Phil. Trans.*, foot-note to second page.

he was making for the purpose of measuring what is known as the "Thomson Effect," viz., the convection of heat by electric currents from a cold to a hot part of a bar, or *vice versâ*. The method had occurred to him while testing the electric conductivity of bars heated for Forbes' conduction experiment.—A paper was read by Dr. Macfarlane and Mr. P. M. Playfair, on the disruptive discharge of electricity, in confirmation of former experiments of a similar nature. They found former anomalies with sparks of more than a certain length between two spheres, to be due to discharge by small sparks, and beyond that to escape into the air from the insulated wire. In the case of discharge between a plate and a point, there was a gradual increase in the difference of potential. Up to a certain limit the sparks were white; beyond that the sparks were violet, and there was very slight increase in the difference of potential required. On discharging through solid paraffin it was found that the first spark was by far the largest, and on examination the paraffin was found perforated in a zigzag manner, and the sides of the perforation were charred. The solid paraffin had twice as great electric strength as the same paraffin in the liquid state, and five times the electric strength of air. They found that the electric strength was a very definite method of distinguishing between different paraffins, but somewhat difficult of application.—Prof. Tait showed some pieces of sheet or tape india-rubber which Mr. Maclachlan of Mitcham had used to insulate wires, and which, after being stretched for some years, were found to be permanently strained; but they immediately regained their former dimensions on being dipped into hot water. The same phenomenon was true, he found, of india-rubber which, while warm, was stretched out nearly to rupture, and then kept stretched till cold. Prof. Clerk Maxwell had found a similar property true of gutta-percha pulled out when cold after being boiled. On heating it before a fire it took a peculiar form.

VIENNA

Imperial Academy of Sciences, December 5, 1878.—On twins; a contribution to human physiology, by Dr. Göhlert.—On the diffusion of liquids, by Prof. Stefan.—Determination of the path of the third comet of 1877, by Herr Zellr.

December 12, 1878.—On the fish species in the two lakes of Lower Austria, the Erlaph and Lunzer Lakes, by Dr. Fitzinger.—New observations on sounding air columns, by Prof. v. Lang.

PARIS

Academy of Sciences, January 13.—M. Daubrée in the chair.—The following papers were read:—On the construction of bridge-arches realising the maximum of stability, by M. Villarceau.—Researches on ozone and on the electric effluve, by M. Berthelot. Oxygen (1 vol.) and hydrogen (2 vols.) do not combine under action of the effluve, though the tension be nearly that which gives, through air, sparks 7 to 8 ctm. long. O will combine with the metals, sulphurous acid, nitrogen, &c., under such conditions. CO (2 vols.) and O (1 vol.) combine under like tensions; but the reaction is incomplete; and even with excess of O it is so. The effluve, acting on a mixture of CO_2 and O partly decomposes the former, and the O contains ozone; acting on pure CO_2 in a space without mercury or oxidable bodies, the effects point apparently to the existence of percarbonic acid.—On the formation of ethers of hydracids in the gaseous state, by M. Berthelot.—Are there, among low organisms, species exclusively *aërobies*, and others exclusively *anaërobies?* Should all these beings be ranged in two or three classes (Pasteur) or in one only? by M. Trecul. He argues for one class only, each species being capable of presenting at once one or several *aërobian* states, and one or several *anaërobian*.—Reply to M. Berthelot, by M. Pasteur.—Researches on the compressibility of gases, by M. Cailletet. He describes the manometer he uses; a tube of soft steel wound helically round a vertical cylinder, by turning which the tube is sent down a deep pit or wound up again. The lower end of this tube is connected with a laboratory-tube, in which is inclosed the piezometer containing the gas, and mercury is introduced into the apparatus. This tube is suspended by a fine graduated steel wire, the length of which unrolled measures the pressure. M. Cailletet tabulates his numerical results with nitrogen, which, it appears, contracts at first more than according to Mariotte's law; its compressibility then decreases (as in the case of air). It is about a pressure of 70 metres of mercury, that the gas presents this curious maximum.—The polymorphism of *Agaricus melleus*, Vahl., by M. Planchon.—Experiments relating to the action of waves on beaches and on artificial rock-work, by M. De Caligny. He reproduces in an artificial canal effects noticed at the rock-work of Cherburg, where large waves which, at low water, rolled the blocks towards the summit of the talus, had an undermining effect at high water.—M. Monot presented some specimens of results he has obtained in manufacture of various kinds of crystal.—The phylloxera in Panama, on the *Vitis caribæa*, D.C., by M. Collot.—On the employment of oil of asphalte against phylloxera, by M. Berton. Some one told him, when exploring the Dead Sea, that this oil had saved the vineyards of Judea from a worm (phylloxera?).—Letter to the President of the Commission on phylloxera, by M. Truchot.—MM. Felson and Chartre communicated a detailed catalogue of those erratic blocks most remarkable as regards the history of glacial phenomena.—The General-Inspector of Navigation presented data concerning flood and low-water of the Seine in 1878.—Observations of Saturn's satellites, at the Observatory of Toulouse, in 1877 and 1878, with the large Foucault telescope, by M. Baillaud.—New compound prism for direct-vision spectroscope of very great dispersive power, by M. Thollon. This sulphide of carbon prism is closed laterally by crown glass prisms, whose refringent angles are in opposite direction to that of the sulphide. The compound prism gives the enormous dispersion of 2'·0 angular distance of the D-lines, as compared with 45" for sulphide of carbon. Substituting the new prisms in his former spectroscope, he got a dispersion equivalent to that of 16 sulphide of carbon prisms of 60°, or 31 prisms of index 1·63. It gave 12' angular distance in the D-lines, and it presents quite new aspects of the spectrum. All the lines (newly) resolved were found to belong to different substances.—On M. Thollon's spectroscope, by M. Laurent.—On determination of the variations of level of a liquid surface, by M. Renou. A claim of priority.—Synthesis of uric derivatives of the series of allophane, by M. Grimaux.—Action of diastase, saliva, and pancreatic juice on starch and glycogen, by MM. Musculus and De Méring.—New observations on the development and metamorphoses of Taenias, by M. Megnin. Certain unarmed and armed Taenias are two adult forms of the same worm, their differences due exclusively to the conditions of their development.—Observations on Majorca and Minorca (continued), by M. Hermite.—New observations on the danger of use of powdered borax in meat-preserving, by M. Le Bon.

THE ART OF SCIENTIFIC DISCOVERY

The Art of Scientific Discovery, or the General Conditions and Methods of Research in Physics and Chemistry. By G. Gore, LL.D., F.R.S. (London: Longmans, Green and Co., 1878.)

IT is not easy to say when scientific research, using the expression in its strictest sense, was first commenced. M. Libri remarks: "Les recherches des Pythagoriciens sur les vibrations des corps, sont les plus anciennes expériences de physique qui soient parvenues jusqu'à nous." Archimedes must certainly be credited with some knowledge of research; and to a lesser extent Ptolemy the astronomer, and Hero, of Alexandria. But, as a matter of fact, experimental researches in physics were not made before the epoch of Galileo, nor in chemistry before the epoch of Lavoisier. The discovery of new methods of mathematical analysis on the one hand, and the invention of instruments of precision on the other, were necessary forerunners of the development of research. Moreover, the advocacy of the abandonment of that blind reverence for authority which had retarded the progress of the sciences for many centuries, tended in the same direction. In this respect, whatever we may say of Campanella, Nizolius, Telesius, and others, our own Francis Bacon did more true service than any of his predecessors; and we must always regard his writings as the most potent engine concerned in the overthrow of Aristotelianism, Scholasticism, and the method of pure logic, and in the substitution of the experimental method blended with just logical induction and deduction.

Mr. Gore, whose own devotion to experimental research well entitles him to act as an interpreter of the art of scientific discovery, has in the course of sixty chapters of condensed matter discussed the various lines of thought and of action which converge towards that bright central focus in which new truths lie hidden. His object has been to describe the nature, the methods, and the conditions of success of original scientific research; to point out the causes of failure, the mental and manual discipline by which they may be overcome; and the special modus of thought by which we may hope to ascend from the known to the unknown.

With this object in view he has divided the work into five parts, the first of which contains a general view of the subject:—the nature of scientific ideas, terms, and beliefs, the criteria of scientific truth, and the great principles of science. In the second part he has discussed the general conditions of scientific research:—the starting points, chronological order of discovery, importance of qualitative knowledge, and necessity of classification. The third part is devoted to the personal preparation for research; the fourth to the actual working in original research; and the fifth to special methods of discovery. This latter is divided into ten parts, which treat respectively of discovery:—

1. By extending undeveloped or neglected parts of science.
2. By the use of new or improved instruments.
3. By the investigation of likely circumstances.
4. By devising hypotheses and questions, and testing them.
5. By means of new experiments and methods of working.
6. By means of additional, new, or improved observations.
7. By classifying and comparing known truths.
8. By means of study and inference.
9. By means of new or improved methods of intellectual operation.
10. By means of calculations based upon known truths.

In the discussion of these subjects, the history of various scientific discoveries is traced, and we are not only brought into contact with the investigator's particular train of thought throughout all the steps which led up to the discovery, but we are often taken into the minuter labyrinths and shown the many collateral ideas which were evoked during the course of the research. The influence of previous discoveries upon the main subject at issue is also developed, so that we gain important information regarding the history of the sciences, while at the same time we are becoming acquainted with the art of original research.

In that portion of the work which relates to method, we are not surprised to find that the author has often quoted Lord Bacon. In fact, Mr. Gore's style is sometimes thoroughly Baconian. So penetrated is he by the spirit of the "Novum Organum," that he sometimes unconsciously embodies its aphorisms with his own; for example, when he says: "Science is the interpretation of nature, and man is the interpreter. Original research is the chief source of new scientific knowledge." His work may almost be called a nineteenth century continuation of the second book of the "Novum Organum"—a sort of *newest* organum. He also quotes pretty frequently the "History of the Inductive Sciences," and sometimes the "Novum Organum Renovatum," with which the "Art of Scientific Discovery" has many points of contact. We are surprised to find Descartes so rarely alluded to, albeit portions of the work relating to Method are thoroughly Cartesian in spirit. Here, for example, is an excerpt from the *Regulæ ad Directionem Ingenii*, which we recommend to Mr. Gore's notice for the second edition:—"By method I understand rules certain and easy, such as to prevent any one, who shall have accurately observed them, from ever assuming what is false for what is true, and by which with no effort of mind uselessly consumed, but always by degrees increasing science, a person will arrive at a true knowledge of all those things which he will be capable of knowing." Also we commend to his notice the answer to *Quid sit Cogitatio* ("Principia," Pars 1, ix.); and to that very notable assertion ("Principia," Pars 2, xxiii.), *Omnem materiæ variationem, sive omnem ejus formarum diversitatem pendere à motu.*

Early in the work Mr. Gore points out a fact which we too seldom recognise. "Original research," he writes, "is not a science; it is not a collection of laws. It is an art, because it is composed of rules which must be followed. It is the method of finding new truths by means of study, observation, travel, or other means." Now although we think that an investigator must be born and cannot be made, and that no one can frame his methods upon hard

and fast lines of thought or operation, we are quite of opinion that those who make original researches, or are about to make them, may gain much from orderly methods of manipulation, and a knowledge of the right application of logical inference. Bacon attempted to describe such methods in his "Inquisitio de Forma Calidi," and failed, because at that time there did not exist a sufficient basis upon which to found an exhaustive experimental treatment of the subject.

Two interesting chapters in the first part of the book are devoted, the one to the facts and propositions in science, and the other to the criteria of scientific truth. We are reminded herein of an interesting treatment of these subjects in the "Philosophie Méthodique" of M. de Strada, to which we venture to refer our author.

Among the conditions of success in research Mr. Gore very justly enumerates enthusiasm. Of this he quotes several examples. Becher, of Phlogiston fame, after speaking of the chemists as "a strange class of mortals impelled by an almost insane impulse to seek their pleasure among smoke and vapour, soot and flame, poisons and poverty," adds: "Yet among all these evils I seem to myself to live so sweetly, that may I die if I would change places with the Persian King!" The fascination of original research is undoubted, the enthusiasm which it sometimes inspires is unbounded. We remember an instance of a schoolboy who seriously proposed staying at school for several days at the beginning of the Christmas holidays, when "home, sweet home," is doubly sweet, in order to continue a research. And truly, were it not for the enthusiasm which it engenders, the amount of original work done in the world would be much less than it is, seeing that it is usually accompanied by numberless vexations and disappointments, and that it requires unwearied application and perseverance, joined to the possession of an undaunted spirit.

Of Mr. Gore's work as a whole we may say that it exhibits great industry in the collection of facts and a considerable amount of logical acumen in their discussion. Perhaps, however, the arrangement might be simplified. The mass of matter to be digested is so great that any increased modes of classification of the subjects that could be adopted would add to the value of the book. This could best be effected by numbering the paragraphs; by adding marginal references giving the gist of each paragraph, and by making some of the chapters more aphoristic in character. These changes could be easily effected in a second edition.

G. F. RODWELL

LEISURE-TIME STUDIES

Leisure-Time Studies; chiefly Biological; a Series of Essays and Lectures. By Andrew Wilson, Ph.D., F.R.P.S.E., &c. With numerous Illustrations. (London: Chatto and Windus, 1879.)

THIS volume of Essays and Addresses does not profess to contain anything new, either in the way of observation or theory. Neither is the author's style sufficiently brilliant, or his treatment of the subjects sufficiently original to raise them much above the level of the average lectures of a well-informed naturalist. They will, however, afford some useful and interesting information to the general reader, and may serve to attract attention to the question of the introduction of biology into ordinary education. This is the special subject of the first address, which, however, though somewhat lengthy and profuse, does not attempt to grapple with the difficulty of finding competent teachers of biology for *all* our schools. It is indeed suggested, that "the amount of knowledge required to pass even the primary stage of the biological subjects, in the government examinations, held under the auspices of the Science and Art Department," should fit its possessor for imparting elementary instruction in biology. But we greatly doubt whether the examiners would be of this opinion; and we rather think it would be a distressing sight to witness a teacher, whose whole knowledge of the subject was derived from a course of study just sufficient to enable him to pass such an examination, exposed to the questions of a lot of intelligent country boys and girls, whose practical acquaintance with native plants and animals was far more extensive and accurate than his own. If biology is to be taught in schools it must not be by the regular school-teachers qualifying themselves by a few months' training in London, but by the employment of good naturalists to give lectures, demonstrations, and out-door excursions to all the schools of a district in succession.

In the succeeding address, on "Science-culture for the Masses," too much stress is laid on the teaching of science as "a pleasant system of mental gymnastics." This seems to us altogether a wrong ground to go upon. Science is not to be taught in order to strengthen the mind to do something else by and by, but because it opens the mind to a more adequate conception of the universe in which we live, and is in itself, truly, the knowledge which is power.

The lecture on "The Sea-serpents of Science" is interesting, both as giving a very fair summary of the most recent evidence on this subject, and as showing that the age of incredulity is past, and that naturalists are now prepared to admit that several distinct kinds of oceanic monsters probably exist, of which no single specimen has yet been obtained. Recollecting, however, the number of clever hoaxes to which this subject has given rise, we think that the newspaper account at p. 104, of the declaration before a Liverpool J.P., made by the master and crew of a merchant-ship, to the effect that they had seen a huge serpent twice coiled round a sperm whale, and a similar serpent with its head raised "sixty feet perpendicularly in the air," should not have been inserted as evidence without first ascertaining that such a declaration was actually made before the magistrate named. The trouble of writing a single letter would probably have been sufficient, and would have settled the preliminary question of whether the whole story, from beginning to end, was not a pure newspaper *canard.*

The article on "The Genesis of Life" repeats the now often-told tale of the fluctuations of opinion as to spontaneous generation, and will be interesting to those who have not read it elsewhere. Dr. Wilson tries his best to be impartial, and to place before his reader the exact position of the question at the present time. He acknowledges that "isolation" and "destruction" are the two great points of all experiments on the subject, and that if

these are perfect the question can be settled. It is not denied that hermetically sealed flasks give complete isolation, the only question remaining being, to secure complete destruction of whatever organisms, with their germs, may be within the flasks at the commencement of the experiment. He refers to Dr. Bastian's experiments on the death-point of minute organisms and their germs, which was invariably found to be 158° F., and he points out no fallacy in these experiments. Yet if they are conclusive, Dr. Bastian's numerous other experiments, confirmed as they are by Dr. Burdon-Sanderson and others, demonstrate the production of living organisms from dead matter. The elaborate experiments of Prof. Tyndall are referred to as giving results directly opposed to those of Dr. Bastian; but it is not sufficiently pointed out,—firstly, that in Dr. Tyndall's experiments "isolation" was not effected in the only perfect manner by hermetical sealing, and that many contradictory results hence ensued;—and secondly, that all the results opposed to those of Dr. Bastian were negative, and could therefore not disprove the latter's positive results. Dr. Bastian in his test experiments did not use "old hay," the germs in which are said to be "indurated," but infusions of turnip and cress, and after these were subjected in sealed flasks to temperatures of 270° F., and to 230° F. for upwards of an hour, they produced living organisms of such varied types as *bacteria, torula, protamœbæ*, and *monads*. ("Evolution and Origin of Life," p. 175-180.) As *similar organisms* and their germs, *produced in similar infusions* have been proved to be killed by a temperature at least 100° lower than that employed in the above experiment, what we require to settle the question is, not thousands of quite different experiments, whose results one way or the other cannot settle the point at issue, but a repetition of the same experiments by other observers with the object of detecting the fallacy, if any, that lurks in them.

The only other article we can here refer to, is that on "The Law of Likeness and its Working," which deals with the question of heredity, and Mr. Darwin's theory of Pangenesis. But no notice is taken of Mr. Francis Galton's very important "Theory of Heredity," published in he *Journal of the Anthropological Institute*, vol. v. p. 329; which, though it may be considered as a mere modification of that of Mr. Darwin, really differs from it in many important points, and affords a more complete and satisfactory explanation of many of the most curious facts; such as the *unlikeness* of children to their parents, the appearance of diseases and even of mental qualities, in alternate generations, and many others. Every one wishing to comprehend this most difficult yet most interesting subject, should study Mr. Galton's paper as a necessary supplement to the theory of Pangenesis.

At p. 70 of Dr. Wilson's book, a letter from the *Times* is quoted, describing the formation of the bees' cell, as due entirely to the *pressure* of opposing bees in adjacent cells. This is not strictly correct; and Mr. Darwin's observations should have been refered to, showing that the cell-walls are first built very thick, and are *gnawed* down to the requisite thinness. There is also some obscurity in the suggested explanation of the "apparent movement" of the crocodile's upper jaw, when it opens its mouth. The fact appears to be that the crocodile, opening its mouth when on land, *must* raise its upper jaw and head (by bending the neck) simply because the lower jaw has not room to move downwards. The movement of the upper jaw is therefore, under these circumstances, real, and not only "apparent" as stated. One of the most interesting chapters is that on "Animals and their Environments," in which an account is given of the curious changes during the growth of flat fishes, and the still more remarkable phenomena which have been recently observed in the metamorphoses of the axolotl, and the alpine salamander.

A. R. W.

OUR BOOK SHELF

An American Geological Railway Guide, giving the Geological Formation at every Railway Station; with Notes on interesting Places on the Routes, and a Description of each of the Formations. By James Macfarlane, Ph.D. (New York: Appleton and Co., 1879.)

DR. MACFARLANE has added a new pleasure to railway travelling, or rather, by means of this geological guide-book, he has done much to make it both enjoyable and instructive. The idea of the book is excellent, and the plan seems to us thoroughly satisfactory. Now that we have this manageable little flexible book before us, it seems strange that such a guide has not been thought of before, but perhaps not so strange that our enterprising friends on the other side should set an example to their Old-World brethren. We believe the prospectus of some such guide was issued in this country several months ago; if so, we recommend its compilers to obtain a copy of Dr. Macfarlane's book, and take several leaves out of it. If no such work is being prepared for the forlorn traveller of our islands, we advise some of our Survey-men to lay their knowledge together, and produce a similar guide as speedily as possible; they will be doing a public service, and if the result is as satisfactory as in the case of the book before us, they will, we feel confident, reap something more substantial than thanks. In compiling his tables, Dr. Macfarlane has had the assistance of some of the most eminent geologists in the States, and some of the information has not before been published. The tables are very similar to railway time-tables, having on the left hand side of the names of the stations, the miles between each, and on the right, instead of the times, the names of the leading formation to be seen along the route. The tables are so constructed as to be useful for a continuous journey through the States in any direction, and, at the same time, to give an idea of the leading geological characteristics of each state. Appended is an index to railroads, and a general geological map of the States. Prefixed are about fifty pages of instructive information, consisting mainly of methodical descriptions of the various formations of North America, and containing Dana's and Hunt's tables of formations. By carefully studying this the traveller will be in a fair position to profit by the tables, and by the faithful use of these much practical knowledge of geology may be acquired even by the ignorant, while to the geologist they will be a constant source of enjoyment; the handy volume is much more easily managed than a map. We may state that the tables refer to Canada as well as the States.

Comment le font les Miracles en dehors de l'Église. Wilfrid de Fonvielle. (Paris: Dreyfous.)

WHY does not M. Dreyfous date his books? We are sure M. de Fonvielle cannot have noticed the suspicious omission. M. de Fonvielle is already pretty well known in France as a popular gossiper on what may be called the eccentricities of science. The present volume is quite equal in interest to anything he has published, and is likely, we should think, to be widely read in France. It

is a series of stories, told with raciness and touches of sarcasm and humour, of the many impostures which have been perpetrated on the public by those who knew how to turn to account some of the results of science. Of course spiritualism comes in for a large share of notice, while the real miracles of science are pleasantly described in one or two concluding chapters. The book is altogether a very curious one, and evidences considerable research in out-of-the-way corners on the part of its author.

On Foot in Spain; a Walk from the Bay of Biscay to the Mediterranean. By J. S. Campion. Illustrated by Original Sketches. (London: Chapman and Hall, 1879.)

MAJOR CAMPION has already proved his power as a charming *raconteur* in his "On the Frontier," and although in artistic finish and exciting incident the present work is not equal to the former, still it is a well-told story of a free and easy walk through a comparatively little-known country. Major Campion did not encumber himself with more baggage than he could carry himself, and with his gun and genial manners and tact he got on without difficulty wherever he went. We should think his work is likely to increase the number of pedestrian tourists in Spain, about the obstacles to travel in which many delusions exist. Major Campion has much to tell in his own way about the places and people he saw, and every now and then we are glad to stumble on a scrap of information about the geology or natural history of the country. His book ought to have many readers.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

Leibnitz's Mathematics

Tempora mutantur, et nos, &c., seems to hold true for Dr. Ingleby, though not for myself, in this matter. His tone has completely changed since December 4, 1871; and he now puts "scientist" (*in quotation marks*) where you had written "scientific man," although in his former letter he said he "hated" the far less obnoxious word "physicist."

That I did not reply to his former letter was mainly because he said that "the question is not susceptible of *proof* until the Council of the Royal Society, who so grossly disgraced themselves in 1712, shall do" a certain "simple act of justice." Recourse to the spiritualists is our only chance in such a matter, and these have now an admirable opportunity for demonstration of their claims.

All I said of Leibnitz was "who, I fear, was simply a thief as regards mathematics." This was completely justified to my mind at the time, partly by my own reading, mainly by some curious documents which Sir David Brewster once showed me. These appeared to me to leave no doubt whatever as to the dishonesty, not only of Leibnitz, but of several of those who have been, at different times, connected with his side of the dispute.

Your allusion to Gregory's series seems to me to bring in no "collateral question" but a very important central one:—it seems to go, in fact, to the root of the matter. For, if Leibnitz was dishonest, this was probably his first (known) offence. Mr. Bottomley's apt quotation looks like a desperate attempt at justification of conduct which the writer felt to be, to say the least, suspicious.

Instead of appealing to the Royal Society Council of 1712, Dr. Ingleby should demand from the proper authorities the publication of that conclusive MSS. of Leibnitz for which Dr. Sloman *asked in vain* in 1858.

P. G. TAIT

The Magnetic Storm of May 14, 1878, Observed in North America

NOTICING in NATURE (vol. xviii. p. 617, and vol. xix. pp. 148, 173, 220) references to the "magnetic storm" of May 14, 1878, I have had prepared by Mr. C. A. Schott, the assistant having direction of our magnetic observatory at Madison, Wisconsin, the inclosed memoranda relative to observations made at that point, as an item of interest to your readers, illustrating the general character and almost simultaneous action of that great magnetic disturbance.

C. P. PATTERSON,
Supt. Coast and Geodetic Survey

Washington, January 6

THE extensive magnetic disturbance of May 14, 1878, of which accounts have been given in NATURE, vol. xviii. pp. 617, 641, 668, and which was observed in China, Australia, and England, was also making its record in North America at our magnetic observatory, established at Madison, Wisconsin, in the winter of 1876–77. This observatory is in latitude 43° 4′ 29″·5, and in longitude 5h. 57m. 36·5s. W. of Greenwich; in it are mounted a set of Brooke's magnetographs, and daily photographic traces of the changes in magnetic declination and in the horizontal and vertical forces have been produced since March, 1877, and are intended to be kept up for some years. The declination traces for several days preceding the 14th were normal, but about midnight, May 13–14, a series of disturbances commenced consisting in part of some large oscillations to the eastward and westward, and in part of a great number of small and rapid oscillations. The characteristic features of the trace may be given as follows:—

	Madison mean time. h. m.		Greenwich mean time. h. m.
The disturbances in *declination* commenced about	14th, 0 00 A.M.	...	14th, 5 58 A.M.
A principal westerly[1] extreme reached...	,, 1 05 ,,	...	,, 7 03 ,,
,, easterly ,, ,, ...	,, 2 36 ,,	...	,, 8 34 ,,
Range of motion 16′·5; after this a series of smaller oscillations continue to past noon; a maximum westerly position is reached about	,, 0 16 P.M.	...	,, 6 14 P.M.
And an easterly extreme at	,, 0 53 ,,	...	,, 6 51 ,,
Extreme westerly deflection at	,, 3 26 ,,	...	,, 9 24 ,,
A sharp motion to eastward commences at	,, 5 40 ,,	...	,, 11 38 ,,
A principal easterly extreme reached at	,, 6 24 ,,	...	15th, 0 22 A.M.
Range of motion of principal disturbance 31′·7.			
There is also a westerly extreme about...	,, 7 10 ,,	...	,, 1 08 ,,
And an easterly extreme about	,, 9 16 ,,	...	,, 3 14 ,,
After 10 P.M. the irregularities gradually subside.			
Last extreme easterly position	15th, 1 10 A.M.	...	,, 7 08 ,,

It will be noticed that at the Greenwich Observatory the storm commenced on May 14 at 6h. 5m. A.M., at Stonyhurst Observatory at 6h. 4m., at Ti-ka-wei, near Shanghai, also at 6h. 4m. (G. T.), and at Melbourne, supposed at 6h. 20m.; the storm may therefore be taken as simultaneous at these places. At Greenwich the north end of the needle moved eastward between 6 and 9 A.M., but at Madison the general motion was westerly. Again, the sharp deflection commencing at 5h. 40m. Mad. T. (11h. 38m. P.M. G. T.) was to the *eastward* at Madison and to the westward after 11h. 45m. at Greenwich, thus deflecting the magnets in opposite directions.

	Madison mean time. h. m.		Greenwich mean time. h. m.
The northern component of the *horizontal* force was sharply affected at Madison, the force diminishing at ...	14th, 0 05 A.M.	...	14th, 6 03 A.M.
The disturbance continued, but between 2.30 and 7.30 A.M.			
The trace is too indistinct to be read; the small oscillations continue to about 11h. 45m., when they become superseded by a series of larger waves culminating in a maximum extreme at ...	,, 2 30 P.M.	...	,, 8 28 P.M.
And in a minimum at	,, 3 58 ,,	...	,, 9 56 ,,
The large disturbances continue till about 10h. 20m. P.M., having reached a maximum extreme about	,, 4 50 ,,	...	,, 10 48 ,,
And a minimum extreme at	,, 9 03 ,,	...	15th, 3 01 A.M.

Range between max. at 2h. 30m. and min. at 9h. 3m $= \frac{1}{154}$ of the horizontal force, nearly.

In the Greenwich account it is stated "The first start in the trace of the declination magnet at 18h. 5m. (A.R.) is most distinct;" now, within two minutes of this time occurs the first and sharpest deflection in our horizontal force trace at Madison, thus

[1] Referring to the end of the magnet.

marking distinctly the commencement and simultaneousness of the storm.

The disturbance in the *vertical* force commenced about May 14, 1h. 10m. A.M. (7h. 8m. G. T.), and terminated about 3h. 30m. A.M. Between this time and 5h. 45m. P.M. the trace was smooth, but between 5h. 45m. and 6h. 45m. a sharp deflection took place in the opposite direction, the maximum force occurring at 6h. 11m. P.M. (May 15, 0h. 9m. A.M. G. T.); the deflection or increase amounted to $\frac{1}{510}$ of the vertical force.

The vertical force trace did not exhibit any of the tremulous motion noticed in the two other curves.

I may state that a description of the Madison Magnetic Observatory, together with the discussion of the first year's observations and results, is nearly ready in MS. for publication.

Coast Survey Office, Washington, D.C., January 6 — CHARLES A. SCHOTT, Assistant, C. and G. S., in charge of Observatory

Migration of Birds—A Suggestion

I BELIEVE that the migration of birds is one of the most interesting problems to the many who dabble in the narrative branch of natural history. It must also be of some interest to those who study biology in its more strictly scientific form. And yet there appears to be but little accurate information on the subject; nor, as far as I can discover, have any attempts been made to collect careful simultaneous observations over a wide extent of country, which would appear to be the readiest, if not the only means of collecting reliable data.

I am therefore induced to suggest that you should devote a small space in NATURE weekly, at certain seasons of the year, to the record of observations made in all parts of the world, from which correspondents can be induced to send them, of the passage of any migratory birds.

The record should, I think, be in a tabular form, giving the place, the date of appearance or disappearance of any migratory bird, the name of the observer, and some few remarks that may appear pertinent, such as the state of the weather, the direction of the wind, the character of the night, whether dark or moonlight, in the case of birds which are supposed to travel at that time. The necessity for recording other facts will no doubt be suggested by those more conversant with the subject. From these suggestions and the experience gained in a short time, detailed instructions might with advantage be framed for observers. The observers should be careful to state whether they were in a position to know with certainty that the date given was that on which the birds really arrived or left, or whether it was the first time their attention had been called to the circumstance.

I should imagine you would soon have a large number of careful observers interested in the subject not only in the country but abroad also. Among these some means should be taken to enlist captains of ships, or other seafaring men. There appear to be few, if any, recorded observations of birds of passage being seen on the wing at sea—though I may be wrong in this, for I do not profess to have gone carefully into the subject. Still, it is curious that one does not hear oftener of flights of such birds as the woodcock, millions of which come to and leave this country every year, being seen at sea, over long stretches of which they are believed to fly.

J. F. D. DONNELLY

The Formation of Mountains

THE letter of the Rev. O. Fisher in NATURE, vol. xix. p. 266, is conclusive as to the more rapid cooling of the interior than the outer crust of a heated globe under the conditions of our earth, and I thank him for clearing up the point. But the question remains, whether the amount of contraction of the interior, and consequent crumpling of the crust, thereby produced in a definite time, is sufficient to account for the elevation of our mountains. It is necessary to take account of the following facts:—

1. That the greater part of the elevation of all our chief mountain ranges occurred during the eocene and miocene periods.

2. The warmer climates of those periods (certainly due to external and not to internal heat) would have tended to diminish the rate of cooling and consequent contraction of the earth.

3. The Rev. O. Fisher appears to have demonstrated that, even allowing for the total shrinkage due to the earth's cooling for the last hundred million years (from a mean temperature of 7,000° F., as calculated by Sir William Thomson), the amount of elevation thereby caused would be *very much* less than that of existing lands and mountains. But we know that these have been lowered by denudation, and again elevated many times over during that period.

The inadequacy of the alleged cause for the production of our existing mountains would therefore seem to be conclusively established.

ALFRED R. WALLACE

MR. WALLACE's letters raise three separate difficulties: How can the interior of the earth be cooling faster than its surface? How can this surface be cooling so slowly (or not cooling at all) as it is assumed to be? and, How can the different rates of cooling of interior and surface account for the corrugations observed in the surface?

As to the first question, Mr. Fisher's explanations should remove the difficulty.

As to the second question. So long as the amount of heat radiated from the surface into space equals the amount received by the surface from the sun and from the interior together, its temperature cannot fall. The rate of radiation depends on the difference between the temperatures of the surface and space. The supply of heat from the interior depends on the difference between the temperatures of the interior and the surface. Since the temperature of the interior is falling, the supply of heat from interior to surface must diminish. Hence the temperature of the surface must also fall. We cannot doubt that it does, though at present imperceptibly. The extreme slowness is due partly to the fact that the difference of temperature between interior and surface must many times exceed that between the surface and space, even if the latter be at absolute zero; partly to the low transmissive powers both of earth and atmosphere; partly to the immense mass of the earth, from which immense quantities of heat must pass away to lower the temperature of the interior but a trifle.

As to the third question, whether this small fall in temperature will account for observed corrugations, I will offer no opinion. The size of the earth must be allowed for. A diminution of a foot in radius would diminish the surface by more than nineteen square miles.

I do not understand why corrugations should be confined to the surface. I should expect them to extend as deep as the solid crust. They are possible in any stratum which is contracting more slowly than interior strata.

E. HILL

St. John's College, Cambridge

Bees' Stings

CAN any of your readers inform me why the working honey-bee has such an imperfect weapon of defence as its sting manifestly is? For purposes of self-defence it is apparently worse than useless, for in nearly every case, almost without exception, the bee lays down its life with the sting. The possession of a sting therefore only leads to its own destruction instead of to its preservation so far as the individual bee is concerned. No doubt the hive generally gains an advantage from all its active members having stings and so indirectly do individual bees from the fact that the welfare of the hive, speaking generally, means the welfare of the individuals that compose it. Directly, however, the possession of a sting can only be a disadvantage to the individual bee, unless there are certain enemies from which bees after inflicting a wound can withdraw their stings and escape with life. This so far as my observations go appears to be very unlikely, and therefore no bee can have any knowledge from experience of what a weapon of offence he possesses for he has never used it, nor can he have knowledge from experience of the consequence of using it. All smaller pests bees attack with their jaws. Is it possible, then, that they are so intelligent as to be well aware of the power for mischief to themselves as well as to others which they carry about with them, and that it is only when they altogether lose control over themselves, either through severe pain or through terror lest their queen should be injured that they sign their own death-warrants on our hands and faces? In the death of a few worker-bees a hive suffers very little loss, perhaps none at all; yet it may have gained much in the shape of security from molestation. Are bees so intelligent as to know this fact and communicate it from one to another, or can their conduct be explained on the lower ground of instinct?

It seems that an interesting point is here raised which perhaps

has been fully discussed elsewhere without my knowledge of it. Is the fact that the sting of the worker-bee is an imperfect weapon of defence, a result of its having nothing to do with the propagation of its species, this being left to the stingless queen and drones? Consequently any tendency to develop a more effective sting in one generation of worker-bees has no hereditary effect on succeeding generations, nor apparently have the worker-bees any influence whatever on the worker-bees that succeed them, except by the way in which they feed and educate them, unless, indeed, they can impress their tendencies on the drones or on the future queen before she leaves the hive. If they have no such power, it seems likely that they will always have to lament the use of a weapon which nature might have made as effective as the sting of a wasp. Finally, are there any other insects in the same predicament as worker-bees, *i.e.*, unable to use their weapons of defence without doing themselves more injury than they inflict on their adversary, and unable to help their successors by the transmission of a continually accumulating instinct? R. A.

Manningtree, January 22

Molecular Vibrations

MR. CHAPPELL is certainly right in stating that "the noises in a belfry are most discordant." He might have said (what no doubt he meant) that the sounds emitted by each single bell are most discordant. Every bell which is at all tolerable, possesses, it is true, one predominating note due to the thick part of the bow, where the clapper strikes, but there are also innumerable other notes, some of which *may* be harmonics, while the majority are not so at all. This is presumably often owing to flaws and other defects in casting, but there is another cause common to every case, which is due to the following fact:—

All bells are cast of a conventional shape, with varying diameters from bow to crown. Now every part of a bell, taken vertically, comes into vibration when struck, and in order to give a true note, each horizontal section ought to have a certain exact thickness of metal proportional to its diameter. This is easily verified to the ear by tapping the bell gently at all parts from the bow upwards. Every inch gives a different rate of vibration, and, consequently, a different pitch.

About the time when the second "Big Ben" was cast, which is a long time ago, I tried experimentally to ascertain what the law was which regulated the thickness of the metal in relation to the diameter of the bell, so that every section might be of identical pitch. This was done by casting a series of bell metal rings of varying diameters, and tuning them, by turning in a lathe, to exact unison. So far as my recollection now serves me, the following was the result:—

Measuring all the rings by their outside diameters, no undeviating rule was apparent, and the same was the case when the inside diameters were compared. When, however, a circle was taken whose circumference was, as nearly as possible, one-third from the outside of the thickness and two-thirds from the inside, then the law came out distinctly that the thickness of the metal must be proportionate to the square of the diameter of such circle. It occurred at once that this circle must, in fact, constitute the neutral axis of vibration. Working on this principle, it seemed worth while to try whether a bell could not be constructed free from discordant sounds. I may shortly say that this proved to be possible, but only by turning the actual casting with great care and accuracy in a lathe. It became evident that the slightest variation in the true thickness vitiated the unisonal character of the tone. A "miss was as good (or as bad) as a mile," and consequently the process of casting itself was too rough for obtaining the desired end.

It may fairly be gathered from Mr. Chappell's letter that he is not enamoured of a "triple bob major," and that he does not class bells generally as musical instruments. I am much afraid he never will. If the present shape and mode of construction (and let me add, the present mode of change ringing) is adhered to, a peal of bells which will quite satisfy a musical ear may be regarded as a practical impossibility. R. H.

Missing Nebulæ

IN the note on missing nebulæ in NATURE, vol. xix. p. 221, I find the nebulæ G. C. 132, 4570, and 5051 mentioned together with the Merope nebula as being diffused objects which are "overlooked in very large telescopes, though obvious in much smaller ones." This alludes, no doubt, to the occurrence of these objects in the list of nebulæ not found with Lord Rosse's 6-foot reflector (*Phil. Trans.*, 1861, p. 745).

With regard to the first object, G. C. 132, it has only been looked for once at Birr Castle, and in the N.P.D. 111° 30′ it is possible to account for its non-appearance either by a tilting of the speculum or by the haziness of the sky in this low altitude. G. C. 4570 has been seen three times, and only twice searched for in vain, both times in twilight. G. C. 5051 was set for twice and not found, but 15° north of the zenith the tilting of the speculum almost always changes the index-error of the setting-circle considerably, as expressly stated by the observer on one of the two occasions alluded to. The Merope nebula was last winter seen very distinctly, and roughly sketched with a low power and large field. J. L. E. DREYER

The Observatory, Dunsink, Co. Dublin, January 13

Time and Longitude

Now that mankind begin to have settlements, even continental, as appears from Mr. Latimer Clarke's account of Sitka, subject to the inconvenience that he and Mr. Layard point out, is it not time that we agreed to make the line dividing "yesterday from to-morrow" avoid all continents, by taking advantage of two very convenient, if not providential, facts, which are certain, though each was *à priori* highly improbable? First, there were great chances against a globe with our existing proportion of land to water, of coast-lines to area, and of large and small lands to each other, having any Behring Strait, admitting one degree of longitude, or thereabouts, to enjoy the above property. But next, there was still greater chance, perhaps, against the exact opposite degree to the strait covering several national observatories; not only more of them, I think, than any equally narrow meridional band, but the only one that, on historical grounds, we can conceive distant civilised nations accepting without jealousy as a common centre. The antimeridians of Copenhagen, Uraniburg, Leipzic, Munich, Padua, Venice, and Florence, seem to avoid both continents; possibly also those of Christiania, Gotha, Verona, and Modena. Those of Berlin, Prague, Naples, and Palermo, seem a very few miles too far east. Europe proper, and its present railways, are very closely bisected by this street of observatories; the local time of the furthest points each way varying but an hour and a half from it. But the chief coincidence is yet unnamed. Would the pride of any existing land, except China, refuse to make a standard meridian of Rome?

The very Chinese must allow Europe a sort of scientific precedence, not as the metropolitan, but the learned continent—earth's university. Europe alone is the adult continent, if there be one; and no other has in a strict sense a metropolis. The history of no other has so turned upon one pivot city as that of Europe has on Rome, nor is likely ever to do so. Some one says that "what a church is to a city, Palestine is (or may some day be) to the world;" but it is less disputable that what the market-place is to a city, Europe is to the world—perhaps permanently. And what the tribunal is to the market-place, Rome has been to Europe, as long as Europe was growing. Observe, too, that in this special connection both our civilised time-reckonings, "Old Style" and New, have come from Rome. Might we not also supersede the distinction of E. and W. longitude, by calling Rome 180°, and reckoning all round, from Behring to Behring, leaving the 0° as yet unmarked? E. L. G.

[E. L. G.'s proposal has been already made by M. de Beaumont. See NATURE, vol. xix. p. 247.—ED.]

Shakespeare's Colour Names

I FEAR you will think that the correspondence on this subjec is becoming a mere criticism on Shakespeare's text, and therefore out of place in your columns, but I trust you will afford me space for a short rejoinder to Mr. Ingleby's letter (NATURE, vol. xix. p. 244).

I am obliged to him for pointing out that Sir T. Hanmer had already suggested the substitution of "keen" for "green" in the passage from "Romeo and Juliet," Act iii. Sc. 5. This had escaped me, but I cannot agree with him that the alteration has been *rightly* rejected by subsequent commentators. I have not at present any opportunity of examining the eyes of any living eagles, but in opposition to Mr. Craig-Christie's evidence (NATURE, vol. xix. p. 221) I must point out that all our best

British ornithologists—Yarrell, Macgillivray, Gould, Meyer, and Morris—describe the eye of the Golden Eagle (the less rare of our two British species, and the one usually referred to by our poets) as *hazel* or *brown*. The eye of the Sea Eagle is described by the same authorities as yellow. I cannot think that so accurate an observer of nature as Shakespeare would call either hazel or yellow eyes *green*. Can Mr. Ingleby cite any authority for such a comparison as "green as is an eagle's eye"? while the keen piercing sight of the bird is as proverbial as the swiftness of its flight. I am well aware that green eyes were held in high estimation by the old poets, especially by those of Spain; Shakespeare, however, does not seem to me to have shared in this predilection, as, setting aside the doubtful play of "The Two Noble Kinsmen," and the passage now in question, he uses the epithet three times only, I think, as applied to the eye, and then always *in malam partem*, viz., "green-eyed jealousy," "Merchant of Venice," Act iii. Sc. 2; "It is the green-eyed monster," "Othello," Act iii. Sc. 3; and in "Midsummer Night's Dream," Act v. Sc. 2, where the "eyes as green as leeks" are met with in conjunction with "lily lips," "cherry nose," and "yellow cowslip cheeks." I cannot think with Mr. Murphy (NATURE, vol. xix. p. 197), that the eyes which the old poets so admired as green were what we call blue; they were more probably *grey*, which often has a shade of green in it—the "eyen grey as glas" of Chaucer's "Prioresse." These green or grey eyes were, I think, usually an attribute of feminine rather than masculine beauty, as in the passage from "The Two Noble Kinsmen," Act v. Sc. 1, where they are mentioned in an address to Diana (not Neptune, as Mr. Ingleby has it). Shakespeare well distinguished between the different colours of eyes—see "Two Gentlemen of Verona," Act iv. Sc. 4, and "Twelfth Night," Act i. Sc. 5, for grey eyes; "As You Like it," Act iii. Sc. 2 for blue eyes; "Romeo and Juliet," Act ii. Sc. 4 for black and grey eyes, and Act iii. Sc. i. of the same play, where hazel eyes are mentioned.

ROBERT BREWIN

Exeter, January 20

Intellect in Brutes

SIR HARRY LUMSDEN allows me to publish the following little incident:—Late last autumn some partridges, which he had tamed and kept about the house, disappeared as usual and became wild. When the excessive cold set in and Aberdeenshire was deep in snow, Sir H. Lumsden was greatly pleased and surprised one morning to find his old friends on the doorstep waiting to be fed. Next morning they appeared with a wild covey of eleven birds, and the tame cock sat on the doorstep and crowed to the wild birds, evidently encouraging them to come and eat the food, which, however, they declined to do till it was put further from the house. Soon after the tame birds appeared with two covies. How did they entice the wild birds except by actual bird talk?

WALTER SEVERN

Feeding a Python

THE attack of a constrictor, at all events in confinement, is very often unsuccessful; but perhaps this may be because the reptile is not hungry. I have often seen the constrictors in the London Zoological Gardens strike several times at birds, pulling out feathers and even getting a firm hold and then releasing their prey, to renew the attack presently either with or without success. When the membrane over the eye is becoming opaque in consequence of the change of skin they frequently fail to hit the prey at all, but still persist until they secure it. I saw one of the large pythons take a rabbit in a way which must be unusual, I think. The rabbit was hopping about near the snake's coils when the reptile suddenly made a loop in its body, and firmly inclosed the victim without touching it at all with the mouth, or even raising its head. The rabbit died there, but the snake paid no attention to it for a quarter of an hour and subsequently swallowed it very leisurely.

ARTHUR NICOLS

THE GRAHAM LECTURE, ON MOLECULAR MOBILITY

THIS lecture, the institution of which was referred to in NATURE, vol. xix. p. 254, was delivered on the 22nd inst., by Mr. W. Chandler Roberts, F.R.S., Chemist of the Mint, before the Philosophical Society of Glasgow, in the hall of the University, where Graham graduated in 1824.

The audience, which was very large, included most of the professors of the University.

Mr. James Mactear, president of the Chemical Section, pointed out that they were doubly fortunate in having secured the services of Mr. Roberts, whose co-operation in his work Graham repeatedly acknowledged in the warmest terms, and in the fact that Mr. James Young, F.R.S., of Kelly, the life-long friend of Graham, had consented to preside on this occasion; he therefore vacated the chair in favour of Mr. Young, who introduced the lecturer.

Mr. Roberts briefly traced the influence of Black and Thomson in turning the attention of Graham to the study of molecular physics, to which he patiently devoted his life. In connection with the law of the diffusion of gases the lecturer claimed that Priestley made in 1799 an observation on the escape of hydrogen from a cracked jar. The subsequent and independent discovery of this phenomenon by Doebereiner in 1823 has hitherto been considered the starting-point of the experimental study of gaseous diffusion to which it undoubtedly attracted Graham's attention. After a brief review of the influence of Eastern and Greek thought on the study of molecular movement, allusion was made to Sir Christopher Wren's model representing the effects of all sorts of impulses that result from the impact of hard globulous bodies, which, according to Dr. Sprat, historian of the Royal Society, he proposed as the principles of all demonstrations in natural philosophy, it being considered "that generation, corruption, and all the vicissitudes of nature are nothing else but the effects arising from the meeting of little bodies, of different figures, magnitudes, and velocities."

Herepath's revival of Bernoulli's view as to the movement of gaseous particles was considered, and Mr. Roberts then described in detail the experiments that enabled Graham to establish the law of the diffusion of gases, and he illustrated experimentally the passages of gases through porous bodies, such as unglazed earthenware and artificial graphite, as well as through a layer of the hard translucent variety of opal known as hydrophane. The mode in which Graham studied the diffusion of the momentum of gases, by observations on viscosity as indicated by rates of flow through capillary tubes, was then described. It was pointed out that his law of diffusion forms the basis of the science of molecular mechanics, and his measurements of the rates of diffusion prove to be the measure of molecular velocities which have been so profoundly investigated mathematically by Clerk-Maxwell, Clausius, and Boltzmann, and experimentally by Loschmidt in developing the dynamical theory of gases. The lecturer then considered the passage of gases through colloid or jelly-like bodies which have no sensible pores, dwelling more especially on the separation of oxygen from air by the transmission of air through a thin film of india-rubber, a circumstance of special interest from a physiological point of view.

The liquefaction of gases formed the subject of one of Graham's earliest papers, in 1826, and it occupied his attention at intervals during his life. He held the view that hydrogen when absorbed by palladium is reduced to the metallic form, a supposition which has received strong confirmation from the success that has attended M. Raoul Pictet's efforts to solidify this gas; and that distinguished physicist stated in a letter to Mr. Roberts that it is probable Graham's indication of the density of solid hydrogen will prove to be nearly correct. Allusion was then made to Graham's opinion that the various kinds of matter now recognised as different elementary substances may possess one and the same ultimate or atomic molecule existing in different conditions of movement, the varying degrees of rapidity of this movement constituting, in fact, the difference between the elementary

bodies. In other words, if the molecular energy of a so-called element could be changed, the element would be dissociated, a view of special interest in relation to the researches of Lockyer. The lecture was illustrated by many effective experiments, and concluded with the statement that it had not been instituted from the merely special interest of Graham's researches to the physicist and chemist, but in honour of the labours of a life the memory of which will be as enduring as its work, and to stimulate others to investigate as patiently and earnestly the varied phenomena whose basis is "molecular mobility."

Sir William Thomson, in proposing a vote of thanks to the lecturer, called attention to a diagram on the wall recording the rates of passage of gases by diffusion, effusion, transpiration, and by the peculiar passage through such "colloid septa" as non-crystalline metals or india-rubber; and he stated that before Graham's time these valuable physical constants were absolutely unknown. They had listened with much interest to the connection which had been traced between Graham's law of diffusion and the science of molecular physics, as well as to the account of Graham's work generally, so carefully set before them by Graham's pupil and friend.

PRELIMINARY NOTE ON THE SUBSTANCES WHICH PRODUCE THE CHROMOSPHERIC LINES[1]

HITHERTO, when observations have been made of the lines visible in the sun's chromosphere, by means of the method introduced by Janssen and myself in 1868, the idea has been that we witness in solar storms the ejection of vapours of metallic elements with which we are familiar from the photosphere.

A preliminary discussion of the vast store of observations recorded by the Italian astronomers (chief among them Prof. Tacchini), Prof. Young, and myself, has shown me that this view is in all probability unsound. The lines observed are in almost all cases what I have elsewhere termed and described as *basic lines*; of these I only need for the present refer to the following:—

b_3 ascribed by Ångström and Kirchhoff to iron and nickel.
b_4 ,, Ångström to magnesium and iron.
5268 by Ångström to cobalt and iron.
5269 ,, ,, calcium and iron.
5235 ,, ,, cobalt and iron.
5017 ,, ,, nickel.
4215 ,, ,, calcium, but to strontium by myself.
5416 an unnamed line.

Hence, following out the reasoning employed in my previous paper, the bright lines in the solar chromosphere are chiefly lines due to the not yet isolated bases of the so-called elements, and the solar phenomena in their totality are in all probability due to dissociation at the photospheric level, and association at higher levels. In this way the vertical currents in the solar atmosphere, both ascending and descending, intense absorption in sun-spots, their association with the faculæ, and the apparently continuous spectrum of the corona and its structure, find an easy solution.

We are yet as far as ever from a demonstration of the cause of the variation in the temperature of the sun; but the excess of so-called calcium with minimum sun-spots, and excess of so-called hydrogen with maximum sun-spots follow naturally from the hypothesis, and afford indications that the temperature of the hottest region in the sun closely approximates to that of the reversing layer in stars of the type of Sirius and α Lyræ.

If it be conceded that the existence of these lines in the chromosphere indicates the existence of basic molecules in the sun, it follows that as these lines are also seen generally in the spectra of two different metals in the electric arc, we must be dealing with the bases in the arc also.

[1] Paper read at the Royal Society on January 23, by J. Norman Lockyer, F.R.S.

ON A THEORY OF THE VISCOSITY OF THE EARTH'S MASS[1]

IN these two papers the investigation is continued of the physical results which follow from the theory that the mass of the earth is either viscous or imperfectly elastic. In the first paper of the series (which was read before the Royal Society on May 23, 1878, and of which an account appeared in NATURE, vol. xviii. p. 265) the theory of the bodily tides of such a spheroid was considered. In that paper it was shown that the bodily tides would lag, and that this lagging would produce an acceleration of the time of high water of the oceanic tides relatively to the nucleus. The author's attention was directed to the tidal reports of the British Association by Sir W. Thomson, and he has tried to find whether the tidal observations give any indications of a yielding of the earth's mass. The theory of the semi-diurnal and diurnal oceanic tides is so imperfect that it is impossible to say whether or not high water takes place earlier than it would do on a rigid nucleus; the long-period tides are those from which alone any indications are to be expected.

The fortnightly tide is the most marked of these, but its height is very small, and the results in the tidal observations show so much irregularity that it cannot be asserted with certainty that they represent the true fortnightly tide. Nevertheless, it is interesting to learn that, out of eleven years of observation at Ramsgate, Liverpool, Hartlepool, Brest, and Kurrachee, the fortnightly tide appears to be accelerated in eight cases and only retarded in three. Although the accelerations are exceedingly irregular, it may perhaps be maintained that these observations give some indications of a tidal yielding of the earth's mass.

The first of the two papers of which we are here speaking deals with the effects of the tidal distortion of the spheroid on its rotation, and with the reaction on the tide-raising satellite. An account of some of the results of the investigation was read before the British Association at Dublin, and an abstract appeared in NATURE, vol. xviii. p. 580, and therefore the principal results will be here merely repeated.

For convenience of diction the spheroid is spoken of as the earth and the tide-raising body as the moon.

It was found, then, that the obliquity of the ecliptic, the length of day and of the month, become variable, and that, if we look into the remote past, we find the obliquity less, and the day and month very much shorter than at present. When the changes were traced backwards as far as possible it was found that the whole diminution in the obliquity was about 10°, and that the beginning from which the earth and moon must have started was a state in which they rotated, as though fixed rigidly together, in 5h. 40m., the moon being then only 10,000 miles distant from the earth's centre.

In the second paper (read before the Royal Society on December 19) some other problems were considered. The first of these is concerning the secular distortion of the spheroid. Under the attraction of the moon the earth becomes distorted into an ellipsoidal shape, with the longest axis in the plane of the equator, but, since the tide lags, this longest axis does not point directly towards the moon. The excess of the attraction of the moon on the nearer protuberance above that on the further one gives rise to the tidal frictional couple. This couple tends to retard the earth's rotation; but it is clear that unless the tidal protuberance has some special form

[1] An account of two papers, "On the Precession of a Viscous Spheroid, and on the Remote History of the Earth," and "Problems Connected with the Tides of a Viscous Spheroid," by G. H. Darwin, read before the Royal Society on December 19, 1878.

the whole earth cannot be retarded exactly as though it were a rigid body. Now the tidal protuberance has not this required form, and therefore there results a slow secular distortion of the earth arising from the unequal distribution over the surface of the forces which constitute the tidal frictional couple.

The greater part of the pull which retards the rotation is applied in the equatorial regions, and therefore the rotation of those regions will be more rapidly retarded than that of the polar regions. As the earth's rotation is from west to east, it follows that the polar regions will outstrip the equator and will move very slowly from west to east relatively to the equatorial parts.

The exact mathematical solution for this kind of a distortion of a viscous spheroid shows that it consists in a simple cylindrical motion round the axis of rotation, each point moving from east to west with a linear velocity proportional to the cube of its distance from that axis.

The distortion of the surface of the globe consists of a motion in longitude from west to east, relatively to a point in the equator, the rate of change of longitude being proportional to the square of the sine of the latitude.

Numerical calculation shows, however, that in the later stages of the earth's history (the development being supposed to follow the laws found in the paper on "Precession") the distortion must have been very small. With a certain assumed viscosity it is found that, looking back 45,000,000 years, a point in latitude 60° would lie 14′ further east than at present. From this it follows that this cause can have had little or nothing to do with the crumpling of geological strata.

As, however, the distorting force varies inversely as the sixth power of the moon's distance, it seems possible that in the very earliest stages this cause may have had sensible effects. It is therefore noteworthy that the wrinkles raised on the surface would run north and south in the equatorial regions, with a tendency towards north-east and south-west in the northern hemisphere, and north-west and south-east in the southern one. The intensity of the distorting force at the surface varies as the square of the cosine of the latitude.

An inspection of a map of the earth shows that the continents (or large wrinkles) conform more or less to this law. But Prof. Schiaparelli's map of Mars[1] is more striking than that of the earth, when viewed by the light of this theory; but there are some objections to its application to the case of Mars. If, however, there is any truth in this, then it must be postulated, that after the wrinkles were formed the crust attained sufficient local rigidity to resist the obliteration of the wrinkles, whilst the mean figure of the earth adjusted itself to the ellipticity appropriate to the slackening diurnal rotation: also, it must be supposed that the general direction of the existing continents has lasted through geological history.

The second problem considered in this paper is concerning the distribution of the heat, which would be generated by the internal friction of the tidal distortion.

It was shown in the preceding paper that a very large amount of heat might be thus generated, and it appeared at first sight as though this might serve to explain in part the observed increase of underground temperature; but the solution of a certain problem concerning the cooling of an infinite slab of rock 8,000 miles thick, in which heat is being generated according to a certain law of distribution, shows that the frictional heat could not possibly explain a rate of increase of underground temperature near the earth's surface of more than 1° Fahr. in 2,600 feet.

It follows, therefore, that Sir W. Thomson's investigation of the secular cooling of the earth cannot be sensibly affected by this cause.

[1] *Memorie della Società degli Spettroscopisti Italiani*, 1878, vol. vii.

The last part of the paper does not lead to results of interest to the general reader, as it is concerned with the part played by inertia in the tides of viscous, fluid, and elastic spheres.

INDIAN METEOROLOGY[1]

IN the article "Atmosphere" of the *Encyclopædia Britannica* it has been justly remarked that one of the most important steps that could be taken towards the development of the science of meteorology would be extensive series of observations from such countries as India, which offers splendid contrasts of climate at all seasons, has a surface covered at one place with the richest vegetation, and at others with vast stretches of sandy deserts, and presents extensive plateaus and sharp ascending peaks, all which conditions are indispensable for collecting the data required for the solution of the problem of atmospheric physics. In working out this problem it is necessary, owing to its extreme complexity and difficulty, to give attention, not merely to questions immediately bearing on the physics of the atmosphere, but also to climatic and other practical inquiries, which may be handled with comparative ease and which afford results that contribute indirectly but very materially to the solution of the higher problem. The publications enumerated below admirably follow up this two-fold line of inquiry, and even already several important practical and theoretical conclusions seem not far from the point of being reached by the meteorologists of India.

The "Report on the Meteorology of India" is the second Annual Report issued since the administration of the Indian Meteorological Establishment was concentrated in the Central Office at Calcutta for the whole of India including British Burmah and the Islands of the Bay. In the scheme of publication of the monthly results of the observations made at the various stations over India, we note with satisfaction that the form proposed by the Permanent Committee of the Meteorological Congress at Vienna has not been adopted in some of its more important details. Thus in Mr. Blanford's tables, instead of a general monthly mean of atmospheric pressure, the mean monthly pressure for each hour of observation is given—an essential requisite for the presentation of the data required in discussing various of the more important problems of international meteorology. Indeed these tables possess the very high merit of being, with perhaps one exception, entirely suited for the discussion of climatic questions of an international character—the single exception being the lumping together of the two or four daily observations of the winds into one monthly mean, instead of a monthly mean for each hour of observation as is so admirably carried out by Professor Rubenson in his annual reports of Swedish meteorology.

The most interesting part of this report is that which deals with the failure of the rains in Western and Southern India which resulted, as is only too well known, in one of the most terrible and wide-spread famines of recent years. The mode of treatment is grounded on the practice adopted by the Office, in framing forecasts of coming seasons to which we have several times drawn the attention of the readers of NATURE (vol. xiii. p. 66, &c.), and which may be described as proceeding on the assumption that there is a certain persistency in meteorological conditions; that, for instance, the longer a given state of weather has lasted, the less the probability of a speedy change; and that as regards the distributions of pressure, on which weather is so dependent, certain states of the atmosphere tend to perpetuate or reproduce themselves in the same region in such a manner as to maintain a

[1] "Report on the Meteorology of India in 1876." By Henry F. Blanford. "The Indian Meteorologist's *Vade-Mecum*." By Henry F. Blanford. "Indian Meteorological Memoirs;" issued under the direction of Henry F. Blanford. Vol. i., part 2. "The Meteorology of the Bombay Presidency." By Charles Chambers, F.R.S.

constant difference between the average pressure of two neighbouring regions which, though protracted, is not permanent, but disappears after a longer or shorter time. Mr. Blanford largely inclines to trace the failure of the rains to an unusually great expanse of snow covering the southern slopes of the Himalayas, much of which fell very late in the season, and which acted as a cooling agent, bringing about an abnormal distribution of pressure, and consequently of winds, temperature, and rainfall, conditions which, once fairly established, went on reproducing themselves so that cyclonic and anti-cyclonic areas of an abnormal character gained a certain persistency over those parts of India where the rainfall was deficient and where it was in excess. Should future observations confirm this hypothesis, the result will be one of the most important yet arrived at in practical meteorology.

The least satisfactory part of the report, perhaps, is that referring to the relation of rainfall to the sun-spot period, in which too much stress appears to be laid on the results of data collected from a wide geographical superficies, and too little stress upon data referring to limited regions; the data of which regions, it may be added, require for their satisfactory discussion to be examined with reference to their seasonal as well as annual variations during the sun-spot periods.

The practical part of the "Indian Meteorologist's *Vade-Mecum*" being part 1 of the work, is in many respects a model-handbook for the observers for whose use it is intended. The clearness with which the difficulties attending the making of real observations of temperature are apprehended is altogether admirable; and the provisions and precautions as regards instruments, hours, and modes of observing actually taken are of such a nature as likely to secure observations of a high quality, owing to an increased intelligence, and efficiency on the part of the observers who work in accordance with the principles and instructions laid down for their guidance.

Mr. Chambers' book is an elaborate and important work on the Meteorology of the Bombay Presidency, based on all the observations made in the Presidency down to 1874. Its splendid porte-folio of eighty highly finished maps and diagrams printed in colours, as well as its excellent typography with 159 tables of results, many of them being wholly or in part laborious and elaborate analyses of the different data of observation, render the work an *édition de luxe*. The contributions with which this work enriches Indian meteorology are twofold, viz., the results of the hourly observations made for many years at Kurrachee, Deesa, Bombay, Poona, and Belgaum; and the monthly averages for numerous stations throughout the Presidency, from which the temperature, rainfall, and winds of this part of Asia are charted with a fulness and consequent approximation to the truth not hitherto attainable. The influence which the broad physical features of the region, such as its lofty mountain ranges, high plateaus, river valleys, and extensive sandy deserts, has on the climatology of the Presidency is worked out with great skill and ability. Still more able are the discussions of the hourly observations of pressure, temperature, humidity, and cloud, made at the five chief stations, together with many suggestive reflections on the results developed, which will well repay the reader's best attention, even though he may sometimes not see his way to agree with the opinions expressed.

A healthy feature of Indian meteorology is the vigorous manner in which the making of hourly observations is pushed at many stations which have been admirably chosen as respects the objects sought to be attained, and the comparatively full and prompt discussions of the results which are published from time to time. Of the problems handled in those discussions the most frequent as well as the most important is that of the diurnal oscillations of the barometer. To this very difficult problem Mr. J. Eliot, for example, makes a valuable contribution in a paper on two storms in Bengal during 1876, which were accompanied with increased atmospheric pressure, and the apparent reversal of the normal diurnal oscillation of the barometer. This reversal was found to be accompanied with an instantaneous and complete change of wind direction and a great fall of temperature, which, as they occurred before the rain began to fall, proved that they were not due merely to an inrush of a strong humid current from the Bay of Bengal. The sudden chilling of the air, accompanied as it was by an increase of pressure, also proved that the changes were not due to the internal action of a mass of air or to horizontal or surface currents from the interior, which would have been warm currents, but that they were probably produced by the down-rush of a cold upper current, a conclusion which will doubtless receive further examination not only from its bearing on barometric fluctuations but also on the theory of storms.

OUR BIG GUNS

WE may leave the explanation of the disaster on board the *Thunderer* for the present to those who have been appointed to inquire into the matter. But in the mean time it will be well to consider what are the elements of weakness, if any, in the construction of our big guns.

The system of building up large guns by shrinking coiled iron tubes over a central steel tube seems extremely well adapted to prevent a *lateral* explosion; for even when the steel tube has had a *longitudinal* crack, the gun has been frequently fired without any further evil consequence.

But our guns are manifestly deficient in *longitudinal* strength, for the steel tube is the only tube continuous from end to end. If, then, there should be any ring-crack in the steel tube, there is little to prevent its separation into two parts beyond the friction of the coiled tubes, and the dove-tailing by which it is attempted to join the coiled cylinders together.

Now considerable longitudinal stress on the steel tube must be caused every round by the rifling necessary to give the shot its proper rotation, and occasionally, by a jamming of the shot. Also every discharge of the gun must cause a violent vibration in every part, and should the junction of the 1 B coil with the C coil and breech-piece work rather loose, this would be likely to cause a ring-crack in the steel tube in that neighbourhood.

When rapidly-exploding powder was used in the service the guns were very properly rifled with an *increasing* twist with a view to remove every possible obstruction to the *initial* motion of the shot. The increasing twist is still in use notwithstanding all the efforts that have been made to manufacture a powder that will burn slowly, so as to make the propelling pressure on the shot more nearly uniform. With a view to distribute the work of giving rotation to the shot uniformly along the bore, the rifling should be calculated to give a nearly constant pressure on the studs. But this depends upon the law of explosion of the powder. And this law is very variable, and very little understood. Only we know this—that the more nearly the force propelling the shot becomes constant, the more nearly the rifling approaches the uniform twist in order to obtain a constant pressure on the studs. Now the objection to the increasing twist is that it throws the chief part of the work of giving rotation towards the muzzle, where the gun is weakest. Also there is a difficulty in arranging the studs on the shot, and it now appears that the increasing twist allows the shot to slip forward when the gun is depressed. It seems, therefore, desirable to revert to the uniform twist of rifling now an improved powder is used.

But in order to give the gun additional strength in direction of its length, it seems desirable that the steel

tube should be supported by an outer tube of equal length and thickness, but composed of more tenacious metal—wrought iron or gun metal.

If this cannot be satisfactorily accomplished, then the steel tube might be covered with at least two layers of coiled tubes—breaking joint. In this case the tubes should be *screwed* as well as shrunk over each other. If the screwed part was slightly conical it would be possible to adjust the tension with nicety. B.

January 25

THE ELECTRICITY OF THE TORPEDO

THE recent researches of Prof. Marey on the electric discharge of the torpedo have been presented by the author in an extended memoir published last year.[1] We propose to present to our readers the main conclusions reached by M. Marey, and the experimental demonstrations on which the principal of these are based. But before entering into details of the experiments let us indicate summarily the processes employed by M. Marey.

In previous researches,[2] made in 1871, he had at his disposal only the reactions of the muscles of the frog to analyse the electric phenomena of the torpedo; he caused to be recorded, upon an inclosed plate, the shock of a frog's muscle produced by the discharge of the electric apparatus of the torpedo. The instant of the excitation of an electric nerve or of the nervous centres of the torpedo was recognised; and it was seen that the movement of the foot of the frog presented, at the instant of excitation, a considerable retardation, equal, *e.g.*, to four-hundreds of a second, measured on the chronographic scale. But into this total retardation entered several diverse elements, which M. Marey took into account by causing the muscle of the frog to contract by an excitation directly acting upon it. The time lost by the muscle of the frog representing nearly the half of the total retardation, it was concluded that the time-test by the electric apparatus is equal to that of the muscle of the frog.

Since these first researches, M. Marey has been able to study more directly the electricity of the torpedo by making use of the electro-magnetic signals of M. Deprez and of Lippmann's electrometer.

M. Deprez's signal is composed of a small electro-magnet provided with an extremely light armature of soft iron, which is applied to the coils when the current which traverses them is closed, and which is drawn from it, without delay in demagnetisation, at the moment of the rupture of the current, by the contraction of the tight india-rubber thread. The armature is provided with a style which traces on the inclosed cylinder the closures and ruptures of a current, the duration and frequency of these successive acts, with such perfection that it is easy thus to obtain the record of 1,000 vibrations per second. In the tracing underneath the apparatus (Fig. 1) is seen the signals which it furnishes when acted on by a non-continuous scale of 500 simple vibrations per second.

It is this electro-magnetic signal which M. Marey placed in the circuit formed by the torpedo, whose apparatus was held between two metallic plates joined to the coils of the apparatus by two conducting-wires. We shall see, further on, what use he has been able to make of this.

The second instrument by means of which certain special points of the experiments have been made is Lippmann's capillary electrometer. This apparatus is formed essentially of a column of mercury sustained by capillarity, in a tube of extremely fine glass, the extremity of which is plunged in a bath of dilute acid. When the mercury of the apparatus and the acidulated water are placed in connection with two points of an electric circuit of unequal tensions the capillary column is displaced and is carried towards the side of strongest tension. This displacement is instantaneous, and if the variations of electric tension are produced successively with great rapidity we need not fear the inertia of the capillary column. All the variations are signalled whatever be their frequency. But as the movements of the capillary column cannot be registered themselves, M. Marey has had recourse to photography in a certain number of experiments.

Let us now consider the results following the order which we have indicated at the outset.

1. *A torpedo's discharge is not a continuous current; it is formed of a series of successive waves added one upon another.*

The fundamental experiment upon which the demonstration of this proposition rests was performed with the electro-magnetic signal (Naples, October, 1876). Having compressed one part of the apparatus of an active torpedo just drawn from the water between two metallic plates furnished with conducting wires, M. Marey placed the signal-machine of M Deprez in contact, and the magnet being stimulated he heard a shrill noise resembling that made by filing the end of a hard splinter of wood. The vibrations of the armature, therefore, had been produced by a series of successive electric acts. In defining these vibrations one is justified in stating that the discharge of the torpedo produced by the animal as the result of a local excitation, was composed of a variable number of waves or currents succeeding each other. Fig. 2 represents two tracings so produced. The great advantage resulting from the use of the electro-magnetic signal was to show definitely that the discharge is complex, an analysis which was not possible with the frog's-foot signal. The muscle used as reagent does not in fact react by means of the shocks apart from impulses which are sudden and frequent; it remains in a state of permanent contraction.

But the electro-magnetic signal, whilst showing the dissociation of the torpedo discharge, furnished no other result. It did not indicate how those successive waves follow each other, it seemed even to lead to the conclusion that one wave is quite completed when the next succeeds. At this point the induction is interrupted and the experimentalist adopts another mode of solving this question of the succession of waves in a discharge. M. Marey, in fact, being convinced that the electric action of the torpedo and muscular action should be assimilated, and wishing to see in the discharge the analogue of induced tetanus and even of voluntary contraction, could not resign himself to the admission of an absolute discontinuity between the successive acts constituting a discharge. Yet the electro-magnetic signal apparatus seemed to pronounce his theory wrong. But on passing through Lippmann's electrometer a slight current from the total discharge, M. Marey observed that the column underwent a series of successive impulses, the effects of which unite together. This progression by successive jerks indicated an increase of the intensity of the discharge, an increase in which each new wave is joined to what remains from those which have preceded it. Thus we derive the proof that the electric waves are *partially* united to one another like the muscular shocks of a tetanised muscle.

This first fact being gained, it was necessary to follow up the analysis of the torpedo-discharge, determine the nature of each of the independent electric acts which the electro-magnetic signal had revealed, measure their duration, phases, &c. These different points have been elucidated, each in its turn.

2. *To measure the duration of the electric-wave in the torpedo,* M. Marey has had recourse to the method devised by Guillemin for determining that of very short current, and used afterwards by Bernstein to measure the

[1] "Compte Rendu des Travaux du Laboratoire de M. Marey." T. iii. Paris: G. Masson. 1877.

[2] "Annales de l'École Normale Supérieure." 2e s., t. i., pp. 86-114.

duration of the negative variation of nerves and muscles. Guillemin's method is applicable in every case where a current passes several times in succession through a metallic circuit, with duration always the same. The electric condition of the circuit is investigated during a succession of very short intervals, beginning at the moment when current is complete.

The apparatus used by Guillemin and Bernstein was the galvanometer; M. Marey preferred to use a frog's foot, which, in the successive investigation, gives a movement which can be graphically recorded, as often as there is an electric current.

The graphic method, by which each duration is transformed into a length easily measured on the paper, is easily applied in performing those experiments of which we are about to explain the principle.

Let the point O (Fig. 3) correspond to the moment of electric excitation of a torpedo-nerve, and let the successive points 1, 2, 3, &c., denote successive hundredths of a second, which correspond to very short intervals during which the torpedo apparatus is put in contact with a metallic circuit passing through a frog's foot. In the two first trials, 1 and 2, after the excitation of the electric nerve, there are no signals recorded; the frog's foot remaining motionless shows that the discharge of the torpedo has not reached it, because, in fact, the phenomenon has not yet had time to take place. But at the instant 3 the frog moves, which is expressed in the diagram by a vertical stroke; at the instants 4, 5, 6, 7, 8, 9, and 10, the frog receives shocks which are indicated on the diagram by vertical lines; and finally, at the instant 11, and those succeeding, the frog shows no action, whence we conclude that the electric wave of the torpedo was finished before these last trials; and we see that, according to the tracing, the wave began three-hundredths of a second after the instant of nerve-excitation and finished ten-hundredths after the same instant.

Fig. 1.

It was exactly in the same way that M. Marey proceeded to measure the duration of the electric wave in the torpedo. An arrangement easily fixed induced electric action in *e* (Fig. 4) at constant intervals. A metallic contact, susceptible of being displaced at will, allowed him, during very short intervals of different lengths, to complete the circuit made by the electric wave of the torpedo to reach the frog's-foot-signal. Moreover, to avoid confusion of the curves which were registered by the successive experiments, he took care to change the position of the style each time, so that the curves appeared one under the other in order.

Fig. 4 shows that the first appearance of the electric wave took place at instant 1; that in a series of successive trials, each later than the preceding, after the excitation of the nerve, the wave was indicated at the instants 2, 3, 4, 5, and 6; and that at the 7th trial the frog gave no signal. The wave, therefore, was completed. Finally, by bringing the instant of trial nearer to that of nerve-excitation, the wave was retraced in experiments 8, 9, 10, 11, and 12; but in the 13th, occurring too soon after the instant of nerve-excitation, it was shown that the electric wave no longer existed.

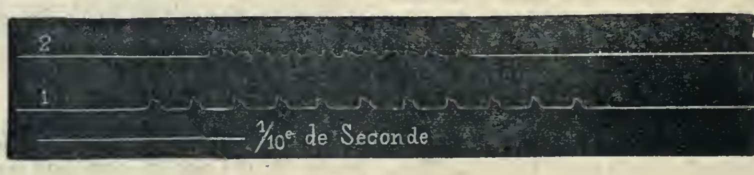

Fig. 2.

The approximation of these measurements necessarily depends on the number of successive trials, and is more delicate in proportion as they succeed each other more frequently.

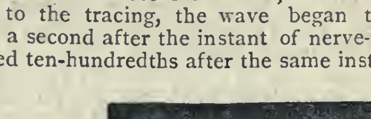

Fig 3.

3. *Each electric wave presents a phase of suddenly increasing intensity, followed by a phase of gradually decreasing intensity.*

On examining the tracings of electric waves obtained by the electric-magnetic signal, we observe an apparent contradiction between the indication, the wave-duration furnished by this apparatus, and that which we have just seen determined by the frog's foot. The waves traced by the signal of Deprez seem to measure not more than one-hundredth of a second; by Guillemin's method, on the contrary, their duration is much more considerable, being seven-hundredths of a second. This apparent contradiction results from the fact that in the torpedo the waves have not sufficient energy during the whole of their duration to act upon the signal, whereas, from beginning to end of their course they can act upon the frog's muscle, which is much more sensitive. There are, then, in every electric wave, phases of increasing intensity and decreasing intensity which remain to be determined.

M. Marey has endeavoured to obtain a tracing of these phases of variable intensity by a modification of the apparatus of M. Deprez. Instead of limiting the excursion of the style between two fixed obstacles, he allowed it an excursion which varies and is proportional to the intensity of the currents acting upon it.

With this object an india-rubber thread, bent over two bridges, was stretched horizontally between the soft iron bars of the armature (Fig. 5). The bars had a groove filed on the top to receive two demi-cylinders of metal which were soldered to the lower part of the armature. In this way the nearer those parts are brought which are subjected to the magnetic attraction the greater is the resistance. Thus if we consider the armature in its different stages when gradually lowered, first it meets the elastic thread with the two demi-cylinders borne on its lower surface, and then the extensibility of the thread is very great. But as the thread is lowered more and more, it rests on points more and more separated, and becomes less and less extensible. Lower down the india-rubber thread stretched

over the groove made in the soft-iron bars is still less extensible; and finally, when the thread has taken the curvature of the surrounding parts, it opposes any further descent of the armature with the resistance which a stretched thread of india-rubber presents against being pressed or crushed.

This apparatus, to which M. Marey has given the name *electrodynamograph*, has still to receive further improvements, but even as it is, it has already furnished some interesting evidence as to the decrease in volume of the electric waves from the beginning to the end of the discharge; also as to the shape of these waves and the occurrence in the electric tetanus produced by strychnine, &c. Of these different results we shall at present consider only one—the form of a wave is traced by the electro-dynamograph:—an investigation which brings us to the analysis of the wave-phases.

In Fig. 6 the continuous line *b* is the tracing of a single wave obtained with the electro-dynamograph. From it alone we already have evidence that the ascending phase is much more sudden than the descending phase as also takes place in a muscular shock. We can

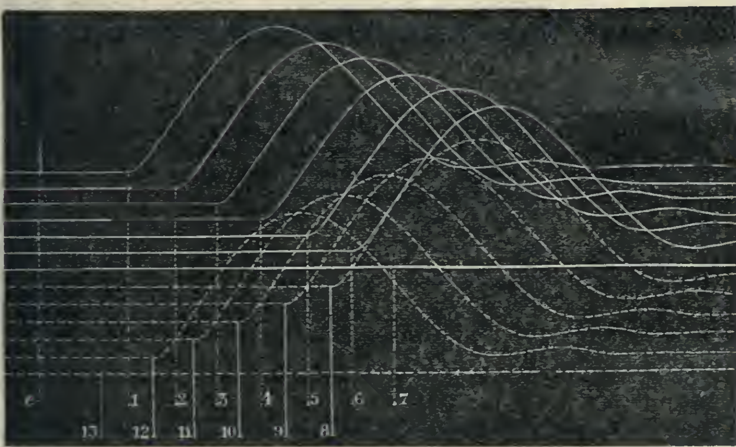

FIG. 4.

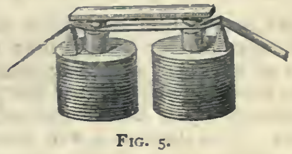

FIG. 5.

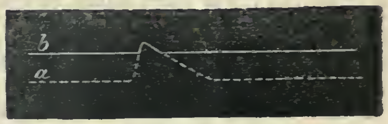

FIG. 6.

further theoretically complete the curve by taking into account what we have learned by Guillemin's method in the preceding paragraph about the duration of a wave. All that is necessary is to produce downwards the two ascending and descending lines till they intercept between them a distance equal to that which represents (on the time-line) the duration of the whole wave. Thus (Fig. 6) the pointed line *a* represents the actual position of the axis of abscissas and that part of the tracing which the instrument was unable to trace on account of its insufficient sensibility.

It is true that this curve is only probable, but there are great presumptions in favour of its reality. The points of origin and termination can determine it experimentally, as we have seen done by Guillemin's method (see 2).

We can now understand the reason of the special characteristics presented by currents induced in a secondary coil by the waves of a torpedo discharge which have been passed through an inducting coil. The phase of sudden increase of each wave is alone capable of giving birth to an inducted current. FRANCOIS FRANCK

(*To be continued.*)

GEOGRAPHICAL NOTES

AT the meeting of the Geographical Society on Monday, Sir H. Rawlinson read a paper, On the road to Merv from the Caspian. After some interesting remarks on the comparative geography of the eastern shores of the Caspian Sea, Sir Henry read some portion of the Russian letters on the earlier stages of the road to Merv, of which a summary appeared in our last issue, and afterwards gave from Russian official documents an account of two ancient cities, the probable relics of Khowrasmian times—Mestorian, or Mestdovran, and Meshed. The former in past ages was one of the most important cities of Central Asia, if one may judge from the remarkable aqueducts leading into it, which were the chief arteries of an entire system of irrigation canals thoroughly watering the whole country, and from the number of its buildings, the remains of which exist to this day. The course of the aqueduct was explored by General Lomakine's orders some two or three years ago, and was traced to the Sumbar, a tributary of the Attrek, a length of some sixty-five versts. The city of Mestorian appears to have consisted of a citadel and of two other inclosures with thick, high walls built of enormous bricks. The mass of the *débris* at the place is so extensive and in such good preservation, that it would be possible, we are told, to make use of it for building a large new town! The bricks, it may be added, are stated to be as hard as stone, and often carved and ornamented with friezes in relief, arabesques, and well-executed inscriptions; the last are sometimes in various colours, illuminated with flowers, and the letters about seven inches in height. Five versts from Mestorian is another remarkable place, known in the country as Meshed; it is, strictly speaking, an ancient necropolis. Here, according to report, is an open coffer holding the sacred books, a hanging lamp, and vases for ablutions, and although in a desert place and wholly unprotected, no one dreams of touching its contents. Sir Henry Rawlinson afterwards dealt at some length with the geography of the country further to the eastward, more especially with that on the northern slopes of the Attock, which is inhabited by three divisions of the Tekké Turcoman tribes.

WE regret to record the death, on Saturday afternoon, at a comparatively early age, of Commander G. C. Musters, so well known as the explorer of Patagonia. His work, "At Home with the Patagonians," is at present the best authority we have on this inhospitable country and its people, and Mr. Musters, as readers of the work know, obtained his information by living with the Patagonians for many months as their "king," and it was only by a *ruse* that he managed to get away from a people who

had learned to adore him. Mr. Musters was a fearless explorer, and a man of unfailing tact and winning manners. Two or three years ago Mr. Musters returned from Bolivia, with which little-known country he had made a thorough acquaintance, and had, we believe, collected material for an interesting work. He recently received the appointment of Consul at Mozambique, and was to have left this month for his post, from which, he was delighted to think, he would be able to do some valuable exploring work in the African interior. By his death Her Majesty has lost a faithful and able servant, and science an eager explorer. Musters was loved by every one who had the pleasure of his acquaintance.

THE prosecution of marine surveys on the coasts of India has been for a long time much hampered by the want of a proper surveying steamer, and we are glad to learn from a Bombay paper that a new vessel—the *Investigator*—has just been launched, which will supply the defect. The steamer is well provided with all the necessary appliances for chart-making, deep-sea sounding, &c.

THE November number of the *Bulletin* of the French Geographical Society contains Dr. Jules Crevaux's account of his exploration in the interior of French Guiana in 1877. Dr. Crevaux, with little assistance and in the face of not a few difficulties, ascended the River Maroni, and striking the River Yary, traced its course to its junction with the Amazon. The two main results of his journey are the crossing for the first time of the Tumuc-Humac chain at the level of the sources of the Maroni, and the discovery and complete delineation of the Yary, an important affluent of the Amazon. The Maroni he describes as a fine river of about 140 leagues in length, with a breadth of 1,200 to 1,500 metres at 20 leagues above its mouth, and from 400 to 500 at 90 leagues. The River Yary, Dr. Crevaux considers as more important than the Maroni; it is 150 leagues long, and both rivers are much obstructed by falls and cataracts. Dr. Crevaux gives some very useful notes on the forests of Guiana and the different species of trees which they contain. The highest summits of the Tumuc-Humac range do not exceed 400 metres above sea-level. In summing up his observations on the geology of the region traversed, he says that all the formations met with from the mouth of the Maroni to that of the Yary have an ancient physiognomy. They are mainly composed of schistose rocks which may be divided into three systems, which are, in order of age—1. The gneiss of the mouth of the Maroni. 2. The schists and mica schists of the middle course of the river. 3. The ferruginous schists and quartzites of the Man-Bari and the Yary; these latter are very wide-spread. All these are frequently traversed by granites and trachytes.

THE possibility of water communication between the Obi and the Yenissei seems to be more and more confirmed by further explorations. Baron Aminoff, after having explored the water-parting between these rivers, arrives at the conclusion that the hydraulic works which would be necessary for the construction of a canal with sluices would not present serious difficulties. The canal would be very short, and the marshes at the sources of the Kas and Yazevaya rivers afford a sufficient amount of water.

THE *Golos* of January 22 says it learns that authentic intelligence respecting Prof. Nordenskjöld's Arctic expedition has been received from Baron Fredericks, Governor-General of Eastern Siberia. According to these advices the steamer *Vega* is ice-bound forty miles from East Cape. The authorities at Jakutsk have been instructed to inform the natives of the dangerous position of the steamer, and to issue a general summons to the people to render assistance to the expedition. At the same time a special expedition has been organised which will attempt to reach the *Vega* by a journey over the ice with the aid of reindeers or dogs. Herr Sibiriakoff has telegraphed to Baron Fredericks, asking him to send a party to the assistance of the Swedish Expedition. He has received a letter from Dr. Lindemann, of Bremen, in which the former says that at the coast where the *Vega* is believed to be lying there is a large native village, and from this village the nearest post of white merchants is distant only about 200 English miles, which may be traversed in winter in three or four days.

A REPORT has been received of a journey by Mr. Baber in the north-west of the Chinese province of Szuchuen. The original intention was to examine, between Suchow and Kiating, the River Tatu, which falls into the Yangtze-Kiang, and then to cross the mountains from Kiating to Fu-lin in long. 103°. At Fu-lin, however, Mr. Baber was induced to extend his exertions into the country further west, and he travelled onwards to a place called Tzu-Tati, the head-quarters of a Sifan chief. Here he heard of the existence of a mountain path to Ta-chien-lu, the French missionary station lying nearest to Tibet. After travelling three days through pine forests, the mountain range was crossed by a snowy pass, and on the northern slope yaks were found grazing, and many slates, inscribed with Sanskrit characters, were noticed. The appearance and language of the people also pointed to the fact that though Tibet proper is many hundred miles west of this point, yet tribes of the Tibetan race and language extend up to the banks of the Tatu River. This confirms the views already expressed by Mr. T. T. Cooper and other travellers.

THE *Japan Gazette* translates an article of some interest from the *Osaka Nippo*, on the subject of Japanese relations with Corea. After commenting on the progress made by Japan during the past few years, the writer remarks that "the Coreans, on the contrary, obstinately cling to the customs of Gio, Wu, and Shin, three Chinese sages who lived 3,000 years ago, and they believe their country is a part of Paradise, next in rank to China, and that western countries are inhabited by barbarians and savages."

COUNT WILCZEK and Lieut. Weyprecht intend to visit the northern coast of Novaya Zemlya in the course of this year, and will remain at that station for a twelvemonth in order to make a series of exact magnetic, electric, hydrographical, and meteorological observations. The cost of the expedition will be defrayed by Count Wilczek himself.

OUR ASTRONOMICAL COLUMN

THE VARIABLE-STAR ALGOL.—Considering the long period during which this star has been under observation, and the many investigations which have been made with the view to reduce its fluctuations of light within some law, much interest attaches to a remark by Prof. Winnecke that the times of *minima* of Algol in the last year have fallen about one hour earlier than those assigned in the ephemerides of variables published by the *Astronomische Gesellschaft*. Dr. Julius Schmidt, director of the Observatory at Athens, to whom we owe the greater number of recent observations on this star, has not yet made known his results for 1878, but we have his determinations of the times of *minima* in 1875-76-77. For comparison with them we may take the last formula given by Prof. Schönfeld in his second catalogue of the variable stars, which appeared in 1875, viz., for Paris mean time:—

Min. ... 1869, Nov. 9, 3h. 39m. 34s. + 2d. 20h. 48m. 53s·67 E.

The following are the differences from the observed times of *minima*, during the last six months of each year, wherein the observations are most numerous:—

1875.	m.	1876.	m.	1877.	m.
Aug. 20 ...	+ 10·1	July 29 ...	+ 26·1	Aug. 20 ...	+ 62·1
,, 23 ...	− 29·6	Aug. 21 ...	+ 7·2	,, 23 ...	+ 18·5
Sept. 9 ...	− 7·2	Sept. 10 ...	+ 9·4	Sept. 12 ...	+ 33·3
,, 12 ...	− 15·8	,, 13 ...	+ 21·9	,, 15 ...	+ 17·1
Oct. 5 ...	+ 7·1	Oct. 3 ...	+ 3·8	Oct. 8 ...	+ 54·0
,, 28 ...	+ 17·2	,, 6 ...	+ 1·8	Dec. 10 ...	+ 70·1
Nov. 20 ...	− 15·1	,, 9 ...	− 1·2	,, 13 ...	+ 30·6
		,, 26 ...	+ 52·0		
		Dec. 11 ...	+ 53·9		

If yearly means of the above differences are taken we have:—

	m.
1875·76	− 4·8
1876·76	+ 19·4
1877·73	+ 40·8

These figures appear to indicate that a perturbation of the period is taking place, which of late has increased the differences between observation and calculation at the rate of about twenty-two minutes annually; the star is evidently one which deserves close attention at the hands of those observers who are following up the variables. With reference to previous observations of Algol and results derived from them, the reader will best consult Argelander in the seventh volume of the Bonn observations, and Schönfeld in *Vierteljahrsschrift der astronomischen Gesellschaft*, vi. p. 60.

The Reappearance of Brorsen's Comet.—It is notified that M. Tempel, director of the observatory at Arcetri, Florence, detected the short-period comet of Brorsen on January 14, in a position north following the nebula No. 4900 of Sir John Herschel's General Catalogue. The ephemeris by Dr. Schulze, of Döbeln, who has carried on the calculation of the perturbations from the last appearance of the comet in 1873 to the present year, does not commence until February 19, so that it appears to have occurred to M. Tempel that, with his advantages of climate and optical means, there was a possibility of an earlier observation of the comet, and he has taken steps to that effect accordingly. Dr. Schulze's elements for 1879 give for the place of the comet on January 14, at 6h. M.T. at Florence, R.A. 23h. 10m. 38s., N.P.D. 118° 57′, which is north—following the nebula named, so that there is no reason to doubt that the object observed, which is described as small, but brighter than the nebula (one of Sir W. Herschel's second class) is really Brorsen's comet. In this case, however, M. Tempel has succeeded in observing the comet, when, according to theory, it possessed a much less intensity of light than at any previous observation. At the time of his observation it would be distant from the sun 1·42, and from the earth 1·915, whence the theoretical intensity of light, represented by $\frac{1}{r^2\Delta^2}$, is 0·135; the smallest value with which it had previously been observed corresponded to the last glimpse of the comet at Berlin on June 22, 1857, viz., 0·337. Dr. Schulze's ephemeris will be found in No. 2220 of the *Astronomische Nachrichten*, commencing, as we have said, on February 19. On February 7 the comet's position at 6h. G.M.T. is in R.A. 23h. 59·9m., N.P.D. 109° 42′, and on February 11, at the same hour, in R.A. 0h. 9·9m., N.P.D. 107° 46′.

SUN-SPOTS AND THE NILE

On the 21st instant Mr. Francis Cobb read a paper on the financial and economical condition of Egypt, at the Society of Arts, in which he of course referred to the periodical rise of the Nile, and spoke of the desirability of discovering some system in the variations of this rise. Mr. Cobb, in considering this subject, has been naturally drawn to an examination of the sun-spot period, and has attempted to discover if any relation exists between this period and the variations in the rise of the river. The period of Mr. Cobb's examination extends from 1866 to 1878, and as might have been expected, he finds no relation whatever between any sun-spot maxima and minima, and the maxima and minima of the Nile floods. The years 1866-67 were sun-spot minima; the rise of the Nile in these years was 28¼ and 24½ feet respectively; 1872 was a maximum sun-spot year, and the rise of the Nile was 25½ feet; 1877 a minimum sun-spot year, with 18 feet rise in the river; last year the rise was 30 feet. As some of the speakers in the discussion remarked, there is at present a desire to find relations between the stupendous cosmical phenomenon of sun-spots, and terrestrial occurrences, without considering local peculiarities. We do not know what might be the result if the records of Nile floods for a century were obtainable, and were compared with the various sun-spot periods during that time; but we should say beforehand that in considering so literally narrow an occurrence as the rise of the Nile, many local considerations would have to be taken into account.

"It is impossible to say," Mr. Cobb went on, "that the rule, maximum spots, maximum rainfall, applies to Egypt. The cause of the irregularities of the Nile must clearly be looked for locally, the Blue Nile and Nyanza lakes having probably more to do with the matter than sun-spots. The telegraph, combined with a vigilant series of the operations of the Upper Nile, especially at the confluence of the Blue Nile, will prove more reliable for the protection of Egypt another year than any calculations based upon solar physics."

We fear Mr. Cobb has but a vague idea of the application of solar physics to meteorology and other terrestrial phenomena. A perusal of the many letters which appear in Nature from our Indian meteorologists, will show that without a careful consideration of local and regional conditions no deduction drawn from sun-spot periods *per se* are of much value.

In the discussion which followed Dr. Mann endeavoured to draw the attention of the meeting to the science of the subject. While he apparently endorsed Mr. Cobb's opinion that the spots on the sun would not be found to have any direct relation to the high and low Niles, he thought it would be perhaps as well to state exactly how this matter stood. The last development of the search after sun-spot influence, Dr. Mann said, took the form of the discovery that the constantly recurring financial crises in this country were due to the sun-spots; and he should like to point out what really was the influence of the sun upon the great physical changes going on in the world. There was no doubt that the presence of sun-spots had relation to the amount of force and energy issuing from the sun, and that when spots were abundant more solar energy was thrown out into space. When that was the case, the earth shared with all the other orbs in getting some increased force from the sun. There was no doubt either that movement of every kind on the earth was dependent on solar action; and when increased energy was thrown out from the sun it told immediately on the water of the earth, and raised more of it into the sky in the form of vapour. But this did not mean that there would be an increased rainfall in one particular spot, but only that, being more vapour, there would be a greater rainfall over the whole earth. In a case like Egypt, the amount of rainfall was due to the presence or absence of an ocean wind blowing over the high grounds of Abyssinia. Therefore, though no doubt the sun-spots had to do with the total rainfall, they had not necessarily anything to do with the local rainfall in one particular country like Egypt.

Dr. Mann explained that in these remarks he did not intend to imply that there was not a periodicity and regular order of some kind in social conditions and events which were connected with the requirements of finance, crisis, and things of that kind. He was quite satisfied that there was. But he thought there was too great an

inclination to refer locally restricted events to large general causes.

Mr. Hyde Clarke, who was in the chair, drew attention to the fact that it was by a paper of his thirty years ago that public attention was first directed in what he might term a scientific form to this periodicity. Prof. Stanley Jevons, who was the great advocate for the application of the sun-spot theory to commercial crises, had reproduced the statements he made thirty years ago, and thus fresh attention had been called to them. For his part, he was no advocate for what was called the sun-spot theory, for he believed the sun-spots had no direct bearing on the periodicity of commercial crises, or upon the height of the Nile; but as what Dr. Mann had said might appear to throw discredit on the periodicity of crises, he would briefly revert to the facts to which he had formerly called attention. He had then gone through the corn harvests, as shown by the prices in England for the last 400 years, for which data could be obtained, and his observations, which had since been repeated by Prof. Jevons, gave a series of facts over six centuries, showing that there was a periodicity in the crops, and consequently in the commercial phenomena dependent on them, of somewhere about ten years. Prof. Jevons had fastened on to that one fact, but had not referred to other observations he had made, which gave the clue to the question Mr. Cobb had raised, whether it was possible to predict these periods. There was certainly, in a long period, a periodicity of about ten years, and if you laid out a diagram you would find this plainly shown, but yet in some places the lines of dearth or plenty would seem to come in the wrong place, and no one has yet been able to hit on the true law. He had stated that, as far as he could discover from the facts before him, there were, besides the periods of ten years, other periods of about twenty-six years, and likewise a period of about 104 years, and the opinion he formed was that these longer periods interfered with the shorter ones, and prevented any absolute calculation as to the future. At the same time the observation of these phenomena was not by any means an idle matter; there was this practical lesson to be drawn from it, that in periods of prosperity we must look forward to a period of adversity and prepare for it. Therefore the observation of Governments, and of the commercial community and financial institutions should be directed to these great phenomena of nature, which, after all, did govern the individual operations of man.

And this is all we contend for. That there is a connection between certain well-known cosmical phenomena, centring in the sun-spot period, is admitted by all whose researches give them a right to pronounce an opinion on the subject. What is the exact nature of this connection has yet to be discovered, though that we are on the road to it every careful reader of NATURE must admit. The immense social and economical results depending on the definite ascertainment of this connection make it the bounden duty and the interest of civilised Governments to do all in their power to further research in this direction, and we have no doubt that when the full truth is known it will be found that even the apparently capricious Nile is obedient to influences that may be regarded as ultimately cosmical.

NOTES

WE are pleased to see a suggestion in the *Midland Counties Herald* that in considering the arrangements for the restoration of the Reference Library, recently almost destroyed by fire, the authorities will not miss the opportunity they now have of supplying an omission in the public institutions of Birmingham, by organising a Natural History Museum, of equal value with the Reference Library which they are doing their best to restore. We heartily endorse this suggestion, and indeed it seems strange that so energetic and intelligent a town as Birmingham, with one of our most enterprising Natural History Societies in its midst, should not have had such an institution long ago. We are sure the matter only needs to be properly brought before the authorities and the citizens to have the blank speedily and properly filled up.

MR. JOHN SADLER, so long assistant to Prof. Balfour, has been appointed to succeed the late Mr. McNab as curator of the Royal Botanic Gardens, Edinburgh.

IT is expected that Russian Turkestan will be very well represented at the anthropological exhibition which will be opened next summer at Moscow. We may already mention a very interesting collection of some dozens of skulls, found at Samarkand and belonging to a very remote epoch. A collection of dresses and implements of the inhabitants of the Zarafshan valley will be accompanied by a collection of ethnographic photographs; and among the inhabitants of this valley, the photographs and the skulls from the Galchi tribe will probably draw the special attention of the scientific world. This tribe, which lives in the clefts of the Hindu-Kush at the sources of Zarafshan river, differs from all other Central Asian tribes, and is said to be the remnant of the army of Alexander the Great; indeed, its features are like those of the Greeks; but the tribe remains almost quite unexplored, because of their wildness and the insecurity of travel in those regions. Altogether, the Zarafshan district sends to the exhibition plenty of very valuable anthropological and ethnographical materials.

THE unveiling of the Humboldt monument in Tower Grave Park, St. Louis, U.S., took place on December 24 last. The monument, as our readers will remember, is cast in bronze and executed after the design of the eminent German sculptor, Herr Ferdinand von Miller.

THE Berlin Humboldt Academy, founded by the Scientific Central Union of that city, was inaugurated on January 13 last.

THE competitive examination held at the Paris Conservatoire des Arts et Métiers for the appointment of a Professor of Physics and Meteorology to the National School of Agriculture is said to have been very brilliant. It has ended by the appointment of M. Duclaux, Professor to the Faculty of Lyons, who was trained by M. Pasteur.

THE *Times* Paris Correspondent telegraphs on January 24 that the eruption of mud at the foot of Mount Etna was still going on, but with varying intensity. For two days after the earthquake of the 24th ult. it was considerably stimulated, but it has since slackened, and the mud is more watery. An area of 7,000 square metres is already covered.

A CORRESPONDENT of the *Colonies and India*, writing from Wellington, New Zealand, on December 7, says that a most important discovery of graphite has just been made in the back portion of the province. The Colonial laboratory has received specimens from boulders found in a creek, and these prove to be the purest and most compact samples yet discovered in the Colonies. The value of the discovery is enhanced by the fact that the existence of coal in immediate proximity is thus indicated. In another spot, between Westport and Keefton, an extensive limestone cave has been discovered, and it is stated that it is traversed by a creek yielding good payable gold. The Geological Survey is being steadily pushed on, and Dr. Hector is now attempting to work his way to Waikato, in order to gather information as to the geology of that hitherto unexplored region.

MESSRS. LECHERTIER, BARBE, AND CO., of Regent Street, have sent us a wonderful shilling moist colour-box, which, in utility and the quality of the colours, surpasses anything we have seen.

It is of japanned tin, can be put in the pocket, has every convenience for immediate use, and is altogether excellent and astonishingly cheap. It is a pity that students of science generally don't know how to use colours to give clearness to their note-books and diagrams.

MR. BRYCE WRIGHT has just issued a catalogue of his extensive mineralogical, geological, conchological, and archæological specimens and collections, with several well-executed illustrations. Those interested in the subjects mentioned would do well to obtain a copy of the Catalogue.

MR. GOWER, an American, who has lectured in America with Mr. Bell on the telephone, has realised an interesting improvement on Bell's instrument. The new telephone differs mainly in the form of the magnet, which has been calculated so precisely that the sounds can be heard at any distance from the speaker in a large room. The telephonic current is so powerful that the contact of a magnet can be worked by it, and a signal given in a central telephonic office.

HERR PETZOLD, of Vienna, sends us several specimens of insects preserved apparently in Canada balsam and mounted on microscopic slides, which surpass in several respects anything of the kind we have seen. Herr Petzold informs us that for years he has been working to devise some means of preserving insects and other small animals in such a way as to prevent their being injured by accident or by any of the numerous enemies of museum collections. By a process of mummification, and inclosure in a transparent material he seems to us to have succeeded. The specimens sent can be clearly seen, are natural and life-like in appearance, and completely protected from all atmospheric influences.

THE fall of sleet which occurred in Central France on January 23 was so terrific that an immense number of large branches were broken by the weight of icicles adhering to the leaves. Almost all telegraphic communication between Paris and Central or Southern France was interrupted by the breaking of the telegraphic wires. The messages from Paris to Marseilles were sent *viâ* London, Lisbon, and Malta. This state of things, which had been anticipated by *Électricité*, raised a number of angry remarks from the principal papers. It is very likely that the German system of entombing the wires of the large lines will be resorted to, and special credits asked from the Chamber of Deputies next session.

THE Postal Microscopical Society is not, as its name would seem to imply, a Microscopical Society for Post Office officials. It embraces a much wider constituency, being commensurate (potentially) with the area of the kingdom embraced by our postal service. It is, in short, an association for the distribution by post of microscopical slides among its members, with facilities for these members making remarks on the slides they receive. From the Report of the fifth annual meeting we see the Society has many members over England, that the organisation is excellent, and works well. Several improvements are contemplated in the sphere of this Society. In consequence of a number of medical men having recently joined the Society, it has been arranged to circulate a special series of histo- and pathological slides. These special slides will circulate almost exclusively amongst the medical members, in addition to the usual fortnightly box of slides which goes the whole circuit of the Society, whether members are medical or otherwise. It is also proposed at the request of many members, to circulate a series of slides devoted to botanical subjects; these, after going the round of the contributors, it is proposed should go the whole circuit of the members. Those desiring to join the Society should apply to Mr Alfred Allen, 1, Cambridge Place, Bath.

AN occasional correspondent of the *Daily Press* of Hongkong, gives a somewhat melancholy account of the condition of affairs in Formosa, where it was hoped that the Chinese were showing signs of progress. The Woosung Railway plant, he says, continues to generate rust, the dredger so urgently needed has not been ordered, and the scheme for introducing Swatow coolie emigrants has fallen through. The accounts of the Kelung Colliery are not hopeful, sickness having prostrated European and native miners alike; in the petroleum region, too, all the members of the exploring party are reported to be laid up with fever. What is worse, however, in that quarter, is, the boring rod has snapped low down, and the American experts are said to have spent three weeks in a vain endeavour to connect it again. The only favourable item of news is that there is every prospect of a large sugar-crop in the south of the island.

A CONTEMPORARY in China states that petroleum is obtainable at several places in both North and South Formosa. Some time back a large spring was discovered in the hills to the south-east of the Port of Owlan, in about 24° 30′ N. lat. and 121° E. long. The principal spring is situated close to the Owlan River, at the foot of a hill. At certain times of the year the river overflows into this spring, and the oil is carried away down the stream. When the discovery of this well was made, the oil could be tasted in the water some distance off. On exploring the hills behind the spring, large fire-holes were found, and a small spring was met with on the top of a high hill. The lofty ranges of hills to the east of the petroleum valley have been explored to some extent, and in almost every range were found evidences of the existence of coal, but none of the veins or seams are being worked.

WE have received the first two numbers of the Italian *La Natura*, a weekly scientific journal, which we understand is the new form of *L'Elettricita*, founded some time since. *La Natura* is mainly devoted to the physical sciences, and, judging from the first two numbers, is likely to take a creditable place among its scientific contemporaries. In the first number Prof. Schiaparelli writes on the Perturbations communicated by Jupiter to Brorsen's comet in 1872, and in the second number on Recent Researches on the Topography and Physical Constitution of the Moon. There are several other good papers relating both to Italian and to foreign science.

Revue d'Hygiène et de Police Sanitaire is the title of a new sanitary monthly edited by Prof. E. Vallin and published by Masson of Paris.

THE *Annuaire* of the Bureau des Longitudes for 1879 contains as usual a great mass of useful and well-digested information. It contains an interesting paper by Dr. Janssen on Recent Advances in Solar Physics.

WE are glad to learn from the *Royal Gazette* of British Guiana that a Bird Ordinance has been promulgated in that colony, which is likely to prevent the stamping out of birds whose feathers are so eagerly sought after by ladies to add to their charms.

WE have received the first number of the *Revue Mycologique*, a three-weekly journal devoted to the subject of fungi, and edited by M. C. Roumeguère. The Paris publishers are Baillière and Sons.

IN the course of a recent excavation for a railway from Persan to Neuilly-en-Thelle, in the north of France, a field has been cut, which contains numerous sepultures, and was probably used as a cemetery at some early period. Nearly all the tombs (M. Millet tells us, in *La Nature*) are of hard stone and composed of two pieces (exceptionally three), with transverse joints, and the cover generally a single piece. One tomb is made of plaster.

Various objects have been met with, arms and armour, vases, ceramics, &c., and in one tomb, it is said, a warrior has been discovered fully equipped, and in such preservation that the beard was intact. M. Millet recalls the fact that in the invasion of Gaul by Julius Cæsar, there was a camp of great importance on the plateau above Gouvieux, some ten kilom. from the place of excavation, and on the route from Chantilly to Persan; the place is still known as Cæsar's Camp. Numerous battles took place in the valley of the Oise, as is attested by the medals, coins, &c., often found by farmers in that region. One of these combats was so murderous that the place where it was probably fought bears the name of *Pres de tuerie;* it is at the foot of Beaumont-sur-Oise. The excavations referred to are still in progress, and will doubtless be watched with interest.

The annual general meeting of the Manchester Field Naturalists' and Archæologists' Society was held on the 21st inst., Mr. John Angell, F.C.S., vice-president, in the chair. Mr. Alfred Griffiths, secretary, read the report for the past year, which stated that 1878 had been devoted to the aims of the Society, with an average success. Mr. Angell gave an address on the science of 1878, in which he reviewed, in an intelligent and appreciative manner, some of the main scientific points of interest during the past year.

The Geological "Landesanstalt" and Mining Academy at Berlin has recently been considerably enlarged. The institution has moved into new buildings which have just been completed, and which contain a rich collection of maps, minerals, rocks, fossils, &c., besides a large library and laboratories for geological, analytical, metallurgical, and technological work.

The existence of a subterranean oak forest in the neighbourhood of Rotenburg, Prussia, was proved last summer by the State geologist of that district, Dr. Moesta, of Marburg. The investigations of this gentleman have shown that in the plain of the Fulda valley an oak forest lies buried at a depth of some two or three metres, the origin of which dates back to the tertiary period perhaps, and of which the river Fulda has laid bare many traces by erosion. The wood of the oak trees thus brought to light has by the long action of the water been stained quite black, but still retains considerable firmness. The size of the trees is very considerable, and it remains yet to be proved whether they belong to the same family as the oaks now existing.

A German paper states that a descendant of the great Copernicus is living now at a small town of Posen, exercising the calling of shoemaker. It is known that Copernicus was a canon of the chapter of Frauenburg, and must be supposed to have died without leaving any issue. It has been said that his true son was Kepler, and that in his turn Kepler was the scientific father of Newton.

The additions to the Zoological Society's Gardens during the past week include an Entellus Monkey (*Semnopithecus entellus*) from India, presented by Mr. J. Mills, R.H.A.; two Prairie Marmots (*Cynomys ludovicianus*) from North America, presented by Miss Agneta B. Dykes; four Common Gulls (*Larus cana*), a Common Widgeon (*Mareca penelope*), four Grey Plovers (*Squatareola helvetica*), three Knots (*Tringa canutus*), a Dunlin (*Tringa cinclus*), European, presented by Mr. F. Cresswell; a Blue and Yellow Macaw (*Ara ararauna*) from South America, presented by F. G. J. Lillingston, Lieut. R.N.; two Coypu Rats (*Myopotamus coypu*), a Brown Coati (*Nasua nasica*), a Chilian Sea Eagle (*Geranoaëtus melanoleucus*), a Dinca Finch (*Dinca grisea*), two Saira Tanagers (*Pyranga saira*), two Dark Green Maize Eaters (*Pseudoleistes virescens*), two Blue-bearded Jays (*Cyanocorax cyanopogon*) from Buenos Ayres, two Garden's Night Herons (*Nycticorax gardeni*), an Ariel Toucan (*Ramphastos ariel*), a White-bellied Thrush (*Turdus albiventris*) from Bahia, a Great Frigate Bird (*Fregata aquila*) from Pernambuco, a Brazilian Blue Grosbeak (*Guiraca cyanea*) from Mexico, purchased; two Cuming's Octodons (*Octodon cumingi*) from Chili, deposited.

EARLY EXPERIMENTS ON THE CONDUCTION OF ELECTRICITY BY SUBMARINE WIRES FOR ILLUMINATING DISTANT PLACES AND PROPOSALS FOR THE DIVISION OF THE LIGHT INTO SEPARATE LIGHTS

I DO not profess to be acquainted with the means which have been recently employed for conveying electricity to illuminate places at a distance or for sub-dividing the electric light, nor is it with the slightest wish to derogate from the merit of recent inventors that I now submit a few facts as to earlier labours in the same field which may perhaps be interesting to the readers of Nature.

So far as I know, the first suggestion of communicating electricity for lighting purposes to distant places was in the fourth volume of the *Trans.* Roy. Scott. Soc. of Arts, vol. iv., 1854. In describing the apparent light on a sunken reef in the sea at the entrance of Stornoway Loch, which was lighted in 1851, I stated that "it occurred to me that in some cases gas-pipes might be laid or even *submarine wires, so as to illuminate a lantern placed on a beacon or buoy.*" I did not, however, consider it safe, "at least in the present state of our knowledge," to adopt either of these plans; but gave the preference to an apparent light illuminated by a beam of rays projected from a lens placed on the shore at a distance of 530 feet from the sunk rock, which plan has been in use since 1851.

In 1852, and therefore not long after the erection of the Stornoway light, Admiral Sheringham used electricity for producing *heat* for the purpose of igniting gas at a buoy.

My friend, Mr. Alan Brebner, C.E., suggested, as referred to in Messrs. Stevenson's Report on the electric light in 1865, that the lighthouses of Scotland might be illuminated from one great central station.

In 1865 I made experiments for the Commissioners of Northern Lighthouses with the sanction of the Board of Trade, on lighting beacons by submarine wires, and on the suggestion of my friend, Prof. Swan, increased the flashes by combining a Leyden jar with an induction coil. On January 13, 1866, I communicated to the Secretary of the Roy. Scott. Society of Arts that the induction spark placed in the focus of lighthouse apparatus gave in all respects satisfactory results at the distance of half a mile, which, owing to intervening objects, was the greatest distance from which it could be seen. The primary current was also kept for a week passing continuously night and day, through 800 feet of wire without any sensible waste of the platinum electrodes. I next attempted to pass the current through a cable under the sea, but without success, when Messrs. Stevenson applied to Dr. Siemens for his assistance in the matter, and he recommended an electro-magnet on the beacon with a contact lever actuated by the armature of the electro-magnet in the manner of a Neft's hammer. The luminous effect was increased by the deflagration of mercury. This plan, as tried at Granton Harbour, was quite successful; but the products of combustion were deposited on the optical apparatus, and some mechanical difficulties interfered with its continuous working.

Being thus thrown back on the old plan of the induction spark, I was enabled to overcome the difficulties by the following expedients:—Mr. Brebner suggested placing the induction coils with condensers close to the optical apparatus on the beacon and the battery and contact breaker on the shore, so as to pass only the primary current through the cable. Mr. Hart, electrician, also designed an improved break for the purpose, and Prof. Tait recommended the enlargement of the earth terminals. By these arrangements the current was passed successfully under the sea. The experiment was repeated at Granton, at the request of the Trinity House of London, in presence of Captains Fenwick and Nisbet, and Mr. Douglass, the engineer, accompanied by Mr. Farrer and Mr. Shaw Lefevre of the Board of Trade.[1] The distance between the battery and break on Granton Pier and the induction coils and optical apparatus on Newhaven Pier is

[1] "Proposals for the Illumination of Beacons and Buoys," by T. Stevenson, p. 14. (Edinburgh: A. and C. Black, 1870.)

upwards of half a mile, but the actual length of wire which was submerged, and through which the current passed, was upwards of a mile. The spark was about ¼ inch in length, bluish white in colour, and very striking and interesting in effect. It was placed in the focus of a holophotalised parabolic reflector.

At the same time in order to ascertain if by means of a single battery under the charge of one keeper a succession of flashes could be produced and a string of isolated dangers illuminated, the light was sub-divided first into two separate flashes and afterwards into six different sparks. The separate lights were quite satisfactory, though they were not as might have been expected of the same power as the original single one. But as the separate sparks were very close to each other this cannot, I presume, be held to be a proper sub-division of the light.

In 1867, at the British Association at Dundee, I suggested that the "effect of the light might be also increased without using additional cells if the same current could be again utilised so as to generate a second spark in the same focus. This was proposed to be done by 'using additional coils' for the same focus or separate sparks in the foci of separate reflectors.[1] I also added that the "time is perhaps not far distant when the beacons and buoys in such a navigation as the entrance to Liverpool may be lit up by submarine conduction from a central station on either shore, while the whole management may be trusted to the charge of one or two light-keepers."[2]

I may add that similar trials were made with Wilde's electromagnetic machine, which gave a light of much greater volume and power. The electrodes employed in all these experiments were made of platinum, but several other metals were experimented with, and of all that were tried bismuth was found to give the brightest light.[3]

A committee of the Scottish Society of Arts, consisting of Dr. Ferguson, convener, Dr. Lees, and the late Dr. Strethill Wright reported in the following terms:—"The peculiar character of the light, which is flickering, though continuous, is well marked and would be easily understood. So far as Mr. Stevenson's experiments go, they seem to prove the practicability of his proposal, and your committee do not anticipate any serious obstacle to its realisation." THOMAS STEVENSON

Edinburgh

UNDERGROUND TEMPERATURE[4]

DR. STAPFF has continued his observations of the temperature in the St. Gothard Tunnel, and has contributed to the Swiss Natural History Society a paper[5] of fifty-six quarto pages, embodying the results.

The following is his description (pp. 26, 27), of the mode of observing the temperature of the rocks in the tunnel:—

"The exact determination of the temperature of the rocks in the tunnel formerly occasioned a notable expenditure of time and money. At first thermometers about a metre long (made by J. Goldschmid, of Zurich) were employed for this purpose; their tubes being cemented into a wooden cylinder, so that only the bulb (surrounded by a perforated steel cap) projected below, and the scale (extending from 15° to 30° C.) above. Tallow was poured round the wooden cylinder, and the whole thermometer was then thrust into a bore-hole a metre deep, so that only the scale projected, from which readings were taken from time to time until the temperature became constant. The final reading had to be corrected not only for rise of zero but also for the temperature of the quicksilver in the thermometer tube which extends from the opening to the bottom of the bore-hole. Another very notable correction was required for the more or less oblique position of the thermometer; for the hydrostatic pressure of the quicksilver presses out the glass bulb so far that without change of temperature the long thermometer reads from 0°·4 to 1°·0 less in the vertical than in the horizontal position.

"After about from three to ten days, the reading of a thermometer luted into a bore-hole ceased to alter.

"Separate trials with thermometers of similar construction, but different length, showed, moreover, that, after months, the temperature of the rock at about a metre deep was still unchanged. This is obviously owing to the small difference of temperature between the rock and the surrounding air.

"From the observations at No. 8 and No. 15, in Table III., it is seen that the temperature at the bottom of the bore-hole was sometimes a little lower and sometimes a little higher than nearer its mouth.

"This mode of observing gave correct results, but was laborious and costly, not only on account of the necessity of making special bore-holes for the purpose, but because almost every experiment cost a thermometer. The projecting end was often maliciously broken off, and on account of the swelling of the wooden case it almost never happened that at the end of an experiment a thermometer was drawn out again uninjured.

"Hermann and Pfister remedied this latter evil by surrounding the thermometer-tube from the bulb to the scale, with a glass case, and this with a steel jacket. This arrangement, however, involves not only conduction through the steel, but also continual interchange of heat by currents of air in the glass case, from the mouth to the bottom of the hole. For these reasons the observations made with these thermometers could not be employed without intricate corrections.

"Later I tried a Thomson's maximum thermometer,[1] kindly placed at my disposal by Prof. Everett, which (after previous strong cooling) was left for several days at the bottom of the bore-hole, closed air-tight. The results agreed with those obtained by other methods; but who can guarantee that the higher temperature prevailing in a newly-bored hole is always just so much depressed by the cold mass of the thermometer and its copper case, that the rock-temperature alone determines the final indication of the maximum thermometer?

"This consideration induced me to employ for rock-temperature observations (and they also serve for air and water observations), the above-mentioned short thermometers with insulated bulbs, the first of which Prof. Everett caused to be made by Negretti and Zambra for this express purpose. These thermometers, inclosed in a metal box provided with a handle, are thrust to the bottom of the bore-hole, which is at least a metre deep. To the handle is fastened a strong cord reaching to the mouth of the hole, by which it can be drawn out again at the end of the trial. The bore-hole, from the thermometer to the mouth, is stopped with greased rag or other similar material, as air-tight as possible. After two or three days, the thermometers have usually assumed the temperature of the surrounding rock, that is to say, their reading has ceased to alter. The insulation of the quicksilver prevents alterations during the drawing-out and reading of the thermometer. The correctness of the result is in no way prejudiced by sediment from the boring which may yet remain in the hole. The pouring in of some water may even be useful in accelerating the experiment. Wet bore-holes with standing-water are, however, to be avoided, because rock-temperature and water-temperature are not identical.

"In the manner last described, at every available opportunity, that is to say, when the work of the tunnel is from any cause compelled to cease for a few days, rock-temperature observations are now instituted in bore-holes ready to our hand. The observations are simple, give exact results if taken with proper precaution and sufficient duration of the experiment, and cause no further expense, since the thermometers, being sunk in the rock, are secured against wanton injury, and there are always bore-holes available."

Dr. Stapff further states by letter that the two original thermometers supplied by Negretti and Zambra having been broken, he has had others made, in which he has introduced the improvement of hermetically sealing the outer glass case, instead of closing it with a waxed cork, which gradually admitted moisture.

In the Report for 1876 an account was given of the observations of Herr Dunker in a bore about 4,000 feet deep at Sperenberg, and allusion was made to the undue weight which had been attached by some writers to the empirical formula in which Herr Dunker sums up his observations; a formula which indicates a retarded rate of increase, and, if extended to greater depths, leads to the conclusion that the temperature reaches its maximum at the depth of about a mile.

A discussion has been carried on in Germany on this subject,[2]

[1] British Association Reports, 1867. [2] *Ibid.*

[1] It was one of the protected Negretti maximum thermometers constructed for the Committee.

[2] See papers by Mohr, Heinrich (two papers), Dunker, and Hottenroth, in the "Neues Jahrbuch" for 1875, 1876, and 1877; by Brauns, in the "Zeitschrift für die gesammten Naturwissenschaften," 1874, p. 483; and by Hann, in the "Zeitschrift der österreichischen Gesellschaft für Meteorologie," 1878, p. 17.

chiefly in the "Neues Jahrbuch für Mineralogie," &c., and the best authorities seem to be unanimous in rejecting the hypothesis of a retarded rate of increase in the earth's surface as unwarranted, either by the Sperenberg observations or any others. Herr Dunker himself concurs in this opinion. Dr. Stapff also, though some of his own empirical formulæ indicate a retarded rate of increase, writes to Prof. Everett in the following terms:—"As to my formulas, I beg you to remember that they are not constructed for expressing laws of Nature. They simply are made for facilitating the view over a heap of figures and data of observation. And generally I beg you to be sure that those formulas, in my mind, cannot express any law for the increase of warmth at greater depths than those in which the tunnel observations were made. The formulas give good means for eliminating empirically some of the influences of the shape of surface which occur in the profile of the mountain."

Mr. W. Galloway, one of H.M. Inspectors of Mines, has taken observations in Fowler's Colliery, Pontypridd, South Wales. The shaft is 846 feet deep, and the air current down it amounts to between 20,000 and 30,000 cubic feet per minute.

In order to determine the normal temperature of the coal, a hole $1\frac{1}{2}$ inch in diameter was bored in the side of a narrow place that was being rapidly driven in the solid coal. The hole was bored in the very face, to the depth of 4 feet. The thermometer (one of the committee's slow-action non-registering instruments) was placed at the inner end; then a wooden cylinder of nearly the same diameter as the bore-hole, and 9 inches long, was pushed in until it came in contact with the copper case of the thermometer; and lastly a wooden plug, wrapped round with cloth, was driven firmly into the mouth of the hole. The thermometer was at 58° F. when it was put into the hole, and after remaining there from 2 P.M. on August 25, 1876, to 3.45 P.M. on the following day, it stood at 62°·7. There was no water whatever in the hole, and the depth below the surface of the ground was 855 feet.

The circumstances of this observation seem to preclude any considerable disturbance of the normal temperature; and combining it with the mean annual temperature at the surface, which is said to be 51°·5, we have an increase of 11°·2 F. in 855 feet; which is at the rate of 1° F. for 76 feet.

Two other observations were taken in other parts of the mine. They are not directly available for the purposes of the Committee, but were intended to test the influence of air-currents on the temperature of the coal; and they show variations of 2° or 3°, according to the season of the year.

Observations are being taken for the Committee by Mr. G. F. Deacon, Borough Engineer of Liverpool, in a bore which has attained the depth of 1,004 feet, in connection with the Liverpool Waterworks at Bootle.

The temperature at this depth is 58°·1. The observation nearest the surface was at the depth of 226 feet, the temperature at this depth being 52°. We have here a difference of 6°·1. in 778 feet, which is at the rate of 1° for 128 feet, and the same rate is approximately maintained throughout the descent. For instance, at 750 feet, the temperature was 56°, which gives 1° for 131 feet by comparison with the depth of 226 feet, and 1° for 121 feet by comparison with the bottom.

The bore is 24 inches in diameter, and the observations were taken with a protected Phillips's maximum thermometer every Monday morning. The operation of boring was continued up to twelve o'clock on Saturday night, and was not resumed till the temperature had been taken on the following Monday. The time that the thermometer remained at the bottom was not less than a quarter of an hour, and was sometimes half an hour.

The rock-formation consists of the pebble beds of the Bunter or lower trias, and most of it is described as hard, close-grained, and compact. The speed of boring is indicated by the dates of the observations at 226 and 1,004 feet, the former being November 12, 1877, and the latter August 12, 1878. A month was lost by the jamming of the drilling tool, in May and June, 1878, when a depth of about 890 feet had been attained.

The depth from the surface of the ground to the surface of the water in the bore has gradually decreased from 66 feet, when the bore was at 318 feet, to 52 feet, when the bore was at 800 feet, and to 51·1 feet, at the present depth. It would thus appear that the inflow of water from below has increased with the depth attained. There is a slow percolation from the upper part of the water-column to an underground reservoir near at hand, the top of the water-column being considerably higher than the top of the water in the reservoir. Mr. Deacon remarks that the slow upward flow which supplies the water for this gradual discharge is favourable to the accuracy of the observations (which have always been taken at the bottom), by checking the tendency of the colder and heavier upper water to descend and mix with the lower. As bearing on the subject of the disturbance of temperature by the stirring of the water in boring, as well as by the generation of heat in the concussions of the tool, it may be mentioned that the last observation before the month's interruption by the jamming of the tool was 57°·5, at 886 feet, and the first observation after the extraction of the tool was 57°·0, at 898·6 feet, the former being on May 20, and the latter on July 1. The smallness of the difference between these two temperatures seems to indicate smallness of disturbance by the action of the tool.

It appears from these various circumstances that the observations are entitled to considerable weight, and that the rate of increase of temperature downwards at Liverpool is exceptionally slow. It will be remembered that the rate found by Mr. Fairbairn, at Dukinfield Colliery, in the adjacent county (Cheshire), was also very slow, though not nearly so slow as that indicated by these Liverpool observations.—(See our Report in the volume for 1870).

Mr. E. Wethered, of Weston, near Bath, has also commenced observations in a colliery in that neighbourhood. Mr. J. Merrivale, of Nedderton, near Morpeth, has received a thermometer for observations in a colliery. Mr. J. T. Boot, of Hucknall, near Mansfield, has received a second thermometer (in place of a broken one) for observations in a deep bore, and Mr. Rowland Gascoigne, of the same town, has received one for a similar purpose.

In the eleven years which have elapsed since the appointment of this Committee a large amount of useful work has been done, by methods of observation not requiring any elaborate or expensive appliances, or any special training on the part of the observers.

Two difficulties are encountered in investigating underground temperature. We have to contrive instruments which shall truly indicate the temperature at the point of observation, and we have further to insure that this temperature shall be the same at the time of observation as it was before the locality was artificially disturbed.

As regards the first of these difficulties the Committee have been completely successful, and have largely increased the resources at the command of observers.

But in regard to the second difficulty the same amount of success has not been attained. The circulation of water in bore-holes and of air in mines are disturbing elements difficult to deal with. Even such firm plugging as was employed to isolate portions of the water-column in the great bore at Sperenberg cannot altogether remove the error arising from convective disturbance; for the long-continued presence of water at a temperature different from that proper to the depth affects the temperature of the surrounding rocks, and the temporary isolation of a short column would not abolish this source of error, even if the plugs themselves were impervious to conduction and convection.

After the experience which has now been gained of rough and ready methods, it is time to consider the propriety of resorting to a more special method, which has been more than once suggested, but has hitherto been postponed on account of the additional labour and skill which would be requisite for carrying it out.

There can be no doubt that the surest way to bring any point of a boring to its original temperature is to fill up the bore, and reduce it as nearly as possible to its original condition. Several instruments have been contrived which, when buried in the earth, with wires coming from them to the surface, admit of having their temperature observed by electrical means.

One of these is Siemens' resistance thermometer, another is Wheatstone's telegraphic thermometer, of which a description will be found in the Report of the Dundee Meeting of the British Association; another is Becquerel's thermo-electric apparatus, which has been employed by its inventor and his son and grandson for some forty years. It is described in the following terms in the first Report of this Committee (1868):—

"The thermo-electric method might also be followed with great advantage. Two wires, one of iron and the other of copper, insulated by gutta-percha or some other covering, as in submarine cables, and connected at their ends, might be let down so as to bring their lower junction to the point where the temperature is to be taken, their upper junction being immersed

in a basin of water, and the circuit completed through a galvanometer. The temperature of the water in the basin might then be altered till the galvanometer gave zero indication."

Sir Wm. Thomson now adds the recommendation that, in carrying out this method, the two wires, each well covered with gutta-percha, should be twisted together; that the wires should be stout and as homogeneous as possible throughout, and that a piece of stout copper tube should be attached to the lower junction, this tube being uncovered and in close contact with the earth all round, its purpose being to insure that the junction takes the proper temperature.

It would probably be desirable, in filling up the bore, to mix clay with the original material to render it watertight, for it would be impossible to render the filling of the bore as compact as the surrounding rock.

Several pairs of wires would be buried in the same bore, with their lower junctions at different carefully-measured depths.

The upper junctions would be kept in a room provided with a steady table for a mirror-galvanometer.

THE RAINFALL OF THE WORLD[1]

1. THE pamphlet referred to below embodies the outline of an attempt to bring into harmony the disconnected, and in some cases apparently irreconcilable results that have hitherto attended comparisons of terrestrial rainfall and sun-spot variations. It relates, therefore, to the entire rainfall system of the globe.

2. The plan by which it is thought this object will be best attained is one which divides the world into a number of rainfall zones where either *à priori* considerations or actual experience would lead us to expect typical changes in the effects of a recurring secular variation in solar radiated heat upon the rainfall; it being immaterial as far as regards the practical advantages secured by this method of hyeto-graphical subdivision, whether the solar radiation be ultimately found to vary directly or inversely with the sun-spots.

3. The way in which typical changes may arise in different parts of the earth from the effects of an assumed recurring secular change in solar radiated heat, is shown by a reference to the general scheme of atmospheric circulation in conjunction with the two leading factors of variability, viz., season and latitude.

4. A consideration of these points leads the author to divide the world into five zones, which either theoretically might, or are actually known to, involve some typical change in the secular variation of the rainfall either of one season or the whole year.

5. Partly to illustrate this mode of subdivision by applying a reasonable working hypothesis, and partly in the absence of absolutely conclusive evidence in its favour, by exhibiting the harmony of existing facts with the conditions theoretically deduced from it, to promote its ultimate adoption, the theory of the inverse variation of solar radiated heat with the sun-spots is assumed throughout.

6. It is also shown in the Introduction that we have a good deal of evidence in favour of the same theory, both *à priori*, from a consideration of the principle of conservation of energy as applied to the sun, as well as indirect, from the results of thermometrical observations.

7. In applying this hypothesis to determine the rainfall variation, account is mainly taken of the direct relation between wind velocity and temperature, the secular changes in solar radiation being assumed to cause *similar* effective secular changes in the velocity of the larger atmospheric convection currents.

8. An induction from Messrs. Blanford and Eliot's theory of cyclone-generation is then made use of, in combination with the preceding hypothesis, from which it appears that while, owing to the diminished solar temperature, evaporation might be lessened in the tropics at the epoch of maximum sun-spot, the diminished carrying power of the wind (by which the prevalence of cyclones at this epoch would be accounted for, according to Blanford and Eliot's theory) might allow of greater precipitation near the place of evaporation, and therefore of a generally heavier rainfall in these regions. At the opposite epoch, on the other hand, the increased velocity of the wind would probably cause a wider distribution of tropical vapour, and therefore in combination with the direct effects of the assumed increase in solar radiation at the same epoch give rise to a deficiency of rain in parts, more especially those in which the local conditions normally tend to produce aridity.

9. These hypothetical results are then shown to approximately agree with the actual results of observations recorded in these regions.

10. It is next shown that the effects of the assumed secular change in the velocity of the anti-trade (the prevailing wind of the temperate zone) should differ considerably from those in the case of the monsoons and trades of the tropics, an increased velocity in the case of the anti-trade causing a greater quantity of tropical vapour to be conveyed to the temperate regions, and consequently a greater degree of humidity to ensue there. When, therefore, the direct effects of the assumed increase of solar heat at such an epoch are at a minimum, that is to say, in the *winter*, the relative humidity, and consequently the rainfall, should be *increased*. It is also evident that such an effect should be most conspicuously felt in those regions where rain falls *only* in the winter, and is due to the descent of the anti-trade.

11. The occurrence of this inverse variation in the zone of winter rains, which in the case of the Mediterranean stations (*Zeitschrift für Meteorologie*, Band viii. No. 6), had hitherto been deemed unfavourable to Messrs. Lockyer and Meldrum's generalisation regarding the direct variation of terrestrial rainfall with the sun-spots, is also shown to be visible in the winter rainfall of Northern India, and the rainfalls of Jerusalem and California, thereby affording some preliminary support to the notion that it holds over a still wider extent of the globe where the rain falls mostly during the winter.

12. The attempt is then made to show that while the direct effects of the secular change in the sun's heat over extra-tropical continents may, during the summer, operate so far as to destroy the indirect effects produced by the corresponding variations in the strength of the anti-trade, and as Dr. Hahn has shown in the case of the summer rainfalls of several stations in Central Europe, actually cause a *direct* variation with the sun-spots, there are, as there should be, in accordance with the hypothesis, some preliminary indications of an *inverse* variation of that proportion of the total which falls during the winter months alone, even in those places where the rain falls throughout the year. This fact, then, would imply that a change of season causes a change of type in the character of the variation, so that in order to render the variations distinctly apparent we should compare the winter and summer falls separately. It may also be inferred that the quality of the variation in the total annual fall will depend on the preponderance of the summer or winter falls respectively, which fact may help to account for the numerous anomalies noticed by those who have hitherto compared the total annual falls of places in the temperate zone with sun-spots.

13. It is finally inferred in the appendix, as a direct result of the hypothesis assumed throughout, that the winter gales of the temperate zone and the cyclones of the tropics should bear a complementary relation to each other, the former being most frequent about the time of minimum, and the latter about that of maximum, sun-spot. Some evidence in favour of this notion was recently communicated to NATURE by Mr. S. A. Hill (vol. xviii. p. 616).

14. The pamphlet is intended by the author to be considered as merely tentative, and not by any means conclusive. It is the method of division into zones and the separate comparison of seasonal falls, rather than the accordance of data with theoretical deductions, to which he desires to give prominence, and which he thinks may be of some assistance to other workers in the same field.

[1] The Rainfall of the World in Connection with the Eleven-Year Period of Sun-spots. With an Introduction and Appendix. By E. D. Archibald, Professor of Mathematics in the Patna College. (Calcutta and London: Thacker and Co. 1878.)

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

THE Cambridge Mathematical Tripos list was published on the 24th. This year the list contains 91 names. There are 28 classed as Wranglers, 33 as Senior Optimes, 29 as Junior Optimes, and 1 Ægrotat. In 1878 the list contained 94 names, 31 being Wranglers, 30 Senior Optimes, 29 Junior Optimes, and 4 Ægrotant. The first three Wranglers are Mr. A. J. Campbell Allen, of St. Peter's, Mr. George Walker, of Queen's, and Mr. Carl Pearson, King's. Mr. Campbell Allen, of St. Peter's College, the Senior Wrangler, is a native of Belfast, and was born in 1856. He received his elementary education at the

Royal Academical Institution, Belfast. In 1872 he became a student at Queen's College, Belfast, where he succeeded in winning several scholarships and also two Peel Exhibitions, one for general proficiency and the second for mathematics. In 1875 he was elected to an open scholarship at St. Peter's, and in October of that year he graduated B.A. at the Queen's University, subsequently proceeding M.A. On each occasion he obtained a first-class for mathematical science, and was awarded a gold medal. He has won several college prizes during his residence at Cambridge. Mr. Walker is a native of Durham, and was educated at Durham University, of which he is a Fellow, and proceeded to Queen's College in October, 1875. He has been a prizeman of the college for mathematics. Mr. Pearson was educated at University College School, and also under private tuition with the Rev. L. Hensley, of Hitchin. He gained an open scholarship at King's College in 1875, and has been each year college prizeman in mathematics.

A REPORT just published by the Swiss Statistical Board gives some information as to the state of primary instruction in the various cantons of Switzerland. Out of 21,875 recruits examined during the year 1877, 11·7 per cent. proved to have primary instruction quite insufficient, and were sent back to the primary military schools. The better educated cantons are those in which manufactures are more developed, namely, Basel (town), Geneva, and Zurich, Schaffhausen and Thurgau. The worst educated are those of Appenzell (land), Uri, Wallis, and Freiburg (Catholic). Primary education seems to have become worse during recent years, as the results for 1877 are far below those of 1876.

SCIENTIFIC SERIALS

Journal of the Franklin Institute, December, 1878.—From experiments here described by Mr. Jacques, it appears that currents of air of varying density, as in Tyndall's well-known experiment, not only diminish the *intensity* of a sound, but affect its *distinctness*. This holds good especially for the human voice, and for musical instruments with few overtones (as the flute). The effect on the voice is that of a repetition of each syllable several times in close succession. Sound-waves were traced out in the space of an auditorium in Boston, and their confusion shown on introducing air-currents. The good acoustic properties of the Baltimore Academy of Music are proved to be due to arrangements by which a large volume of air is conducted, in gentle current, across the stage and diagonally towards the roof. When, by closing certain valves, ventilation was arrested and currents of circulation generated, the sound was noticed to be "dead," or "confused and indistinct."—Dr. Dudley investigates the chemical composition and physical properties of steel rails, deducing some rules for guidance of the Pennsylvania Railroad Company.—Mr. Dupuy writes on the direct process of making wrought iron and steel,—Mr. Dumont on tests of boiler iron,—and Prof. Haupt on the use of the heliotrope in geodetic surveys.

THE *Archives des Sciences physiques et naturelles* (parts 251 and 252, November and December) contain the following papers of interest:—On ytterbina, a new earth contained in gadolinite, by C. Marignac.—On a transformation of dibromethylene into an acetone with four atoms of carbon, brought about by the action of hypobromous acid, by E. Demole.—A note on Dr. Heine's work on the formation of mountains, by E. Renevier.—On the geography and archæology of forests, by Dr. Asa Gray.—Recent researches in solar chemistry, by J. Norman Lockyer.—Observation of a case of migration of carps, by A. Bartholoni.—On a general method of continuous integration of any numeric function, applied to several theorems furnished by the mathematical analysis of the calculation of the curves of a new thermograph, by Raoul Pictet and Gustave Cellérier.—On the limnograph of Secheron, near Geneva, by Ph. Plantamour.—A note on the useful effect of magneto-electric machines and the production of electric light, by A. Achard.—On the reappearance of Encke's comet of short period, with a history of this comet, by Alfred Gautier.—Some remarks on the migration of carps by G. Lunel.—On the ophite of Spain, by M. Calderon.

Bulletin de l'Académie Royale de Belgique, Nos. 9 and 10, 1878.—This contains an account, by M. Dupont, of a recent important "find" of fossils in the Sainte Barbe, one of the coal mines of Bernissart (a village near the French frontier), consisting of five skeletons of large adult iguanodons together with tortoises, numerous fishes, and plant-impressions, constituting a fauna and flora wholly new for the country. The bones are unfortunately impregnated with pyrites, so that they are readily disaggregated on contact with air, but they have been carefully removed in plaster to Brussels, after precise noting of position, &c. The fossils were found at several different levels separated by layers of sterile clay. There is no indication of molluscs of any kind. The deposit is thought to be of the Wealdian horizon, and is remarkable, both in itself, and in its relations to the subterranean orography of the valley of Mons, and the lower cretaceous strata of Hainaut.—M. Plateau writes on a law of the persistence of impressions in the eye. With two disc having the same number of sectors, and the white sectors of the one being equal in angular width to the black discs of the other, the "times of apparent constancy," of the two impressions are to each other in inverse ratio of the brightnesses of the two grey tints producing these impressions. A complete impression, whether intense or weak, has no appreciable time of apparent constancy; and the time is longer, the more incomplete the impression. The degree of illumination of the object has but a weak and indirect influence on the time of apparent constancy.—M. Longchamps contributes further additions to the synopsis of the Gomphines; and M. Renard lithological researches on the phtanites of the carboniferous limestone of Belgium.—M. Montigny describes an experimental arrangement for the study of coloured stars.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, December 19, 1878.—"On the Torsional Strain which remains in a Glass Fibre after Release from Twisting Stress," by J. Hopkinson, D.Sc., F.R.S.

It has long been known that if a wire of metal or fibre of glass be for a time twisted, and be then released, it will not at once return to its initial position, but will exhibit a gradually decreasing torsion in the direction of the impressed twist. The best method of approximating to an expression of the facts has been given by Boltzmann ("Akad. der Wissensch. zu Wien," 1874). He rests his theory upon the assumption that a stress acting for a short time will leave after it has ceased a strain which decreases in amount as time elapses, and that the principle of superposition is applicable to these strains, that is to say, that we may add the after-effects of stresses, whether simultaneous or successive. Boltzmann also finds that, if $\phi(t)\tau$ be the strain at time t resulting from a twist lasting a very short time τ, at time $t = 0$, $\phi(t) = \frac{A}{t}$, where A is constant for moderate values of t, but decreases when t is very large or very small.

The glass fibre I examined was about twenty inches in length. The glass from which it was drawn was composed of silica, soda, and lime; in fact, was glass No. 1 of my paper on "Residual Change of the Leyden Jar" (*Phil. Trans.*, 1877). In all cases the twist given was one complete revolution. The deflection at any time was determined by the position on a scale of the image of a wire before a lamp, formed by reflection from a light concave mirror, as in Sir W. Thomson's galvanometers and quadrant electrometer.

The first point to be ascertained from the results was whether or not the principle of superposition, assumed by Boltzmann, holds for torsions of the magnitude used.

The experiments indicate a large deviation from the principle of superposition, the actual effect being *less* than the sum of the separate effects of the periods of stress into which the actual period may be broken up.

They also appear to indicate the form $\phi(t) = \frac{A}{t^{\alpha}}$, α being less than, but near to, unity. If $\alpha = 0·95$ we have a fairly satisfactory formula for the case in which the fibre was twisted two hours.

In the author's paper on "Residual Change of the Leyden Jar" that subject is discussed in the same manner as Boltzmann discusses the after-effect of torsion on a fibre, and it is worth remarking that those results can be roughly expressed by a formula in which $\phi(t) = \frac{A}{t^{\alpha}}$. For glass No. 5 (soft crown) $\alpha = 0·65$, whilst for No. 7 (light flint) it is greater: but in the electrical experiment no sign of a definite deviation from the law of superposition was detected.

January 16.—"On the Effect of Strong Induction-Currents upon the Structure of the Spinal Cord," by William Miller Ord, M.D.

Conclusions.—1. That, in young dogs, the protoplasmic constituent of the grey matter contracts under the influence of strong faradaic currents.

2. That it contracts unequally and irregularly by reason of its unequal and irregular sectional area, causing thereby condensations at certain points—notably in the anterior horns and around the central canal—and rarefaction at others—notably in the middle of each crescent, such rarefaction going on sometimes to rupture of tissues.

3. That nerve-corpuscles contract in various degrees according to the strength and duration of currents, and that while they tend in contraction to become spherical, they also tend to become vacuolated.

4. That the vessels are in some places strongly contracted and empty; in others dilated and filled with blood-clot, having the appearance of embolus.

5. That the appearances correspond so decidedly with appearances in chorea and tetanus as to give ground for the supposition that contractions, such as are produced by electricity, do actually occur during life under the effect of nervous shock, and may be phenomena, casual, or associate, of such diseases.

"On some Points connected with the Anatomy of the Skin," by George Thin, M.D. Communicated by Prof. Huxley, Sec. R.S.

It is partly the object of this paper to describe some methods by which it can be demonstrated that the connective tissue-bundles of the cutis are, as has been long ago pointed out by Rollett, composed of subdivisions, which are again composed of minute fibrillæ. These subdivisions the author terms primary bundles to distinguish them more markedly from the fibrillæ, and also to describe some other points in the anatomy of the skin which were observed by means of these methods.

The primary bundles isolated by these methods were flattened, cylindrical elements, even contoured, homogeneous in appearance, and uniform in breadth over the whole length isolated. The difference in breadth between individual bundles was very slight. By measurement he found that they were from 0·004 to 0·005 millim. broad.

In gold preparations the following facts regarding the disposition of the elastic fibres were noted:—

If a portion of skin is hardened in bichromate of potash, and the sections moderately stained by eosin, all the large elastic fibres are stained much more intensely than the bundles, and it is then observed that they lie on the surface of the bundles, and run parallel to them. In the gold preparations, after maceration in formic acid, further details regarding the fibres can be detected. It is then seen that there is a close network of minute elastic fibres, of which no traces are observed in eosin-stained bichromate preparations, on the surface of the bundles, and that at certain points the larger fibres give off branches which join this network. At these points the network is so dense over a small defined space that the size of the meshes is nearly equalled by that of the fibres.

Elastic fibres which penetrate the bundles enter between the primary bundles, and the primary bundles are embraced by the fibres which entwine them very closely.

The dark very finely granular deposit produced by the reduction of the gold chloride had a special relation to the elastic fibres. Strictly defined narrow strips of this deposit were found investing the fibres, and this so closely that it was only at points where it had been disturbed in the preparation that the fibre itself could be observed.

The distinctly localised character of the deposit around the elastic fibres supports, according to the author, the idea that the larger ones are surrounded by an albuminous fluid, of a like nature to that shown by gold preparations, to be present between the laminæ of the cornea.

The "spiral" fibre, as observed on the bundles of the skin, is an elastic fibre that encircles the bundles like a ring, and is stained yellow by pikro-carminate of ammonia.

The cells seen in the preparations were in two positions. Some of them were found in a delicate tissue between the bundles; other cells were found in direct connection with the bundles. Of the latter cells the greater number seen were applied to the surface of the bundles, but others were found in the substance of the bundles between the primary bundles.

These cells were all of the endothelial type. In all of them the cell-contour was clearly marked, and in none of those observed was there a trace of a process, or of ridges and depressions similar to those described by some histologists in tendon.

"On Hyaline Cartilage and Deceptive Appearances produced by Reagents, as observed in the Examination of a Cartilaginous Tumour of the Lower Jaw." By George Thin, M.D. Communicated by Prof. Huxley, Sec. R.S.

This paper is written with a twofold object: firstly, as a contribution to the histology of hyaline cartilage; secondly, to illustrate how much the apparent structure of a tissue which is being examined microscopically depends on methods of preparation.

The author was able to isolate the cells from the cartilaginous substance of the tumour after the action of osmic acid. All the cells thus isolated were flattened, rounded, or somewhat polygonal bodies, with round nuclei. Their contours did not correspond exactly with those of the rounded cartilage "capsules."

The examination of this tumour showed that most delusive appearances as regards the nature of cartilage cells may be sometimes produced by staining and hardening agents. Carmine and eosin by staining an unformed substance that exists in the structure in a localised form, may simulate branched protoplasmic cells, and bichromate and logwood preparations, either in sections or teased out, may as closely simulate cells with fibre processes.

The facts adduced by the author justify, as he believes, serious doubts as to the correctness of interpretation in all cases in which histologists have described branched cells in hyaline cartilage, whether the latter existed as a normal structure or as a pathological growth. They further show that, taken alone, carmine or eosin staining should not be held as conclusive evidence of the existence or limits of cellular protoplasm in any animal tissue.

Meteorological Society, January 15.—Annual Meeting.—Mr. C. Greaves, president, in the chair.—The Report of the Council showed that the chief features of the proceedings during the year 1878 had been the final completion, on a comprehensive and well-organised basis, of the arrangements for systematic inspection of the Society's stations, an object which has engaged the sedulous attention of successive Councils for the last four years; and the delivery of a series of lectures on Meteorology by certain Members of the Council. The total number of Fellows now amounts to 425, forty-one having been elected during the year.—The President having delivered his address on Dryness *versus* Humidity, the following gentlemen were elected officers and Council for the ensuing year:—President: Charles Greaves, M. Inst. C.E., F.G.S. Vice-Presidents: Charles Brooke, M.A., F.R.S., F.R.C.S., Henry Storks Eaton, M.A., Rev. William Clement Ley, M.A., Capt. Henry Toynbee, F.R.A.S. Treasurer: Henry Perigal, F.R.A.S. Trustees: Sir Antonio Brady, F.G.S., Stephen William Silver, F.R.G.S. Secretaries: George James Symons, F.R.S., John W. Tripe, M.D. Foreign Secretary: Robert H. Scott, M.A., F.R.S. Council: Arthur Brewin, F.R.A.S., Edward Ernest Dymond, William Ellis, F.R.A.S., Rogers Field, B.A., M.Inst.C.E., Rev. Charles Higman Griffith, William John Harris, M.R.C.S., James Park Harrison, M.A., John Knox Laughton, M.A., F.R.A.S., Robert John Lecky, F.R.A.S., Hon. Francis A. Rollo Russell, Richard Strachan, Henry Samuel Tabor.

Royal Microscopical Society, January 8.—J. W. Stephenson, treasurer, in the chair.—Five gentlemen were proposed for election as Fellows, and the list of nominations for the Council was read.—The following papers were read:—Observations on *Dactylocalyx pumiceus* (Stuchbury), with description of a new variety, *D. Stuchburyi*, by Mr. W. J. Sollas.—Note on a revolver immersion prism for sub-stage illumination, by Dr. James Edmunds.—Immersion illuminators, by Mr. J. Mayall, jun.—Is not the genus Pedalion of Hudson synonymous with Hexarthra of Schmarda? by Mr. J. Deby.—The thallus of Diatoms, by Mr. F. Kitton.—Mr. Crisp (secretary) described the two new sense-organs in insects discovered by Prof. Graber, of Czernowitz.—The following were exhibited:—Specimens showing parasitism of a coral on a sponge (Dr. Matthews); the Sorby miniature micro-spectroscope; Recklinghausen and Meyer's pathological micro-photographs and specimens of microscopic printing (Mr. Crisp); sections of mistletoe on an apple tree double stained (Mr. Ward); Amici's original form of camera lucida referred to at the December meeting (Mr. Ingpen).

Entomological Society, January 15.—Anniversary meeting. H. W. Bates, F.L.S., F.Z.S., president, in the chair.—The following gentlemen were elected Members of the Council for the ensuing year, viz.:—H. W. Bates, F.L.S., F.Z.S., W. L. Distant, Rev. A. E. Eaton, M.A., E. A. Fitch, Ferd. Grut, F.L.S.,

R. Meldola, F.C.S., Edw. Saunders, F.L.S., J. Jenner Weir, F.L.S., J. W. Dunning, M.A., F.L.S., Sir Jno. Lubbock, Bart., V.P.R.S., Saml. Stevens, J. Wood Mason, F.G.S. The following officers were elected:—President: Sir Jno. Lubbock, Bart., V.P.R.S. Treasurer: J. Jenner Weir. Librarian: F. Grut. Secretaries: R. Meldola and W. L. Distant. The retiring president delivered an address which was immediately ordered to be printed.

WELLINGTON, N. Z.

Philosophical Society, November 9, 1878.—Mr. Carruthers, vice-president, in the chair.—Further contributions to the ornithology of New Zealand, by Dr. Buller, C.M.G. This paper consisted partly of technical matters and partly of observations on the habits and life-economy of a number of the more common species of native birds. The author gave the results of his examination of the group of *Platycerci* in the British Museum, and showed that many of the so-called species had no real existence, the same bird having been described under different names by different naturalists. He gave his reasons for considering *Platycercus Rowleyi*, described by himself from specimens in the Canterbury Museum, a good and valid species. He disputed Mr. Sharp's generic substitution of *Harpa* for *Hieracidea* in the British Museum catalogue of Accipitres, and his reduction of *H. ferox* to the rank of a "sub-species," as being unintelligible; either the two forms of sparrow-hawk represent distinct species, as the author and others believe; or they are one and the same, as contended for by Captain Hutton in the controversy which took place some time ago. Referring to that discussion and to Captain Hutton's emphatic denial that the New Zealand kingfisher ever caught fish, he proceeded to give some further facts in support of his own view to the contrary. In treating of the kaka (*Nestor meridionalis*) he mentioned the singular circumstance that at a certain season of the year, when these birds are migrating across the Strait at its widest part, numbers of them, owing to their fat condition, succumb to fatigue, and are washed up in Golden Bay and on the spit beyond, the set of the current being in that direction. The paper contained many other interesting notes, and a full account of the capture and subsequent history of a specimen of the plundering gull (*Stercorarius antarcticus*) still living in the author's garden.

PARIS

Academy of Sciences, January 20.—M. Daubrée in the chair.—The following papers were read:—On the development of the perturbative function in the case where, the eccentricities being small, the mutual inclination of the orbits is considerable, by M. Tisserand.—Observations on the second reply of M. Pasteur.—Reply by M. Pasteur, &c.—On the special apparatus of nutrition of phanerogamous parasite species, by M. Chatin. He distinguishes in the sucker a *cone de renforcement* (the central, mostly solid part), and a *cone perforant*, or parenchymatous cone continuing the other, and capable, notwithstanding its delicacy of tissue, of progressing through the hardest woods. (There are variations from this in some cases.) The suckers of parasites show great analogies to ordinary roots of plants.—On the temporary magnetic properties developed by induction in different specimens of nickel and cobalt, compared with those of iron, by M. Becquerel. The ratio of the temporary magnetic effects developed at ordinary temperature, by increasing magnetic inductions, in any of the nickel bars and in a bar of soft iron of the same length, weight, and section, is a number variable with the magnetic intensity to which the metals are submitted. This ratio, for very small intensities, first decreases, passes a minimum, then increases to a maximum, and lastly decreases to an inferior limit. Carburetted and forged nickels show the variations most. Pure cast or porous bars of nickel give results very like those of soft iron. Cobalt behaves similarly to nickel. The variation of the ratio considered is due to unequal saturation of the two metals.—On linear differential equations of the third order, by M. Laguerre.—On the classification of colours, and on the means of reproducing coloured appearances by three special photographic negatives, by M. Cros. Under the word colours he distinguishes lights and pigments. To get immediately the elementary tints of lights and pigments, look through a prism at a white bar on a dark ground, and a black bar on a white ground; in the first case you see a spectrum orange, green, violet; in the latter a spectrum red, yellow, blue. In the one case the orange, green, and violet are elementary lights; in the other, the blue, red, and yellow, are lights combined two and two. This he demonstrates with an apparatus he calls a *chromometer* (which distinguishes the colours by numerical data); and he makes this act on the positions from three negatives obtained through green, violet, and orange screens, ultimately reproducing coloured appearances.—Researches on the effects of induction through telephonic circuits, by means of the microphone and the telephone, by Prof. Hughes. A battery of three Daniells, a microphone, an inducing spiral, and a clock, were put in one circuit; another helix (to receive induction) and a telephone in another circuit. The sounds were still heard in the induced circuit when the spirals (containing 100 m. wire) were 30 ctm. apart. Conducting plates interposed weakened the effect, and spirals with closed circuit better. Flat helices gave more intense reproduction than long ones. Putting a telephone bobbin, in circuit with a microphone, to one ear, and the bobbinless telephone to the other, one can hear thus; and the arrangement is a sort of electric analyser revealing what passes in organs traversed by currents. (Other experiments are given.)—New voltaic element with constant current, by M. Heraud. The exciting liquid is chlorhydrate of ammonia, the depolarising body protochloride of mercury, or calomel. The former, in presence of zinc, gives chloride of zinc with ammonia and hydrogen. The hydrogen reduces the protochloride, giving metallic mercury, chlorhydric acid, and consequently, chlorhydrate of ammonia. To prevent deposition of ammoniacal oxychloride of zinc on the zinc, the solution of sal ammoniac used is diluted one-tenth with liquid ammonia. The zinc is suspended by a coated copper-plate about the middle of the liquid. The positive electrode is carbon in a canvas bag. One element, after 248 days' use, retained 0·66 of its original intensity.—On tetric acid and its homologues, by M. Demarçay. —Researches on the development of eggs and of the ovary in mammalia, after birth, by M. Rouget.—Description of the strata forming the ground in the department of Meurthe-et-Moselle, by M. Braconnier.

ENTOMOLOGY IN AMERICA

First Annual Report of the United States' Entomological Commission. (Washington: Government Printing Office, 1878.)

WE have received the first annual report of the United States Entomological Commission for the year 1877, "relating to the Rocky Mountain locust, and the best means of preventing its injuries and of guarding against its invasions." The title-page bears the heading, "Department of the Interior, United States Geological Survey, F. V. Hayden, U.S. Geologist in charge;" but the report is by C. V. Riley, A. S. Packard, Jun., and Cyrus Thomas, and it simply passes, *pro formâ*, through Dr. Hayden's hands to the Secretary of the Interior. The amount of entomological work previously done by the Survey is well known.[1] Before speaking of this report it may be well to refer to the circumstances which have led to its being made. During the years 1873–76 the injury done by the Rocky Mountain locust in states west of the Mississippi was so great as to create a feeling that steps should be taken by Congress towards mitigating the evil. A conference of the governors of various western states and territories was held at Omaha (Nebraska) in October, 1876, the result of which was a memorial to Congress for an appropriation of 25,000 dols. and the creation of a commission of five experts to thoroughly investigate the subject. Congress acceded partially to this and an act was passed "appropriating 18,000 dols. to pay the expenses of three skilled entomologists to be attached to Dr. F. V. Hayden's United States Geological and Geographical Survey of the Territories," and the Secretary of the Interior appointed the gentlemen above-named. As soon as the commissioners were appointed they met at Washington and agreed upon the division of labour. Their scheme was laid before the Minister of the Interior on March 22, 1877, was approved, and was immediately put in operation. Within eleven months from that date the report was prepared and ready for presentation. When it is considered how vast was the district to be examined, how numerous were the records of the movements of locusts during the year that were collected, and what a range of subjects the report includes, it seems astonishing that so much should have been accomplished in the time. The locust-area was divided into three districts for convenience. Mr. C. V. Riley took the region east of the Rocky Mountains and south of the 40° N., the western half of Iowa, and conjointly with Mr. Packard, British America west of 94° W. Mr. A. S. Packard took Western Wyoming, Montana, Utah, Idaho, and the Pacific coast. Mr. Cyrus Thomas took the portion north of Mr. Riley's region, including the eastern half of Wyoming, Northern Colorado, the southern and eastern part of Dakota, Nebraska, the eastern half of Iowa and Minnesota. Circulars asking for information were distributed among farmers and others, and every assistance seems to have been offered by the officials of the different states, of the Post Office, and of the railways. On the subject of the movements of locusts as many as 2,500 observations were thus obtained for the year.

The report is divided into nineteen chapters, and the scope of the work will be most conveniently indicated by giving a brief *résumé* of each.

Chapter I. is devoted to classification and nomenclature. It is pointed out that the words "locust" and "grasshopper" are often very loosely used, including diverse insects belonging even to different orders. The limitation of the use of the word "locust" in the report is explained at p. 33. "This family [speaking of the *Acrididæ*] contains the true locusts, such as those of Oriental countries and the Rocky Mountain locust; also such so-called grasshoppers as the common red-legged species of the States and those found hopping on the ground in open waste fields, along roadsides, &c. Therefore, in speaking hereafter of these species, we shall use the term *locust*." So that, insects belonging to the family *Locustidæ*, are not here included under the general term locust. The family *Acrididæ* is divided into three sub-families, the *Proscopinæ*, the *Acridinæ*, and the *Tattiginæ*. The first is an exotic family, and dismissed from further consideration. The *Tattiginæ* are comparatively few, quite small, and seldom noticed by unscientific observers. It is, therefore, only with the *Acridinæ*, which includes all the migratory locusts, that the classification deals. This sub-family contains several subordinate groups; but of these the writers remark, "no arrangement we have seen can be considered satisfactory." Reasons are given for excluding from consideration all genera except *Acridium* and *Caloptenus*. *Acridium* is limited in its permanent region to districts south of the latitude of St. Louis. *Caloptenus* has a wider region, and causes far greater losses by its ravages. After discussing Stål's *Calliptenus* the writers describe *Caloptenus* as they understand it (p. 40). There are twenty-nine species recognised in the United States, but of these there are but three which, for the purposes of the work, have to be considered, "as they are the only ones generally distributed, which are so closely allied to each other as to render it difficult to distinguish them." These are the *C. spretus*, Thomas, *C. atlanis*, Riley, *C. femur-rubrum*, De G. Three plates are devoted to illustrating the details of their appearance in different stages of growth. Throughout the report they are spoken of by their popular names: *atlanis* is called the lesser locust; *femur-rubrum*, the common red-legged locust; and from among the many names for *spretus*, such as "the hopper," "the army grasshopper," "hateful grasshopper," "Rocky Mountain locust," &c., the commission have adopted the last. It is with this Rocky Mountain locust and its depredations the report is mainly concerned, though the damages by others are not excluded.

Chapter II. (pp. 53 to 114) gives a chronological history of the ravages in past years, beginning with the imperfect records of as far back as 1818, and this is summarised in a tabular form (p. 113). With regard to this history it is pointed out that while the later years are recorded as years of wide-spread emigrations, it must be remembered that our means of obtaining statistics have improved. "There are no facts tending to show that the locusts themselves have been any more numerous of late years than previous to, for example, the years 1866-1867."

[1] See especially 4th, 5th, 6th, and 9th reports.

Chapter III. gives "Statistics of Losses." The estimate of losses is made by taking a "locust year" for comparison with one when there was no locust visitation. Dr. Hayden in his letter to the Secretary of the Interior, which accompanied the Report, has thus summarised it. The great practical importance of an exhaustive study of this destructive insect throughout all the immense extent of the locust area, which lies between the 94th and 120th meridian, embracing nearly two million square miles, may be realised from the fact that on a careful estimate from all the data obtainable, the States and territories lying west of the Mississippi and east of the great plains, suffered by the depredations of the locusts an aggregate loss in destruction of crops alone during the years 1874-77 of 100,000,000 dols., to say nothing of the indirect loss by stoppage of business and various enterprises which must have been as much more, thus making the direct and indirect losses at not less than 200,000,000 dols.

Chapter IV. (pp. 123 to 131) is occupied with considering the agricultural bearing of the locust problem, points out what crops suffer most, and discusses what is likely to be the effect of agricultural operations in the future. Such precautions as accurately knowing the dates of invading swarms and planting early or late accordingly are referred to.

Chapters V., VI., VII. (pp. 131 to 212) are occupied respectively with an account of observations on the "permanent breeding grounds," the "geographical distribution," and the "migrations" of the Rocky Mountain locust. Previous to 1877 very little was known of the breeding grounds. The Commission has been able to map the area and also map the districts subject to invasion, while the directions taken by invading and returning "armies" are also given. It is found that, as a rule, flight is undertaken only during a part of the day and in fair, clear weather, so that the desire for food, cloudy or rainy weather, and adverse winds, may keep them from rising and taking wing. In all flights it seems the locusts rely much on the wind to carry them, usually turning their heads towards the wind and drifting backwards. When the wind is slight, however, they use their wings and turn their heads forwards. Their flights can be continued for several days over a distance of several hundred miles. The rate at which they travel is variously estimated at from three to fifteen or twenty miles an hour, determined by the velocity of the wind. There are facts which show that they can fly two miles and a half above the general surface of Kansas and Nebraska, and far out of sight of the keenest vision. This will explain their often sudden and mysterious appearance in areas without anything having been seen of them on the line along which they travelled. Sometimes two swarms have been seen moving in opposite directions, one in an upper and one in a lower current. With regard to the return migrations, the Commissioners remark that they are led to the conclusion "that by some law governing them there is a tendency in the resulting broods hatched in this visited area to return to the native habitats from which their progenitors came." The connection of meteorological phenomena with migration is entered into at considerable length, and many pages of meteorological data are given.

Chapter VIII. (pp. 212 to 257) is devoted to habits and natural history. Various observations are collected as to the quantities of eggs laid and the conditions of hatching. The laying season is from six to eight weeks; the average interval of laying is two weeks, and the average number of egg-masses is three. The idea that locusts are led by kings or queens is unfounded. The reasons assigned for migrations are (1) hunger, (2) the desire to find fresh breeding-grounds, (3) to escape natural enemies, (4) "instinctive impulse." Though by choice their food is the various cereals, they will eat almost anything at a push, even "dry leaves, paper, cotton and woollen fabrics. . . . They do not even refuse dead animals, and have been seen feeding on dead bats and birds." They often strip fruit trees of their leaves. "Forest and shade trees suffer in different degrees, and some, when young, are not unfrequently killed outright." At the end of this chapter reference is made to unnecessary alarm often caused by comparatively harmless locusts.

Chapter IX. is on "Anatomy and Embryology," and this, according to a statement in the introduction, is by Mr. Packard. Two diagrammatic drawings and several figures illustrate this part of the work; and Mr. C. S. Minot has contributed a few pages on the "fine anatomy," illustrated by plates.

Chapter X. is on "Metamorphoses." The Rocky Mountain locust requires about seven weeks from hatching to attain full growth, and during that time it passes through six stages. Plate 1 illustrates these. Though in European migratory species there is a difference of opinion as to whether there are four or five moults, the writers say they have "thousands of mounted and alcoholic specimens of all ages" showing the six stages. "The number of moults may vary according to the amount of nutrition and rapidity of development."

In Chapter XI. on "Invertebrate Enemies," the life-histories of many insects are given, and this part of the work occupies fifty pages.

Chapter XII., on "Vertebrate Enemies," gives a *résumé* of what is known of the usefulness of birds. Blackbirds, prairie-hens, and quail, are found to be good locust destroyers, while a special section is given to stating reasons why the English sparrow should not be introduced.

Chapter XIII., seventy pages in length, is largely of interest to mechanicians, and deals with "remedies and devices for destruction." Many of the remedies are agricultural operations to be performed at particular times, according to varying circumstances, but the special devices, both protective and for "catching or bagging" eggs and insects are numerous and are illustrated by woodcuts. The three succeeding Chapters are on "influence of prairie fires on locust increase," "influence of weather on the species," "Effects that generally follow severe locust injury." Then follows a Chapter (XVII.) on the uses to which locusts can be put, in which it is urged they form an abundant and nutritious article of food. "Why should the people of the West, when rendered destitute and foodless by these insects, not make the best of the circumstances, and guard against famine by utilising them as food?"

The different methods of cooking locusts are entered into, and an account is also given of the use of them by different nations. They were counted as clean animals

by the Jews [Levit. xi. 22], and Herodotus mentions a tribe of Ethiopians which fed on locusts, which came in swarms from the southern and unknown districts.

Mr. Riley speaks of good broth being made "by boiling the unfledged *Calopteni* for two hours in a proper quantity of water, and seasoned with nothing but pepper and salt; the broth is hardly to be distinguished from beef broth." Boiled, fried, or roasted the full-grown are said to make pleasant food, and ground and compressed they will keep a long time. The other uses suggested are as fish bait, as manure, and as a source of formic acid.

There are altogether twenty-seven appendices occupying 279 pages, the last appendix giving the bibliography of the subject.

GUTHRIE'S PHYSICS

Practical Physics, Molecular Physics, and Sound. By Frederick Guthrie, Ph.D., F.R.SS. L. and E., Professor of Physics in the Royal School of Mines, London. (London: Longmans, Green, and Co., 1878.) [London Science Class-Books, edited by G. Carey Foster, F.R.S., and Philip Magnus, B.Sc., B.A.]

"THE works comprised in this series," the editors tell us, "will all be composed with special reference to their use in school-teaching; *but*, at the same time, particular attention will be given to making the information contained in them trustworthy and accurate, and to presenting it in such a way that it may serve as a basis for more advanced study."

The little word *but*, which we have taken the liberty to emphasise, seems to hint at some opposition between accurate statements and school-teaching, which, if not a fundamental necessity, is at least a universally existing phenomenon in the present order of things. This series of class-books is by no means the first attempt to procure books for children from writers of scientific reputation; and Prof. Guthrie, the author of this little book on practical physics, has himself invented several experimental methods at once interesting, ingenious, and simple.

If a child has any latent capacity for the study of nature, a visit to a real man of science at work in his laboratory may be the turning-point of his life. He may not understand a word of what the man of science says to explain his operations, but he sees the operations themselves, and the pains and patience which are bestowed on them; and when they fail he sees how the man of science, instead of getting angry, searches for the cause of the failure among the conditions of the operation.

Accordingly, in this little book the parts which are most interesting, whether to young or old, are those in which Prof. Guthrie describes his own beautiful experiments on the size of drops and bubbles, or teaches us how to blow glass. But if he once opens his ears to the siren song of the scientific imagination, floating down from heights unprofaned by experiment, through the window of the laboratory, and makes three paces through the room from the blowpipe to the lecture-table, we know that the curse has come upon him, and that for him it will never more be possible to reconcile the claims of accuracy with those of school-teaching.

What but some vile enchantment could have induced an intelligent man to begin his discourse to the poor little children in this style:—

"§ 1. **Hardness. Form-elasticity.**—The pressure required to alter the relative positions of two contiguous parts of a body measures its hardness. As this pressure is greater with greater surface of contact, some unit of surface must be fixed upon. The term hardness is generally applied loosely to difficulty of fracture. The following remarks may show that our speech and ideas in regard to hardness are deficient in precision. Glass is said to be harder than lead, yet a glass cup is more easily broken than a leaden one—more easily broken, though not so easily bent. Hard bodies are always elastic; elastic bodies are not necessarily hard, nor are they necessarily brittle, nor are soft bodies necessarily plastic. Toughness seems to imply a resistance to change of form, which resistance increases more rapidly than the displacement; thus, while a band of vulcanised caoutchouc will be extended to a degree proportional to the weight hung at one end, a leathern strap will not be extended twice as far if the weight on it is doubled. Toughness is generally associated with texture, and stretching causes partial fibration in the line of pull."

Here is a teacher who, with all the stores of science to choose from, selects, as the first lesson to a child, the necessity of fixing on a unit of surface, which, however, he makes no attempt to do, but goes on to harangue him on the deficiency in precision of our ideas and language in regard to hardness.

The poor child is not responsible for this want of precision; his first duty is not to reform his language, or even to criticise it, but to learn it, and if there is any part of human knowledge about which our speech and ideas have become tolerably precise, let us teach him that first, so that he may have some hope that knowledge is attainable before we let him see, as we must at last, how confused our own notions are.

Whether a child receives any special instruction in science or not, it is of unspeakable advantage to him if he is not put in the way of explaining things by false hypotheses. The difficulty which we have in recognising the paradoxical character of some of the most celebrated paradoxes shows how much has been done by the teachers of the last two centuries in causing false principles to be forgotten. The paradoxes are no longer paradoxical, because the dogmas which made them so are now known only to the owls and the bats.

We have selected a few statements in this book which we do not remember to have seen before.

(When a wire is stretched by a weight) "it may be assumed that the volume of the metal remains approximately unchanged, so that if the elongation is such that the length m becomes n, the original diameter d becomes $d\sqrt{\frac{m}{n}}$" (p. 4).

"A drop of water on a board strewed with powdered resin is nearly spherical." "The spherical is the form in which the mean distance of all parts from the centre of mass is the least. It is the most compact form for a given mass. This shows that cohesion moulds the drop to the spherical form" (p. 8).

Does Prof. Guthrie take his science from Rogers' verses on a tear? We refer him to Shakespeare ("King John," Act iii. Sc. 4) as a better authority on Capillary Attraction:—

"Bind up those tresses: O, what love I note
In the fair multitude of those her hairs!
Where but by chance a silver drop hath fallen,
Even to that drop ten thousand wiry friends
Do glue themselves in sociable grief,
Like true, inseparable, faithful loves,
Sticking together in calamity."

"A more exact method" (of measuring the viscosity of gases) "is to place timed chronometers under bell-jars containing various gases, and also *in vacuo*" (p. 19).

"**Diffusion of Gases into Gases.**—The unhampered diffusion of gases into gases has been little studied" (p. 39).

"Experiments show that the more a gas is soluble in a liquid the more is the liquid volatile in the gas" (p. 45).

"Whether the feeling called pitch depends upon the appreciation of the rapidity of sequence or upon the duration of each distortion of the ear-drum is not easy to decide, for the one is the inverse of the other. Perhaps the fact that a single long wave produces a different impression from that produced by a single short wave, and that this difference reminds one of the differences between grave and shrill notes, may be regarded as evidence that duration of individual impression rather than rate of sequence is to be considered as the origin of pitch" (p. 77).

After reading these statements, we have come to regard it as a decided merit, that in this book on Molecular Physics we are not told anything about molecules. The value of the book would be increased by cutting out "Molecular Physics" from the title, together with everything in the book included under that heading, and devoting the whole book to Practical Physics as adapted to the capacities and opportunities of young students.

J. CLERK MAXWELL

OUR BOOK SHELF

The Journal of the Royal Agricultural Society of England. Part II. (London: John Murray, 1878.)

THIS is no ordinary number of an agricultural journal. It is, in fact, a memoir on the agriculture of England and Wales, prepared under the direction of the Royal Agricultural Society, and presented by them at the International Congress held in Paris during the present summer. The memoir is now issued as the second part of the Society's *Journal* for the current year.

The memoir is well worthy of the Society under whose auspices it has appeared. It forms a large volume of over six hundred pages, and contains ten treatises on different aspects of English agriculture, each the work of a distinct author.

The first article in the memoir is a "General View of British Agriculture," by Mr. Caird. He commences with statistics as to the home and foreign supply of food, then glances at the changes introduced in agriculture during recent years by the increased use of machinery, and of artificial foods and manures, and last, though not least, by free trade. After a very brief notice of the differences of climate and soil in England he comes to his main subject—"the landed property of England," its character, distribution, ownership, improvement, value, and relation to Government. The whole essay is written with remarkable ability, and is full of important information.

The second article is on "English Land-law," by F. Clifford and J. A. Foote. It treats of succession, tenancies, agreements, leases, and recent legislation on the subject of unexhausted improvements. The third article is by Capt. Craigie; it deals with "Taxation," and describes the various kinds of taxation, and their incidence on the various classes connected with agriculture. This is followed by a short paper on "Farm Capital," by E. P. Squarey.

The fifth article is by much the longest in the volume; it has for its scope the whole subject of "Practical Agriculture"; it is written by Mr. J. A. Clarke. The article commences with a sketch of the climate and geology of England, and then proceeds to give statistics as to the crops produced, the number of live-stock maintained, the imports of manure and food, and the prices of agricultural products. Then follow chapters on the management of cattle, sheep, and pigs, with a description of the various breeds of live-stock, including horses. Crops and manures are then discussed, the practice of good farms in different parts of England being indicated. The concluding chapter is on machinery, and cultivation by steam. The whole article covers nearly two hundred pages; it is full of practical information, condensed into a small compass.

The sixth article treats of "Dairy Farming," and is written by Mr. J. C. Morton; to this is added an appendix on "Pastoral Husbandry," by W. T. Carrington. Mr. Morton, after reviewing the statistics of the subject, proceeds to describe the various breeds of cattle employed for dairy purposes in England, illustrating this part of his paper by wood-cuts. He then treats of the rearing of calves, the sale of milk, and the production of cheese and butter, describing in each case the practice of different parts of the country.

The seventh article treats of "The Cultivation of Hops, Fruit, and Vegetables," and is the work of Mr. C. Whitehead. It is naturally divided into three chapters. The subjects are treated statistically and practically, and much important information is given.

The next paper is of special interest at the present time, it is on "The Agricultural Labourer," and is written by Mr. H. J. Little. The past history of the British labourer is sketched, and his condition in various parts of the country described. His earnings, expenses, domestic life, education, and provident societies are treated of, and evidently by one who can speak from personal knowledge of the subject.

The ninth paper is the only one of a strictly scientific character; it deals with the "Influence of Chemical Discoveries on the Progress of English Agriculture," and is the work of Dr. A. Voelcker. The scope of this paper is hardly so large as its title, as the author generally limits his remarks to investigations made since 1860, and has nothing to say of Continental discoveries. The paper is for the most part an account of the investigations made by Messrs. Lawes and Gilbert at Rothamsted, and of the work done by the author himself. The subjects treated of are—The Soil, Continuous Cropping, Manures, Improvement of Permanent Pastures, Feeding and Rearing of Stock, Industries attached to the Farm, Experimental Stations.

The volume fitly concludes with an article on the history and work of "The Royal Agricultural Society," written by Mr. J. M. Jenkins, the Secretary of the Society.

It will be seen that the memoir issued by the Royal Agricultural Society includes a wide range of subjects; it would be hard indeed to find another volume containing as much information on English agriculture in the same compass. The whole is published at the extremely low price of six shillings. We trust that it will find a large circulation

R. W.

A Visit to South America; with Notes and Observations on the Moral and Physical Features of the Country, and the Incidents of the Voyage. By Edwin Clark, C.E. (London: Dean and Son, 1878.)

MR. CLARK'S modest little narrative is considerably superior to the ordinary run of modern books of travel, which have become as plentiful, nearly, as novels, though we are glad to say, on the average, much more worth reading. Mr. Clark has certain scientific qualifications

which give him an advantage as an observer of phenomena both on sea and land, and the results of which are apparent in the volume before us. Mr. Clark's narrative relates to the years 1876-77, during which he resided for nearly two years in Buenos Ayres, Paraguay, and Uruguay. The two latter regions are yet sufficiently unknown to make any contribution from a competent observer who has visited them, welcome. The information, especially, which he gives us on Paraguay, is of much importance, and is a valuable addition to that obtained by Mr. Keith Johnston, in his visit two or three years ago. From a scientific point of view, perhaps the most valuable portion of Mr. Clarke's book are the numerous meteorological notes which he made both during his voyage out and his stay in South America. His knowledge of meteorology in its widest sense seems to us both extensive and accurate, and his observations on the instruments he used, on doldrums, tropical evaporation, and other such topics, are really interesting. But Mr. Clark knows something also of botany, as is evident from the frequent observations in this direction to be found throughout his volume. A whole chapter is devoted to the climate and meteorology of Buenos Ayres, important both from a scientific and practical point of view, as it is one of the great centres of emigration for South America. Many interesting sketches are given of the people and their mode of life in the various districts visited by Mr. Clark, and altogether his work is one of substantial value and real interest, and we trust it will find many readers.

Our Railways: Sketches Historical and Descriptive, with Practical Information as to Fares, &c., and a Chapter on Railway Reform. By Joseph Parsloe. (London: Kegan Paul and Co., 1878.)

MR. PARSLOE'S volume contains a large amount of very varied information on railways, their origin, their working; its object, he tells us, being to present a sketch of our railway system in its general details. The contents are so varied it would be difficult to give any idea of their nature without a lengthened notice. Mr. Parsloe goes back to the old days of stage-coaches, coming down to the origin of railways, then speaks of their construction, of navvies, working expenditure, signals, gauges, tickets, and a multitude of other topics all of much interest to the travelling public. The book is certainly both interesting and instructive.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

The Formation of Mountains and the Secular Cooling of the Earth

THE letters of Mr. Wallace and Mr. Fisher in NATURE, vol. xix. pp. 121, 172, 244, 267, raise the question as to whether or not it is possible that the interior of the earth can be cooling more rapidly than the exterior. The following is an attempt to answer the query as to where the loss of temperature per unit time is greatest.

Sir W. Thomson (see Thomson and Tait, "Nat. Phil.," App. D) considers the cooling of "a solid extending to infinity in all directions, on the supposition that at an initial epoch the temperature has had two different constant values on the two sides of a certain infinite plane." The solution given is—

$$v = v_0 + \frac{2V}{\sqrt{\pi}} \int_0^{\frac{x}{2\sqrt{kt}}} e^{-z^2} dz$$

where k denotes the conductivity of the solid, measured in terms of the thermal capacity of the unit of bulk;

V, half the difference of the two initial temperatures;

v_0, their arithmetical mean;

t, the time;

x, the distance of any point from the middle plane;

v, the temperature of the point x at time t.

The above solution shows that for all values of the time when $x = 0$, $v = v_0$, so that the temperature at the medial plane is constant.

Then differentiating v with regard to the time we have—

$$-\frac{dv}{dt} = \frac{V}{2\sqrt{\pi k}} \frac{x}{t^{\frac{3}{2}}} e^{\frac{-x^2}{4kt}}.$$

This expression is that required for the rate of cooling. We now wish to find where it is a maximum. Consider the function ze^{-z^2}; this is clearly a maximum when $\log z - z^2$ is a maximum, and by the ordinary rules this is a maximum when $\frac{1}{z} = 2z$, or when $z^2 = \frac{1}{2}$.

Hence it follows that $-\frac{dv}{dt}$ has its maximum value where $x^2 = 2kt$.

Now when the unit of length is a foot and of time a year, $k = 400$; hence $x = \sqrt{800t}$.

This formula shows that the seat of the maximum rate of cooling moves inwards as the time increases. If the time which has elapsed from the initial state be two hundred million years, or $t = 2 \times 10^8$, we have $x = 400{,}000$ feet, or a little less than eighty miles.

Sir W. Thomson shows, in his paper on the Secular Cooling of the Earth, that the solution of his ideal problem will be very nearly correct for the case of the earth, which is supposed to be a hot sphere cooling by radiation.

It follows, therefore, from the numerical result which is given above that the seat of the maximum rate of cooling must probably be something like 100 miles below the earth's surface.

It does not, of course, necessarily follow that the seat of the maximum rate of contraction of volume should be identical with that of the maximum rate of cooling; yet it seems probable that it would not be very far removed from it.

The Rev. O. Fisher very justly remarks that the more rapid contraction of the internal than the external strata would cause a wrinkling of the surface, although he does not admit that this can be the sole cause of geological distortion. The fact that the region of maximum rate of cooling is so near to the surface recalls the interesting series of experiments recently made by M. Favre (of which an account appeared in NATURE, vol. xix. p. 103), where all the phenomena of geological contortion were reproduced in a layer of clay placed on a stretched india-rubber membrane, which was afterwards allowed to contract. Does it not seem possible that Mr. Fisher may have under-estimated the contractibility of rock in cooling, and that this is the sole cause of geological contortion?

G. H. DARWIN

Storm Warnings

A NEW YORK telegram occasionally announces that a cyclonic storm will probably reach the coast of Europe in a few days.

Such warnings are often of great value; but many storms are deflected in the Atlantic, while others—without having touched the American coast—come unannounced with destructive violence.

A floating buoy might be constructed to serve the purpose of a marine observatory, when placed in the usual track of storms at a sufficient distance from exposed coasts to be useful for *warnings* for ships in and near harbours.

The chief meteorological "elements" which are of essential significance in such a case are the *height* and changes of the barometer, and the varying force and direction of the wind.

If an experimental buoy were fixed by means of a slightly elastic cable about eighty miles off Valencia Observatory, and connected therewith by submarine telegraph wire, a slight modification of the aneroid lodged therein would enable the observer on shore to determine to about a tenth of an inch the height and changes in its *readings*.

A wind-vane in connection with a magnetic bar, and presenting a disk to the air-current, might be made the means of registering approximately the force and direction of the wind.

If the plan were successful, other meteorological facts might be determined by passing a current through mechanical indicators attached to each piece of apparatus.

Changes of temperature, electric conditions, and rainfall, might ultimately be brought within the scope of such a plan of telegraphic registration, and three or four floating observatories might be arranged at considerable distances apart.

The problem thus presented to the mechanician is the construction of apparatus such that in passing an electric current successively through indicators specially devised for each instrument, *readings* could be made and announced to all concerned.

By such means all coasts liable to be visited by progressive storms might have timely warning of danger.

The cost of such work would be very small in comparison with the saving of life and property concerned.

The Board of Trade might be induced to offer a substantial reward for the most efficient models of such floating stations.

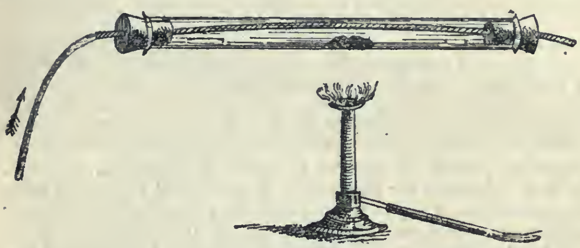
The essential feature of this proposal is, that new instruments should be devised as entirely different in form from those in use as the aneroid is from the old barometer.

There is no reason to doubt that whenever instruments are devised in which the passage of an electric current can be made through the indicators, it will be as easy to take readings of meteorological instruments at the distance of a thousand miles as when in sight, and with sufficient accuracy for the purposes in view. A HUTTON BURGESS

The Dissociation of Sal-Ammoniac—An Experiment

ALL chemists admit that when sal-ammoniac is volatilised the vapour consists, if not wholly, at least in great part, of hydrochloric acid and ammonia gases in the free state. But this fact, so far as I am aware, is very seldom, if ever, demonstrated experimentally by teachers. The following modification of Pébal's original experiment renders this proof very easy and available for lecture purposes:—

The stem of a long clay tobacco-pipe is passed loosely through a couple of perforated corks fitted into the two extremities of a piece of ordinary combustion tubing about a foot long. The tube contains in the middle a small lump of sal-ammoniac, and



near each end a strip of blue litmus paper. When the middle of the tube is heated the vapour of the sal-ammoniac surrounds a portion of the pipe-stem. If, now, a rapid stream of air or any other indifferent gas is sent through the pipe, it is found to be strongly charged with ammonia, so that it answers freely to all the usual tests. At the same time the litmus papers contained in the glass tube become red owing to the accumulation of hydrochloric acid in the residue. This experiment, of course, depends upon the diffusion of the lighter ammonia through the clay more rapidly than the hydrochloric acid also present.

WILLIAM A. TILDEN

The Sting of the Bee

IN "The Origin of Species," p. 242, fourth edition, Mr. Darwin says, "If we look at the sting of the bee as having originally existed in a remote progenitor as a boring and serrated instrument, like that in so many members of the same great order, and which has been modified, but not perfected, for its present purpose, with the poison, originally adapted for some purpose such as to produce galls, subsequently intensified, we can, perhaps, understand how it is that the use of the sting should so often cause the insect's own death; for if, on the whole, the power of stinging be useful to the social community, it will fulfil all the requirements of natural selection, though it may cause the death of some few members." In a lecture given as it happens, this day ten years ago, I ventured to suggest that bees may have derived advantage, not in spite of the fatal condition annexed to the use of their sting, but from that condition itself, since "it may have proved expedient for a creature to be armed with a weapon capable of inspiring terror, yet so contrived, that its possessor should of necessity be peaceful towards its neighbours." It is very certain that many gentle-hearted human beings wage remorseless war upon wasps, who would never think of harming a bee or a bluebottle. On the other hand there are many mischievous persons ready enough to trifle with the feelings of a bluebottle, who keep at a respectful distance from a bee, simply because they know it possesses a certain power of revenge. In this way the sting is not, as your correspondent "R.A." is inclined to think, worse than useless to the individual bee, but an effective protection, albeit rather as a shield than a sword. What is needed for its efficacy is not so much intelligence in the bee as in those who would otherwise attack the bee, and though to the individual bee a single experience ending in its own death could be of no avail, yet the other animal, the wounded survivor in the fray, would have its understanding wonderfully quickened to the advantage of all bees it might meet in the future.

If, then, the bee is actually better off with its imperfect sting than it would be with one theoretically more perfect, it may be scarcely worth while to inquire whether a more effective weapon could or could not be developed on the principles of natural selection. But assuming that under given circumstances bees would derive advantage if the sterile workers had stings which they could use without sacrificing their own lives, the very statement of the hypothesis implies that a swarm, in which such workers were developed, would have an improved chance of surviving in the struggle for existence. Enemies would be more certainly vanquished; food would be more securely stored or in greater abundance; and thus the particular strain which had produced the improved variety would be more likely than others less favoured to be transmitted to future generations. The power of producing the better-armed warriors would be transmitted just as the power of producing the worse-armed warriors is transmitted, neither in the one case nor the other through the warriors themselves. Fossil Forests and Silicified Trunks

IN NATURE, vol. xix. p. 257, the discovery of fossil forests in the spring region of the Yellowstone River is referred to. I have visited the United States National Park, and its geysers, and observed exactly how silicified trunks *in situ* originate. All geologists suppose that this must have happened beneath water, and consequently Mr. Holmes supposes a constant alternation of land and sea throughout a long period of subsidence. My observations show the contrary, as silicified trunks originate only in air, never in water. The siliceous hot water of the geyser basins runs off periodically in another direction; if it comes to a forest, then all green leaves, all bark, and most of the branches fall off, but the trunks remain erect. Now the siliceous water rises by capillary attraction in the stem, but only on the outside of the trunk does the siliceous acid become solid by drying in the air; from the outside the silicification of the wood cells enters very slowly to the inner part; the trunks are mostly struck down by the wind before the inner part gets petrified, and then the inner part shows no ligneous structure, is only filled with foreign matter, or sometimes with other minerals, or it is hollow, for the inner wood decays. The white silicified wood is for a long time soft, less coherent than common wood, and if such trunks fall down into water, as I observed, they never get hard. Those white forests without leaves, bark, and branches, are not rare around the geysers. With my observations accord all characteristics of silicified trunks, *i.e.* such carbonaceous trunks excepted, that consist only of outfilled matter, stone kernels, for all real silicified trunks are barkless, leafless, branchless, often with inside hollow or partly filled, and always found along with common opal derived also from geysers.

Is silicification of trunks with well-preserved structure possible beneath water? No proof has yet been given. And further, would it be possible for stems, which are lighter than water, to remain *in situ* and erect by sinking under water? Scarcely—only if previously silicified and heavy.

Besides, most statements of travellers on fossil forests relate to the tropics. I saw several on my voyage round the world, which consisted only of stems lying together.

Leipzig-Eutritzsch, January 28 OTTO KUNTZE

Force and Energy

YOUR correspondent, Mr. R. H. Smith (NATURE, vol. xix. p. 194), speaks of "the fine old crusty Newtonian maxim . . . 'force is any CAUSE which,' &c." Now Newton's words are these: "Definitio IV.—Vis impressa est ACTIO IN CORPUS EXERCITA, ad mutandum ejus statum vel quiescendi vel movendi uniformiter in directum." It will be observed that Newton avoids the use of the obnoxious word CAUSE. I suppose that some translator, or commentator on Newton, adopted the word "cause" (in the sense, probably, not of an efficient cause in itself, but, by a common figure of speech, of the *action* of some cause), and that other writers transcribed the expression.

Prof. Tait, who is specially referred to by your correspondent, seems to have overlooked the above definition when he wrote ("Recent Advances," ed. i. p. 16): "the definition of force in physical science is implicitly contained in Newton's 'First Law of Motion,' and may thus be given: *Force is any cause*," &c. Newton, in that law, speaks of "vires impressæ," but forbears there to define, or explain, "vis." Clearly he refers back to Def. IV., where, as I have shown, he defines "vis impressa" by "actio," not by "causa."

In justice to Prof. Tait, however, it should be pointed out that in the passage referred to he proceeds at once to discuss the difficulty introduced by the word "cause." He has, in fact, anticipated your correspondent in the idea of his definition of force. Prof. Tait writes thus: "In every case in which force is said to act, what is really observed . . . is either a transference or a tendency to transference of what is called energy from one portion of matter to another. Whenever such a transference takes place there is relative motion of the portions of matter concerned, and the so-called force in any direction is merely the rate of transference of energy per unit of length for displacement in that direction."

J. G. H.

Electrical Phenomena

MR. GREEN, in his letter to NATURE, vol. xix. p. 220, omits to state the route by which he ascended Monte Rosa "not long since." This is a detail of interest, because the rocks of that range are decidedly magnetic, and much hidden on the north side by ice.

In 1875, much out of sorts, I was training by short climbs, and at the Kiffleberg, well known for its effect upon the magnet, strolling up the Gorner Grat in company with three other members of the Alpine Club, and several more, the sky quickly clouded over, it thundered, and the axes of the Alpine men fizzed in most orthodox fashion, especially when held up, and the long sticks of the non-climbing men also crackled. A transitory but vivid lightning storm followed.

Several days later, during an attempt to ascend the Stockhorn, in company with a young Englishman, from the north side, by the Triftje glacier, the same fizzing, concurrently with snow, thunder, and lightning, took place, and half up the last glacier a violent storm came upon us, and throwing caution to the winds, we both skeltered down the snow and ice slopes with scant respect for crevasses seen and hidden. But for the mountaineer's axiom, "never part with your axe," we were much inclined to throw ours on one side. Soon we got below this critically charged stratum of air and earth, and the fizzing ceased. I shall never forget that terrible half-hour, only to be imagined by mountaineers or seafarers. Forbes, in his splendid work on glaciers, relates a similar incident somewhere in this same range.

Positive and negative changes of earth and air, conductibility of these and of axes, and involuntary experimenters suggest themselves. In our latter case all were more than *damp!*

I have not Forbes' book here, and can therefore quote no details. Thunderstorms are characteristic. In 1849 (I think it was) I made a new pass, called the Neue Weiss Thor. Overhead it was fine. A mile below was a thunderstorm, and during our descent on the Italian side, we came into it, and were refreshed first by snow, then by rain, till we reached Macuguaga.

Ear Affection

SEVERAL years ago, during an attack of whooping-cough, I found that one of my ears was so affected as to cause sounds heard by that ear to seem flatter than their true pitch as heard by the other ear. The difference was about a semitone, as I ascertained by holding a tuning-fork to each ear alternately; and when I whistled I heard two notes in discord. The affection lasted about ten days.

Will one of your readers kindly render me an explanation.

Adelaide, November, 1878 P.

RELATION OF METEORITES TO COMETS[1]

I HOLD in my hand a stone that weighs about two and a half pounds. Over a part of its surface is a thin black crust. A part of its corners are cracked off, showing a gray interior, and on looking closer you see small points of iron all through it. It is heavy—about one half heavier than granite, or marble, or sandstone. Altogether it is a very curious stone, totally unlike any of our rocks.

That stone was once a part of a comet.

Do you want my reasons for saying it? Or, does any one doubt it? I propose to-night to give those reasons; to set in order, as clearly and simply as I can, the facts and lines of thought that lead me to say as I did—*that stone was once a part of a comet.*

It came to us from Iowa. Three years ago, on February 12, about ten o'clock in the evening, the light of a bright meteor was seen by nearly everybody then in the open air in the south-east part of that state. I will quote from a vivid description of the meteor given by Mr. Irish, a civil engineer of Iowa City, who has collected and published many facts about it: "The observers," he says, "who stood near to the line of the meteor's flight, were quite overcome with fear, as it seemed to come down upon them with a rapid increase of size and brilliancy, many of them wishing for a place of safety, but not having the time to seek one. In this fright the animals took a part, horses shying, rearing, and plunging to get away, and dogs retreating and barking with signs of fear. The meteor gave out several marked flashes in its course, one more noticeable than the rest. . . . Thin clouds of smoke and vapour followed in the track of the meteor. . . . From one and a half to two minutes after the dazzling, terrifying, and swiftly moving mass of light had extinguished itself in five sharp flashes, five quickly recurring reports were heard. The volume of sound was so great that the reverberations seemed to shake the earth to its foundations; buildings quaked and rattled, and the furniture that they contained jarred about as if shaken by an earthquake; in fact, many believed that an earthquake was in progress. Quickly succeeding, and blended with the explosions, came hollow bellowings and rattling sounds, mingled with clang, and clash, and roar, that rolled away southward, as if a tornado of fearful power was retreating upon the meteor's path."

From accounts collected from eye-witnesses by Prof. Leonard and Mr. Irish, I conclude that the meteor when first seen was not less than sixty miles high over Northern Missouri; that it descended at an angle of about 25° with the horizon, in a right line, and disappeared at a height of five or ten miles. Those in the east, as at Kiokuk, saw it low in the west. From St. Louis it was seen in the north-west. In the western part of Iowa it was seen to pass north across the eastern sky. To persons in the north it passed straight down on the southern sky, while to those under the path named it passed nearly overhead, rising in the south and south-west and descending in the north north-east. The path thus determined is at least 120 miles long, and was passed over in a few seconds, probably not over ten. The country near the explosion was prairie or alluvial, where stones on the surface are rarities, and about 800 lbs. of stones like this one, nearly 200 in number, have been picked up in a region seven miles by four, a little east of the end of the

[1] A lecture delivered in the Mechanics' Course at the Sheffield Scientific School of Yale College, U.S., by Prof. H. A. Newton.

meteor's path. These are all supposed to come from the meteor. Some were picked up on the surface of the frozen ground. One was found on the top of a snow-bank, and about forty feet away were marks of a place where it had first struck the ground. Some were ploughed up in the spring. The two largest found, of 74 lbs. and 48 lbs., fell by the roadside, and a law-suit to settle whether they were the property of the finder as being wild game, or of the owner of the lands adjacent as being real estate, was decided in favour of the owner of the land.

No one saw this stone come from that meteor. But in many cases peculiar stones very like to this one have been seen to fall from meteors, and this is one of a group of about twenty stones belonging to Yale College which were gathered at the places and directly after the time of the fall. They are in the Peabody Museum in a case by themselves, and are about one-tenth of all that has been found.

But though we have no eye-witnesses to speak of its fall and finding, the stone as we look at it tells its own story. This rounded side is not waterworn. From your seats you cannot see them, but over these rounded hills and down these valleys run streaks showing that melted matter has flowed over them. On two of the smaller sides is collected a real lava deposit, giving in smallest miniature the twisted gnarled forms that some of you have possibly seen in the large lava beds at the foot of the cone of Vesuvius. This other surface had just begun to be melted, as though the fracture that formed it had been made late in the meteor's flight. This larger face is only smoked, and we might even doubt whether the stone had not been broken here after its fall. But the rounded edges of the thin black crust at the angles of the stone show clearly that, except perhaps at some of the corners, the stone was in its present shape when it struck the ground.

Now what caused that brilliant light, that terrific explosion which was heard for forty miles around, that rain of stones? The only explanation which we can admit is that a stone weighing not less than 800 lbs.—how much more we know not—perhaps two, perhaps fifty times as much, came into the air from without.

What ought to happen upon the passage of such a stone through the air? At the height of thirty to eighty miles, the region where the meteor-tracks are most frequently seen, the air is very rare, rarer than in the so-called vacuum of an air-pump. Yet the rapid velocity of the stone condenses the air in front of it. If we admit the truth of the kinetic theory of gases we must regard the molecules of air as in rapid motion, each molecule driven this way or that, coming in contact with and bounding back from other molecules. The average velocity of these dancing molecules of air at usual temperatures is a fraction of a mile per second. They therefore bound back from any heavy body that moves only a few hundred feet per second, only slightly checking its velocity. But the air is here met by a stone moving, say, fifty times as fast as the average molecule. The molecules are driven together beyond the possibility of getting away, until the temperature of the air is raised enormously. Probably the air is liquefied by the pressure, and then pushed aside by main force till the meteor has passed, when it is driven back again into the vacuum behind, giving us a flame shaped like that of a candle.

What effect has all this on the stone? *It* is solid and firm, as you see, and can withstand not a little pressure. It is not, therefore, heated within; but on the outside it is in contact with, or rather rubbed hard against, an intensely hot stratum of air. It is therefore melted off just as a piece of tallow would be melted if drawn across a white hot iron. There is no time for the heat to pass by conduction deep into the stone. The melted matter is wiped off by the air. A part clings to these hinder faces of the stone, but the far greater portion helps to make up the meteor's train. It is scattered in eddying currents in a long, narrow, whitish cloud, at first straight, then twisted. That cloud broadens and floats away in contorted forms, remaining visible sometimes a second, sometimes an hour even. The pressure and the heat generally keep cracking the stone, just as any stone is cracked by pressure or when thrown into a hot fire. Parts may survive this treatment and reach the ground. Those who have picked them up as they fell have generally said they were hot, as they must be on the outside. But some have been found, it is said, that were very cold. This, too, we may well believe, for they should retain in their interior the intense cold of space.

This stone in my hand shows the breaking up, one fracture being very clearly more recent than another, and if you were near me you might even see fractures that were begun but not ended when the stone reached the ground.

We often *see* this breaking up. On the wall is a picture of the principal explosion of the Iowa meteor, as given by one who saw it, representing, it may be, the cracking when this fragment was broken off from the main mass. There is also one of a meteor seen in Greece in 1863 by Dr. Schmidt. He was standing on the roof of his house in Athens when he caught sight of a magnificent fireball, moving so slowly that he was able to turn his telescope upon it. The head had two main parts, which were chased by a motley troop of followers, each drawing a bright line on the sky, all of which, at a distance of three or four degrees, melted into a reddish cloud of light. Often a meteor is to the naked eye made up of a group of smaller ones, the whole being like a flock of birds.

I have traced back the history of this stone to its entrance into the air on February 12, 1875, when it was part of a mass not less than two feet, and I suspect not more than ten feet each way. It looked larger, but men saw the flame around the stone, not the stone itself. By itself, and strictly taken, this history has gaps; but taken along with the history of like stones and meteors that are numerous in the records of science, the story is easily filled out as I have given it above. No scientific man today would question it.

The next step in my argument, though admitted by most, is not admitted by all of those whose opinions in this matter are entitled to special respect. I am not aware, however, that anybody has given any formal reasoning against it. I claim that between this stone-producing meteor of Iowa and the faintest shooting-star which you can see on a clear night in a telescope there is no essential difference as to astronomical character. In all their characteristic phenomena there is a regular gradation in the meteors from one end of the line to the other. They differ in bigness, but in their astronomical relations we cannot divide them into groups. They are all similar members of the solar system.

To prove this we must of necessity rehearse the points in which the large and small meteors are alike and unlike.

First. They are all solid bodies. The Iowa meteor sent down these stones, and we know that they are solid. This other stone which I show you is one of about 4,000 which fell from a meteor in Poland in 1868, and this you can see is solid. In the Peabody Museum is a goodly collection of such stones from other meteors.

A year ago last December, early on the evening of the 21st, a meteor entered the air sixty miles or more in height over the north-west corner of the Indian Territory, or it may be still farther west. It crossed at a height of between sixty and thirty miles the states of Kansas, Missouri, Illinois, Indiana, and Ohio and passed on over Lake Erie and the state of New York. No sound was heard, so far as I know, in the state of Kansas; but in Missouri, and still more, in Illinois, the explosions were

fearful, and multitudes of fragments were seen to fly off by every one who saw the meteor. In Indiana it was thought that the explosions were heard at Bloomington 150 miles from the nearest point of the path. In New York State the sky was wholly overcast, so that of course nothing was seen. But at many places the people thought there was an earthquake. Was this a solid body? As if to remove this from the class of detonating into that of stone-producing meteors, one single small fragment three-fourths of a pound in weight, was heard to fall and was picked up the next morning on the snow in Indiana. A piece of this is in the Peabody Museum.

In 1860 a meteor went north-west across Georgia and Tennessee and exploded, disappearing nearly over the southern boundary of Kentucky at a height of about twenty-eight miles. There was the same terrific explosion heard, the same scattering of fragments seen. The meteor was seen over all the region from Pittsburgh to New Orleans, and from Savannah to St. Louis. But from this meteor no stone was found, but you cannot doubt for all that that it was a solid body.

So, a few weeks ago a meteor fell in broad daylight in Southern Virginia, the sound of which, over a limited region, seemed like an earthquake. It, too, must have been solid.

In July, 1860, some of you, I presume, saw a meteor cross from the west to the east. It came from over Northern Michigan, and was seen until it had passed at least 200 miles east of us, passing between us and New York City at a height of a little more than forty miles. One pear-shaped ball chased a second and a third across the sky. People listened for the sound to come, and one or two thought that they heard it but would not affirm that it was sound from the meteor. I cannot doubt that that too was solid. It was seen to break in two, and the parts passed on one after the other for hundreds of miles. To be sure no stone was found from it, and perhaps no sound heard, yet that it was solid seems to me almost as sure as if I had a piece of it in my hands.

Again, going one step farther, how can we avoid calling all the meteors solid which are seen to break into pieces, and all those which glance, describing a curved course, or a course having an angle? The number of such cases is large, and often they are very faint shooting-stars. But it is doubtful whether a small gaseous mass could exist permanently as a separate body in the solar system. Its repulsion would keep the parts so far asunder that the sun's unequal attraction would scatter the substance beyond all its own power of recovery. A liquid would probably freeze and become solid. In any case neither a gas nor a liquid could for an instant sustain the resisting pressure which a meteor is subjected to in the air, much less could it travel against it ten, or forty, or a hundred miles. In short, every shooting-star *must be* a solid body.

Second. The large meteors and the small ones are seen at about the same height from the earth's surface. The larger meteors may become visible a little higher than shooting-stars, though that is doubtful; they come down in general a little lower, some of them even come to the ground, but that is due rather to the size of the body. The air is a shield to protect us from an otherwise intolerable bombarding. Some of the larger balls come through that shield, or, at least, are not all melted before their final explosion, when the fragments, their original velocity all gone, fall quietly to the ground. The small ones burn up altogether, or are scattered into dust.

In the *third* place, the velocities of the large and small meteors agree. These velocities are never very exactly measured directly; but we are sure that in general they are more than two and less than forty miles per second. This is true both for small and for large meteors. The average velocities for each class are not widely different.

We sometimes need a name for the small body that will, if it should come into the air, make a shooting-star or larger fireball. We call such a body a meteoroid. Now, velocities of from ten to forty miles a second imply that the meteoroids are bodies that move about the sun as centre, or else move through space. These velocities, as well as other facts, are utterly inconsistent with a permanent motion of the meteoroids about the earth, or with a terrestrial origin, or with a lunar origin.

Fourth. The motions of the large and small meteors, as we see them cross the sky, have no special relations to the ecliptic. If either the one or the other kind had special relations to the planets in their origin or in their motions we should have reason to expect them, if not always, at least in general, to move across the sky *away from* the ecliptic. But the fact is otherwise. We see both small and large meteors move *towards* the ecliptic as often as *from* it. Neither class seem, therefore, to have any relation to the planets.

Again, in general character the two classes are alike. They have like varieties of colour, they have similar luminous trains behind them; in short, we cannot draw any line dividing the stone-producing meteor from the shooting star, at least in their astronomical relations. We cannot say that the Iowa meteor is different from the Georgia meteor of 1860, on the ground that stones were found in one case and not in the other; or that the meteor of December, 1876, was different from that of July, 1860, on the ground that one had a series of terrific explosions and the other was only seen to break into parts; or that the meteor that is seen to break into parts differs from one evidently solid, that burns up without any appearance of explosion. They all are astronomically alike. They differ in bigness; but this has nothing to do with their motion about the sun or in space.

When, therefore, we learn something about the origin and motions of the smaller meteoroids, we can infer like facts about the larger ones. I propose, then, to show that shooting stars were once pieces of comets.

(*To be continued.*)

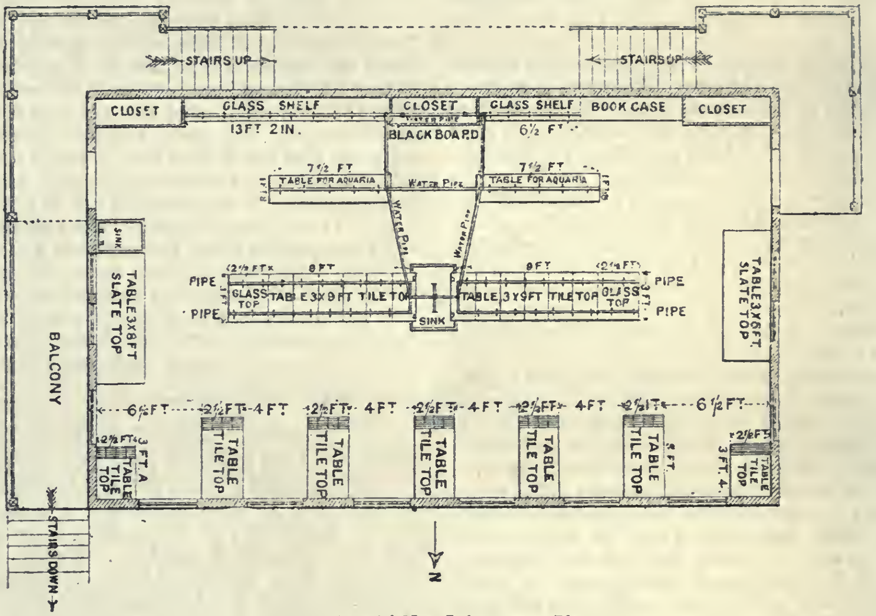
A ZOOLOGICAL LABORATORY

PROF. ALEXANDER AGASSIZ, in his Report to the President and Fellows of the Harvard College Museum for 1877 and 1878, to September 1, gives an account of his new laboratory at Newport, a plan of which he has been good enough to send us. This is the first report which has been presented since the Museum has come under the care of the President and Fellows of Harvard College, and the description given by Prof. Agassiz sufficiently indicates that the Museum is a model of its kind. During the past eighteen months increased funds have been placed at the disposal of the Museum, and excellent use has been made of them. Not only is the Museum arranged so as to make it of the greatest service to students, but in such a way that the portion thrown open to the public must have an excellent educational effect. Everything has been done to make visitors clearly understand what they see, and evidently this attention is appreciated and is answering its purpose.

The new laboratory, erected by Prof. Agassiz at his own cost, and which is a model of what such a place should be, is described by Prof. Agassiz as follows:—

The new laboratory erected by me at Newport is twenty-five feet by forty-five. The six windows for work are on the north side, and extend from the ceiling to within eighteen inches of the floor. In the spaces between the windows and the corners of the building are eight work-tables, three feet by five, covered with white tiles, one foot of the outer edge being covered, however, with black tiles for greater facility in detecting minute animals on a black background. Between the windows, movable brackets with glass shelves are placed; while similar

brackets extend across the windows and between the tables, thus providing a shelf at any desired height. The tables for microscope work are three-legged stands of varying height, adapted to the different kinds of microscopes in use. The whole of the northern side of the floor upon which the work-tables and microscope stands are placed is supported upon brick piers and arches independent of the main brick walls of the building, which form at the same time the basement of the building. The rest of the floor is supported entirely upon the inside walls and upon columns with stretchers extending under the crown of the arches reaching to the northern wall. This gives to the microscopic work the great advantage of complete isolation from all disturbance caused by walking over the floor. This will be duly appreciated by those who have worked in a building with a wooden floor, where every step caused a cessation of work, and was sure to disturb any object just at the most interesting moment. The floor is cemented and covered by a heavy oil-cloth. The centre of the large room is occupied by a sink, on each side of which extend two long tables, three feet by twelve. These are covered with different coloured tiles, imitating mud, sand, gravel, sea-weed, black and white tiles, as well as red, yellow, blue, green, violet, to get all possible variety of background. A space at each end is covered by a glass plate, allowing the light to come from underneath, thus enabling the observer to examine larger specimens from the under-side, without disturbing them when fully expanded. Two shorter and narrower tables, eighteen inches by seven feet, are placed halfway between these central tables and the southern face of the building. These tables are intended for larger aquaria or dishes, and are covered with common marble slabs. There is a blank wall on the south side, the whole of which is occupied by closets and shelves for storing glass jars, reagents, bottles, dishes, and so forth. A space is devoted to books. The open shelves for jars and dishes are of heavy rolled glass, supported upon iron brackets. The basement is used for the storage of alcoholic specimens, dredges, trawls, and other similar appliances. In the attic there is a large tank for salt water and another for fresh: the rest of the attic space will be eventually devoted to photographic rooms and room for an artist. The laboratory is supplied with salt water by a small steam-pump



Prof. Agassiz' New Laboratory: Plan.

driven by a vertical boiler of five-horse power: this is kept going the whole time day and night, the overflow of the tank being carried off by a large pipe. The water is taken some distance from the laboratory, and drawn up at a horizontal distance of sixty feet from the shore in a depth of some four fathoms, the end of the suction pipe standing up vertically from the ground a height of five feet, and terminating in an elbow to prevent its becoming choked. The water is led through iron pipes coated inside with enamel. From the tank the salt water is distributed in pipes extending in a double row over the central tables, over the long narrow tables for aquaria, and along the whole length of the glass shelves on the south wall. Large faucets to draw off salt water are placed at each sink, and by a proper arrangement of valves it is possible to lead fresh water to a part of the pipes, in case it is needed. The pipes leading over the tables and shelves are provided with globe valves and nozzles, to which rubber pipe can be attached and the water led to a vessel below: there are fifty such taps, each of which can supply water or air to at least three or four jars. The overflow runs into gutters laid alongside the tables, leading into the main drain-pipe. To aerate the salt water I use an injector invented by Prof. Richards, of the Institute of Technology. This can be used to supply aerated water directly to the jar by providing it with a siphon overflow, or the aerated water can be kept in a receiver, from which air alone is then led to the jar. This latter course is the only practical one for delicate specimens and for the bulk of the work of raising embryos. The east and west sides have large windows and doors provided with blinds; they always remain open with the blinds closed to keep out sunlight, and serve to ventilate the laboratory thoroughly. Large tables for dissection, covered with slate and adjoining a sink provided with fresh and salt water, are placed across the windows of these sides. Ever since the closing of the school at Penikese it has been my hope to replace, at least in a somewhat different direction, the work which might have been carried on there. It was impossible for me to establish a school on so large a scale, but I hope by giving facilities each year to a few advanced students from the Museum and teachers in our public schools, to prepare, little by little, a small number of teachers who

will have had opportunities for pursuing their studies hitherto unattainable. The material to be obtained at Newport is abundant. The dredging is fair and not difficult, as the depth in the immediate neighbourhood does not exceed twenty to thirty fathoms. The pelagic fauna, however, is the most abundant. During the course of each summer, by the use of the dip-net, representatives of all the more interesting marine forms are sure to be found. With my small steam launch a large space can always be traversed any evening and advantage taken of the condition of the wind and tide, the launch being amply large for easy dredging in the moderate depths of the entrance of Narragansett Bay. The laboratory is placed on a point at the entrance of Newport Harbour, past which sweeps the body of water brought by each tide into Narragansett Bay and carrying with it everything which the prevailing southwesterly winds drive before it. Newport Island and the neighbouring shores form the only rocky district in the long stretch of sandy beaches extending southward from Cape Cod—an oasis, as it were, for the abundant development of marine life along its shores.

BIOLOGICAL NOTES

Caspian Sea Algæ.—Herr A. Grunow has quite recently published a detailed catalogue of a collection of algæ, made by himself at Baku and Krasnowodsk, on the Caspian, and also of some collections made by his friend Czermak in Baku Bay and by Thieme in Krasnowodsk Gulf, in addition some specimens preserved in spirits were given him by Dr. Schneider. Excluding the diatoms only eleven species are alluded to, and but two (Cladophora) appear as new. Of the diatoms there is a goodly list. Many of the species of these diatoms appear to occur everywhere. Go where one will, they are to be found, and what a marvellous geographical distribution!—Baku on the Caspian, St. Paul's Island in the Southern Ocean, and then the Frith of Clyde, or the mouth of the Thames. Two beautiful plates representing the new species of diatoms accompany the paper. Many of the species are marine forms.

Natural History of the Caucasus.—A very important contribution to the natural history of this region has been made by Dr. Oscar Schneider based on collections made by himself during a summer spent there in 1875. The series of memoirs before us, edited by Dr. O. Schneider, has been reprinted from the *Journal* of the "Isis" Society of Dresden, and consists of an account of the mollusca, by the editor; the arachnoids, by Dr. L. Koch, many new species are figured; the hemiptera, by Dr. G. v. Horvath; the algæ, by Dr. A. Grunow, a memoir we have already noticed; the minerals, by Dr. A. Frenzel; the rocks, by Dr. Moehl; the fossils, by Dr. Geinitz. These reprints form a small volume of 160 pages with five plates.

On Sprouting in Isoetes.—K. Goebel records in some detail and with illustrative figures the fact that he has found buds developed from the base of the leaves below the lingule in *Isoetes lacustris*. The specimens were collected in Longemer Lake in the Vosges, and the discovery was made during an investigation into the embryology of both *I. lacustris* and *I. echinospora*. The examples in question showed neither macro- nor microsporangia, but in their place were found on the leaves little Isoetes plants. The first appearance of the buds was under the lingule in the furrow of the still young leaves. A pretty compact swelling made its appearance on the under half of the glossopodium. This swelling was the commencement of a conical protrusion of the cellular tissue, in which a side cell did not take any leading part; later on this swelling appeared to be more rounded off; the stages between this and that in which one to two leaves were found, was not specially observed. A section through the young bud shows that the median plane of the young leaves is precisely that of the mother leaves, and they lie so tightly packed together that the lingule of the first new leaf is parallel with the surface of the mother leaf. The root formation of these buds appears to be quite normal. Some of the leaves only gave rise to these buds. The author thinks this is an instance of De Bary's apogamy. Interesting and novel as these observations of Goebel are, they yet leave a good deal to be desired (*Bot. Zeitung*, i., 1879).

The Brittle Stars of the *Challenger*.—In order that persons who are interested in echinoderms may get early information, and to secure a just priority of discovery to the *Challenger* expedition, Mr. Th. Lyman has just published, as No. 7, vol. v. of the *Bulletin* of the Museum of Comparative Zoology at Harvard College, Cambridge, Mass., a Part I. of a catalogue of the new species found, which contains brief diagnoses, with figures, of the more essential parts of no less than thirteen new genera, and ninety-six new species of Ophiuroids. Part II. will contain some remaining species of the family Ophiuridæ, and those of Astrophytidæ. All matter beyond the mere necessary description is reserved for the volume to be devoted to this group, and which is to be brought out by the British government under the general superintendence of Prof. Sir Wyville Thomson.

Spines of Echini.—The last published part of the *Transactions* of the Royal Irish Academy (vol. xxvi., Science, part 17) contains a memoir by H. W. Mackintosh on the structure of the spines in the sub-order of the Desmosticha (Hæckel). In indicating four series into which, judging from the structure of the spines, this suborder may be divided, the author expresses his opinion that the characters derived from the spines are just as useful as any other characters drawn from the comparison of individual parts. He finds it just as easy and as certain to recognise a Diadema, an Echinus, or an Arbacia by the structure of its spines as by the arrangement of its pores, or the disposition of its anal or genital plates. The memoir is accompanied by three plates containing twenty-seven figures, all drawn by the author with the assistance of a Wollaston's camera lucida. The figures represent transverse sections of primary inter-ambulacral spines of some twenty-six species, and have been drawn on stone by Tuffen West with great care and accuracy.

The Food of Fishes.—Mr. S. A. Forbes publishes a very interesting paper on the food of fishes in the *Bulletin*, No. 2, of the Illinois State Laboratory. The importance of the subject to the scientific student and to the practical fish-breeder cannot be doubted. Some valuable fishes are found dependent on food too liable to injury or destruction by man or nature to make it worth while to cultivate them, while others, equally valuable, may subsist on food absolutely indestructible. The contents of the stomachs of some fifty-four species of Illinois fish were carefully examined, and the details of the food found are in each case given. In some instances the enormous quantity of food devoured, especially in insect-feeders, is noteworthy, and much of the food consisted of land-insects which had fallen into the water, thus bringing fish and land birds into competition for food. Some of the species were herbivorous, others carnivorous, and several, such as the cat-fishes, were quite omnivorous; the dog-fish (*Amia calva*) was herbivorous, but only one small specimen was examined. The shovel-fish (*Polyodon folium*), supposed by the fishermen to live on the slime and mud of the river-bottom, was found to feed to an enormous extent on Entomostraca, and fully one-fourth of the entire food was made up of vegetable matter, algæ being largely eaten, and there was very little mud found mixed with the food. The interlacing of the gill-rakers of this species, which are very numerous and fine, and arranged in a double row on each gill arch, doubtless form a strainer which allows the passage of the fine silt of the river out with the water, but arrests everything as large as a cyclops.

THE ELECTRICITY OF THE TORPEDO[1]

II.

4. *CURRENTS induced by a torpedo discharge are all produced at the beginning of each wave. There are currents induced on the completion of a circuit,* i.e., *the inverse of the inducting currents, as is shown by the electrometer.*

Fig. 7 will show the arrangement of the experiment to prove that the torpedo's discharge in the inductive coil

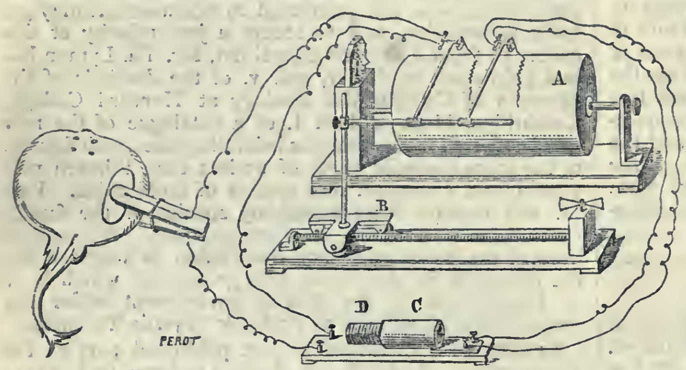


FIG. 7.

(D) produces, in the secondary coil (C) currents of sufficient energy to cause movement in the second signal placed in the circuit of the inducted coil. It must be remarked, however, that the electric apparatus which furnishes the indications of the passage of the discharge is not, as shown in the diagram, that which produces the inducted currents. Currents of sufficient intensity would not have been obtained to act upon the electro-magnetic signal, if we had opposed to the passage of the discharge a resistance so considerable as that of the coils of the electro-magnet. The difficulty has been averted by using the opposing apparatus for signalling; and this we are authorised in doing, since the discharges are absolutely symmetrical to the right and left when the nervous centres are excited by the magnet.

That exception made, let us examine the results of the experiment. The traces were placed one over another; one (as 1 in Fig. 8) indicating the successive waves of the discharge, and the other (as 2 in Fig. 8) the currents inducted by the waves. This figure already shows an important fact: that the number of inducted currents is equal to that of the inducting waves; and that each inducted current is produced at the commencement of each wave, just as in a galvanic current an inducted current is produced at each completion. But here we only find currents inducted by the completion or, more exactly, at the commencement of the waves; none are produced during the decreasing phase of each wave, or at least if they are produced they do not act upon the electro-magnetic signal.

From the preceding it should be inferred that the currents, inducted by the torpedo-waves and produced at the commencement of these waves, must in that be analogous to the inducted currents resulting from the completion of a galvanic circuit.

No instrument could be better than Lippmann's electrometer for giving us information as to the direction of the currents inducted by the torpedo waves. Its instantaneous action enables it to indicate, by a sudden displacement in a determinate direction, the direction of each inducted current.

If a weak current derived from the main discharge is passed through the electrometer, we see the column after moving to one side of the reticule always oscillate to the same side, thus showing that the successive waves are

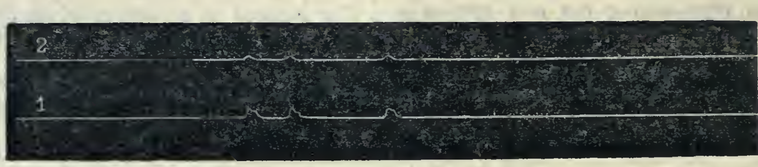

FIG. 8.

joined one to another, so that there is never an absolute break in the current. In Fig. 9 the arrows show the oscillation of the column towards the right side.

If the induced currents are directed through an electrometer by the discharge which causes the column of the instrument to deviate to the right, the direction of oscillation is immediately reversed (Fig. 10).

The comparison of those two diagrams showing that the inducted current has a contrary effect to that of the inducting current, brings together the inducted currents of the torpedo and those obtained by completing a galvanic circuit. To be more exact, since the circuit which comprises the torpedo remains always complete, we shall say that the inducted currents are produced at the beginning of each electric wave of the animal. Thus the torpedo calls forth in each of its electric waves an initial inducted current and does not give a terminal inducted current. This conclusion goes to support what we learned from the wave-writing of the electro-dynamograph, viz., that the initial phase of each wave has a suddenly increasing intensity, whereas the terminal phase presents a gradual decrease.

5. *The discharge of the torpedo is analogous to muscular tetanus; every electric wave in the discharge corresponds to a muscular shock.*

In what precedes we have endeavoured to give an idea of the torpedo discharge from the nature of the successive acts which constitute it, insisting only upon points relating to experimental science and to the direct results of M. Marey's investigations.

We are now enabled to meet the question on higher

FIG. 9.

FIG. 10.

ground and consider the electric function from a philosophical point of view, by classing it with the muscular function.

Let us first compare the elementary action of electric discharge to the elementary action of muscular contraction, *i.e.*, the electric wave to the muscular shock.

[1] Continued from p. 297.

The simple excitation of the remote end of an electric nerve produces a single wave, as the simple excitation of a motor nerve produces a single shock. In both cases, at the moment of the nerve-excitation produced in the neighbourhood of the electric apparatus or of the muscular apparatus, the amount of delay is sensibly the same, about seven-hundredths of a second. The electric wave, like the muscular shock, has a phase of increase and a phase of decrease; the former, as we have seen, is abrupt or sudden from one part to another; the decreasing phase is much more gentle. The same agents modify the wave and shock in the same manner; heat renders both these actions more speedy and more energetic up to a certain point at which both electric reaction and muscular reaction disappear; cold acts equally upon movement and electric action, rendering both more slow, more feeble, more extended, and at last extinguishes them when the temperature is lowered to about zero C.

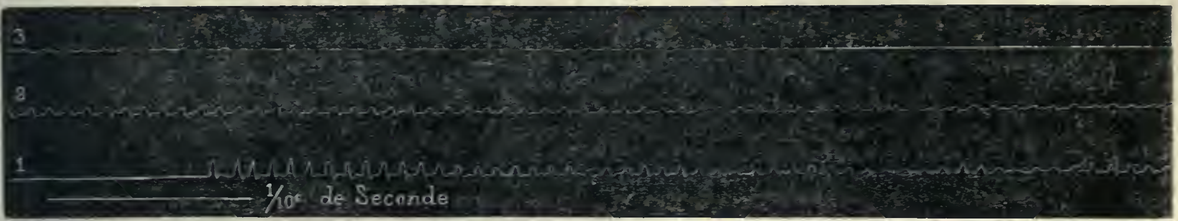

FIG. 11.

In the complex muscular act which is called contraction, as in the electric act which constitutes the discharge, the elementary phenomena which we have just been comparing, the waves and the shocks are added on one to another in the same manner; they succeed each other with a rapidity so great that each has not time to complete all the phases before its successor is produced. The floor and the shock are interrupted during their decreasing period by a new wave or shock coming to join on its effect to what remained of the preceding act. But, as there are imperfect muscular contractions, cases of tetanus where the shocks are not completely fused together, not being rapid enough in their succession, so in the same way certain electric discharges present a remarkable discontinuity, such that the elements of the perfect act are seen arranging themselves, the waves following each other with less rapidity, the shocks separated from each other by a larger interval of time.

FIG. 12.

Let us now compare the effects of fatigue upon muscular contraction and upon the discharge, as we have compared them upon the muscular shock and upon the electric wave; we shall see the two acts modified in the same direction. It is even possible to see the torpedo-wave and discharge gradually becoming extinguished, just as muscular shocks disappear under the influence of exhaustion. This gradual extinction of the electric waves is very evident in Fig. 11, obtained by means of the electro-dynamograph.

Poisons which act directly or indirectly upon the muscular function modify in the same manner the electric function. Thus strychnine, for example, which in a very special manner exaggerates the excito-motor power and that which might be termed the excito-electric power of nervous centres; a complex reaction, a muscular tetanus on one side and a real electric tetanus on the other, is produced in reply to a simple excitation, the mere touch of the skin, or a slight noise.

Fig. 12 shows a type of muscular strychnine contraction in the frog. Here we observe a diminution of intensity produced in the middle of the muscular tetanus between two maxima, one at the beginning and the other at the close.

In agreement with this characteristic phenomenon, the cause of which is unknown, we observe in torpedo poisoning by strychnine a weakening or interruption towards the middle of the discharge. Fig. 13 shows on line A a type of this species of interruption which must be compared with that which we have just seen on the tracing of muscular tetanus.

We might still further extend the comparison of those two functions, the electric and the muscular, by studying the action of other fishes, such as the *Gymnotus*, the electric ray, &c.; and by showing that the results are identical when heat and cold act upon muscular contraction and upon the discharge of the torpedo. The preceding paragraphs are sufficient to justify the functional assimilation which, let us hasten to say, is in accordance with the anatomical assimilation.

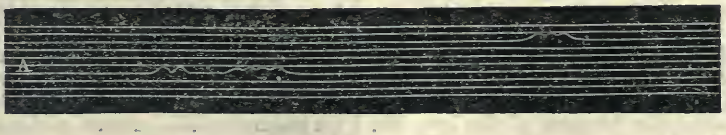

FIG. 13.

We shall only add that these identifications are of higher interest than curiosity; the more our knowledge of muscular phenomena and electric phenomena becomes perfected, the more enlightened is our knowledge of the motor nerves. Does the fact that a voluntary discharge of the torpedo is a complex act not prove that the voluntary contraction of the muscles is also a complex act? Very certainly, the comparison of the voluntary contraction of the muscles with the tetanic phenomena produced by electricity or by strychnine, the existence of a muscular sound during the contraction, the quivering or

dissociation of the shocks which are produced under the influence of cold, all these seem arguments in favour of the theory which considers muscular contraction as the result of very frequent shocks; but the complexity of the voluntary discharge of the torpedo, the manner in which the waves composing it succeed each other and are added together, forms a very important confirmation of the numerous presumptions already made.

FRANCOIS FRANCK

SCIENCE IN LANCASHIRE AND CHESHIRE

AT Liverpool the annual associated *soirée* of the Literary, Scientific, and Art Societies, eighteen in number, of which twelve are scientific, held at St. George's Hall on the 31st, was a marked success, and will tend much not only to foster scientific tastes in this district, but inculcate an element of scientific co-operation, in the various institutions of the town, that will be of the highest practical value. The fourteenth Winter Course of Free Lectures for the People, given at the Free Library and Museum, by order of the Corporation, commenced on the 6th of last month. Amongst the forty-one lectures announced, thirteen are on scientific subjects, given by the Rev. W. H. Dallinger, Mr. Moore (Curator), Mr. De Rance, Rev. H. H. Higgins, and others. The Liverpool Geological Society is also doing good work; a valuable paper on the carboniferous limestone of Denbighshire was lately read by Mr. Morton, and a short but important mineralogical paper was given by the President, Mr. Semmons. Geological knowledge has been increased by a boring at Bootle, sunk to determine the water-bearing properties of the new red sandstone at great depths, by Messrs. Mather and Platt, for the Liverpool Corporation, who were urged to this course by Alderman Bennett. The boring has reached a depth of 1,300 feet, is 25 inches in diameter, is filled with water up to a height of 50 feet from the surface, and, according to Messrs. De Rance and Morton, has proved the pebble beds of the Bunter to reach the extraordinary thickness of 1,200 feet, and the existence of the lower mottled sandstone beneath. The pumps not yet being fixed, it is impossible to judge how far the well will add to the supply of 6,000,000 gallons a day at present pumped from the corporation wells.

At Wigan, in addition to the ordinary course of lectures given at the Mining and Mechanical School, a special course has been arranged for candidates for colliery managers' certificates, and gives to the teaching of the school a special technical direction. The extension scheme for turning the very numerously attended evening classes of this school into a Mining Collegiate Centre for Lancashire, has necessarily languished under the unexampled and continued depression in the coal trade, though from the number and extent of the promised subscriptions and donations to the building-fund, there can be little doubt that, when better times again visit this country, this school will develop into an important centre of technical education. The town has lately had the good fortune to have presented to it a magnificent library, stored in a handsome building erected for the purpose, the former being the bequest of the late Mr. Winnard, the latter the gift of Mr. Thomas Taylor. The reference library is well stored with standard scientific works in all branches, and the selection reflects great credit on the industry and acumen of Mr. Gerrard Finch, barrister-at-law, who selected them, under the terms of the will. Some important works are of course conspicuous by their absence, but doubtless this will soon be remedied. The reference portion of this library will henceforth be opened on a Sunday to readers who have asked for special tickets, the extra cost of assistants being defrayed for three years by Mr. Taylor, the donor of the building. This town has also now a flourishing Literary and Scientific Society, with Lord Lindsay as president; it is divided into botanical, microscopical, and other sections, at which papers are read by the members, and discussed, and, in addition, special lectures are given to the united sections; amongst those delivered have been "Spectrum Analysis," by Lord Lindsay, and "Local Geology," by Mr. de Rance: others are announced by Prof. McKenny Hughes and Prof. Rudler.

At Southport there is at present little done for fostering a taste for either technical or scientific education, but the very fine aquarium is maintained in great efficiency, the contents of the table tanks, to which we have previously referred, being especially beautiful.

At Preston, meetings of the Scientific Society have been numerously attended, and the president, Dr. Arminson, and others, do good microscopical work. The meetings are held at the Avenham Institution, which is well filled with scientific works, including the natural history library of a defunct Naturalists' Society, and it is a matter of regret that the town, in adopting the Free Libraries Act, should not have carried out an amalgamation scheme, instead of running a new and inefficient library in opposition to the existing useful and self-supporting institution. The Gilchrist Trust lecturers here and at Burnley have been listened to with much interest by large audiences; and at the latter place Prof. Boyd Dawkins has inoculated his hearers with his taste for cave-hunting investigations, and searches have been organised into the wild hills which fringe the county boundary of Lancashire and Yorkshire, and form the backbone of England, a district which for the most part appears to be above the level of the glacial sea deposits.

At Chester the flourishing Natural Science Society that looks back with pride to Kingsley, its founder, and forward with hope to its president, Prof. McKenny Hughes, is divided into several sections like a small British Association. The most noticeable paper read was one by Mr. Shrubsole, on the Fenestellæ of the carboniferous limestone, which was an important and valuable contribution to our knowledge of this group, proving from perfect specimens that several supposed species are, in fact, portions of the same organism. General lectures have been given to the united sections by Prof. Judd and Mr. De Rance, who opened the winter session. The Society possesses a very good local museum, but unfortunately it is exhibited in the disused ball-room of an ancient hotel in an out-of-the-way part of the city, and is known to few of the scientific visitors of Chester, and is but seldom visited by the inhabitants. The collection would, however, form an admirable nucleus of a museum for teaching purposes, should the Corporation ever recognise the need of technical education in this town, and erect a building to hold a library, museum, and science and art schools by the side of their fine town hall. Towards filling museums of this class, great advantage would accrue if the duplicate specimens at the British and Jermyn Street Museums were either given, or allowed to circulate, in the same manner as the art treasures from South Kensington Museum. For valuable as are *local* collections for the scientific *specialists*, no one can doubt the importance of giving wide and varied knowledge to the general public, such as, perhaps, can only be imparted by the inspection of typical specimens of the natural and artificial products of all countries. Such a collection may be seen on a small scale in the admirable little museum at Castleton, in Derbyshire, formed by Mr. Rooke Pennington, which at once furnishes the visitor with all that can be collected for forming a mental local picture of the past, and affords the inhabitants of the district an opportunity of knowing something of the world around them.

At Manchester the museum at Owens College now includes the entire collections of the Manchester Natural

History Society and Manchester Geological Society, as well as a small typical collection originally belonging to the College and the complete mineralogical and metallurgical collections of the late David Forbes; the series are admirably arranged for the purposes of study. Prof. Boyd Dawkins is curator.

A REAL TELEGRAPH

A NEW invention of a real practical character, not a mere "paulo post futurum" invention like many we have heard of lately, has just been made by Mr. E. A. Cowper, the well-known mechanical engineer. It is a real telegraphic writing machine. The writer in London moves his pen, and simultaneously at Brighton another pen is moved, as though by a phantom hand, in precisely similar curves and motions. The writer writes in London, the ink marks in Brighton. We have seen this instrument at work, and its marvels are quite as startling as those of the telephone. The pen at the receiving end has all the appearance of being guided by a spirit hand. The apparatus is shortly to be made public before the Society of Telegraph Engineers. We give a facsimile of the writing produced by this telegraphic writing machine.

GEOGRAPHICAL NOTES

THE Spanish Ministry of Public Instruction has just issued a very important publication, being a collection of letters of Christopher Columbus, and of his contemporaries, as well as of reports sent in, during the sixteenth century by governors of the new American provinces, the originals of these letters and reports being now in the State Archives of Spain. The work, which bears the title "Cartas de India" (Letters from India), and forms a large volume of 877 folio pages, contains the following highly interesting documents: (1) Two autograph letters from Columbus, written in 1502 to King Ferdinand and Queen Isabella, the first letter dwelling upon the necessity of measures for increasing the population of the island "Española" (San Domingo), and the second being a discussion on the art of navigation; (2) a letter from Amerigo Vespuchi to the Cardinal Gimenes di Cuneros, Archbishop of Toledo, dated Sevilla, 1508, and dealing with the merchandise to be sent to the Antilles; (3) two letters from Fra Bartholomeo de las Casas, Archbishop of Nicaragua, to the Infanta Don Filippo, dated Gracias a Dios, in Guatemala; (4) two letters from Bernaldo Diaz del Castillo, one of the warriors of the small army of Cortes, and author of a history of Mexico, to Charles the Fifth (1552), and to Philip the Second (1558); (5) letters from the baccalaureates Don Pedro de Gasca and Don Christophor Vaca de Castro, dated Quito, 1541 and Cusco (1542), announcing to Charles the Fifth the death of the Marchese Don Pizaro and the insurrection of Don Diego de Almagro; both letters are very interesting, being accounts of eye-witnesses; (6) a very interesting letter of Donna Isabella Quivara to the Regent, Donna Huana, about the remarkable courage displayed by women during the expedition of Cortes, when all male members of the expedition were exhausted by disease. The work contains 652 pages of text and 225 pages of appendix, in which we find twenty-nine autograph letters and reports of various important historical persons; twenty-one sheets of autographs of Columbus, Vespuchi, Las Casas, Diaz del Castillo, Gimenez, &c.; a map of the fortifications where the gems of the Incas were found; and maps of Australia, of the River Amazon, the Antilles Archipelago, and Magellan Strait, drawn in the sixteenth century. We are sure that all friends of historical geography will feel grateful to the Spanish Government for this valuable publication.

COL. PRJVALSKY has left St. Petersburg to make another trip in Central Asia. He will proceed by Orenburg, Omsk, and Semipalatinsk to the Chinese frontier, thence to Hami, Hansu and Lassa. From Lassa he intends to reach the Himalaya by the Brahmapootra. Returning then to Lassa, he will visit Khotan, Kashgar, and cross the intervening plateaux to Russian Khokand. The journey is to occupy two years.

PÈRE HORNER has addressed a letter, dated Zanzibar, December 12, to *Les Missions Catholiques*, announcing that the members of the German scientific expedition have returned in bad health. This expedition, under the command of Herr C. Denhardt, started from Melinda, and explored the course of the River Dana, which has hitherto been supposed to take its rise in the slopes of Mount Kenia. They experienced many difficulties, and did not succeed in getting more than about sixty miles into the interior. According to Père Horner's report, in the place of Mount Kenia, covered with snow, they found only plains, and though they questioned more than 200 persons on the subject, they could find no one who had heard of the mountain. Père Horner thinks that the German travellers have not been far enough into the interior, and he says that they are going back again shortly to solve the problem. The truth, however, we believe is that Herr Denhardt has found that the Dana has a widely different course from that generally assigned to it, and that it does not flow anywhere near Mount Kenia. The party obtained a very complete series of meteorological observations, and they report that at some distance from the coast they met with a quiet and industrious tribe called the Vakopomo, who, it is thought, would welcome missionaries among them, if the fanatic Somalis of the coast region would allow them to pass.

IN the February number of the Geographical Society's new periodical we find a curious and learned paper by Sir Henry Rawlinson, entitled "Rough Notes on Prehistoric Cyprus, and another on the "Upper Basin of the Kabul River," from Mr. Markham's versatile pen, accompanied by a carefully drawn map of the Hindu Kush. Some of the geographical notes are of considerable interest. A St. Petersburg correspondent reports finding Prjvalsky restored to his habitual vigorous state of health and busy preparing for his next expedition, in which he hopes to reach Lhassa by the Hami and Sha-chau road, accompanied by young Eklon. Prjvalsky's Lob-Nor plant-collection turns out to be not very rich, the number of species being exceedingly few. Under the heading "Explorations North of India," we have the leading features of an unpublished report by Capt. Woodthorpe, R.E., and Lieut. Harman, of their recent work in the unexplored Miri and Mishmi Hills. In the latter region Capt. Woodthorpe obtained a fairly accurate knowledge of the sources of the Dihong River and the course of its main stream in the hills. The result of these explorations proves that the volum of the Subansiri is only one-fourth of that of the Dihong, which tends more than ever to identify the latter with the great river of Thibet. Some particulars are also furnished respecting the Dar-es-Salaam road in East Africa.

AT the last meeting of the Berlin Geographical Society several interesting communications were read. Gerhard Rohlfs had left Tripolis about Christmas, and proceeded southwards for twelve days' journey, there awaiting the presents intended for the Sultan of Wadai, sent by the German Emperor. The Society has also received news from Count Szechenyi, who has undertaken the task of investigating the Lo-floa. He arrived at Pekin in October last, and succeeded in obtaining passes for his journey to Thibet, a favour which has never before been bestowed upon any European by the Celestials.

HERR J. M. HILDEBRANDT is about to start on a scientific tour through Madagascar, at the request of the Berlin Academy of Sciences. He will direct his principal attentions to the botany, zoology, and topography of the island. A report has reached Bremen through the French Secretary for the Navy, that the young Bremen traveller, Dr. Rutenberg, who is also investigating Madagascar, has been murdered there. Direct news from Nossi-Bé, however, states that Dr. Rutenberg stayed there till November 29 last. He was then about to start on a tour through the interior in a southerly direction, and hoped eventually to reach Fort Dauphin, near the southern extremity of the island.

THE Paris Geographical Society intend holding a meeting in commemoration of Capt. Cook on the 14th inst., that being the hundredth anniversary of his death. M. W. Hüber, Dr. E. H. T. Hamy, and M. Crosnier de Varigny have agreed to address the meeting respectively on Capt. Cook's life, the ethnographical results of his voyages, and the present state of the countries discovered by him. Mr. J. Jackson has taken charge of the bibliographical researches, and Mr. W. Blakeney, R.N., secretary to the hydrographer, has been requested to lend the assistance of his knowledge concerning the great voyager. The Royal Geographical Society have been invited to be represented at the meeting. It seems strange that it should be left to a foreign society to commemorate the death of England's greatest scientific voyager.

A PHENOMENON causing much anxiety amongst the inhabitants of the shores of the Amazon is the continued rapid decrease of that generally colossal river. It appears that navigation above Manaos has become an impossibility. The cause of the continued decrease of the quantity of water is entirely unknown at present, and it is most desirable that men of science should thoroughly investigate the matter.

THE "Berlin Central Union for Commercial Geography and for the Furthering of German Interests Abroad" has just issued its first publication under the title "Geographische Nachrichten für Welthandel and Volkswirthschaft;" the editor is Dr. O. Kersten, and the publishers Herren Puttkammer and Mühlbrecht of Berlin.

A SINGAPORE paper states that the suitability of the soil of Perak for planting enterprise is exciting more and more attention. Five or six more planters from Ceylon are now there engaged in examining the soil. A similar remark applies to Johore, where the Maharajah has invited an ex-planter in Ceylon to become a sort of Minister of Lands; he is expected to arrive early this year, accompanied by several planters, who intend to explore Johore.

THE position of the missionary settlement at Blantyre which lies to the east of the Murchison Falls on the Shiré, East Africa, has never hitherto been known within several miles. It will, therefore, be interesting to record that as the result of a series of observations taken some five months since, Mr. Louis Carr has determined it to be in S. lat. 15° 45′ 25″, and E. long. 35° 14′ 11″.

ENGINEERING RESEARCH

THE Institution of Mechanical Engineers have decided to take a step which must meet with the approval of all who have the progress of engineering at heart. Like all other arts, that of the engineer, to be fully efficient, must be based on the laws which govern matter; and it is evident that the better we know these laws the more efficiently will our engineers be able to do their work. The only method of discovering these laws and their action under all the conditions with which engineering has to deal, is by systematic and thorough research; and since in this country our Government are so slow to see its true interests, the work, as far as possible, must be undertaken by individuals and bodies such as the Society of Mechanical Engineers. That Society is to be congratulated on its enterprise and the clear perception possessed by its members of the foundation on which their all-important art should be established. At a recent meeting of the Society it was resolved that the Council should be empowered to expend during the present year a sum of not more than 300*l.* "for the purpose of promoting practical research in mechanical subjects." What the nature and aims of this research are likely to be we learn from a circular which has been distributed among the members for the purpose of eliciting suggestions.

It is proposed that a Research Committee, consisting of five Members of Council, be appointed by the Council annually, and that a sum be voted at each annual general meeting to be expended by the Committee. The first duty of this Committee, when appointed, will be to prepare a list of subjects on which further research is desirable, and present it to the Council, recommending certain subjects to be first investigated. The Research Committee will then appoint a Sub-Committee for each of the selected subjects, and invite gentlemen (not necessarily members of the Institution), to give assistance to such Sub-Committees. This proposed condition we think exceedingly praiseworthy and liberal, and augurs well for the comprehensiveness and thoroughness of any research that may be undertaken.

The circular referred to proposes that each Sub-Committee be instructed that its first duty is to collect and collate all the records of experiments and other information already existing on the subject; then to determine what further experiments, if any, are needed, and ascertain their probable cost; and to present a report to the Research Committee, embodying a summary of the information so obtained, a description of the experiments proposed to be made, and an application for the requisite funds. Upon the approval of any report of a Sub-Committee by the Research Committee, the latter, it is proposed, will apply to the Council for a suitable sum for the use of the Sub-Committee in carrying out their investigations.

Then it is proposed that ample provision be made for the publication of the results of any research, and for the continuation of investigations as far as circumstances seem to demand. The whole scheme seems to us to be conceived in a thoroughly liberal spirit, and with a true idea of the value of scientific research, and of the conditions under which it can be carried out with efficiency. That the scheme is likely to be carried out in as intelligent a manner as it has been devised will be evident from the names of those who have been appointed in the first instance as a Research Committee. These are: Dr. Siemens, Mr. Wm. Anderson of Erith, Mr. E. A. Cowper, Mr. A. Paget, and Mr. F. W. Webb. "The names of these gentlemen," as the *Engineer* rightly remarks, 'are a sufficient guarantee that the work will be carried out both with energy and discretion; and we can only conclude by wishing them success in their labours."

NOTES

THE Council of the Royal Society of Edinburgh has recommended for the four vacancies in their list of Foreign Honorary Members the names of Donders of Utrecht, Asa Gray of the United States, Janssen of Paris, and Listing of Göttingen.

AT the meeting of the Royal Society on Monday last the Keith Prize was presented to Prof. Heddle of St. Andrew's for his papers on the Rhombohedral Carbonates and the Felspars of Scotland.

OUR readers will be glad to hear the latest news from Madeira, that Prof. Clifford is certainly better, and able to be carried out in the sunshine.

THE following are the lecture-arrangements at the Royal College of Surgeons for the present season:—Prof. Parker commences a series on Monday, "On the Evolution of the Vertebrata," to be continued on Mondays, Wednesdays, and Fridays, to March 3. On the same days of the week, from March 5 to 24, Prof. Flower will lecture "On the Comparative Anatomy of Man," in continuation of his course of last year. In June, Prof. Jonathan Hutchinson will give six lectures: "On Certain Diseases of the Eye, Skin, and Joints which are produced through the Influence of the Nervous System;" and in the same month Mr. B. T. Lowne, F.R.C.S., will give three lectures "On the Physiology of the Nervous System," in continuation of his course of last year.

AT the General Monthly Meeting of the Royal Institution of Great Britain on Monday, Dr. Warren De La Rue, F.R.S., was elected Secretary of the Institution, and Dr. William Spottiswoode, Pres. R.S., was elected Manager.

WE learn from the *Journal de St. Pétersbourg* that the epidemic in Astrakan was discussed before the Russian Medical Society at a gathering where 800 were present. It seems that the people call it the plague, though it is not officially so known. M. Botkine mentioned that at the time of the last plague at Moscow in 1770, the question was discussed whether it was the true plague or a marked form of typhus, and he added that the diagnosis of the various forms of typhoid infection in Russia is very difficult. He believes that the spots on the body and the quickness with which death follows indicate that the present epidemic of Vetlianka is not a European malady. Dr. Nicolaïew, describing the symptomatology of the plague, said that its action is both physical and moral, and that to impose quarantine often helps rather than retards the spread of the disease by the fear it awakens.

ADMIRAL MOUCHEZ will soon resume, at the Paris Observatory, the series of *soirées scientifiques* which had been commenced by Leverrier. The first will be given at the end of the present month or the beginning of March. M. Wolf will lecture on astronomy.

THE second International Meteorological Congress will be opened at Rome on April 14 next. At the same time an exhibition of meteorological instruments will take place, and the Italian Government invites home and foreign institutions and private men of science to participate in the Congress.

WE regret to announce the death of Herr Georg Peter Winther, of Copenhagen, an eminent Danish naturalist, well known through his excellent treatises on the fishes of Denmark. He died on January 14 at the early age of thirty-five years.

A CELEBRATION of the fourth centenary of the introduction of the art of printing into Leipzig will take place during this year and will be coupled with an exhibition comprising all branches of the graphic arts.

THE little town of Hohenstein in the Erzgebirge will celebrate the centenary of one of its most celebrated sons on April 26, 1880. The eminent naturalist and philosopher, Gotthilf Heinrich von Schubert was born at Hohenstein, in 1780, and died at Munich on July 1, 1860. It is intended to erect a monument to his memory and to establish a school under the name of Schubert Institution.

A BOTANICAL society is in course of formation at Strassburg. Its object, apart from a special study of the botany of the Reichsland, is to provide all the higher schools of the country with complete herbaria.

WE hear that the coal-mining experiments at Kaiping in the north of the Chinese province of Chihli are proceeding successfully. The boring has reached a depth of nearly 500 feet, passing through six seams of good coal, one of which is three feet and another eight feet thick. It is proposed to bore to a depth of 550 feet.

A CORRESPONDENT asks us whether the "microphone electromagnetique," said to be invented by Dr. Frank, rue St. Honoré, Paris, is really a useful invention for deaf persons, or not? We have not yet heard of any microphone which in any way assists the deaf.

ON January 30, when the National Assembly of Versailles, was voting on a successor to Marshal MacMahon, M. Paul Bert, a representative of Yonne, was lecturing on Claude Bernard and his works, in the large hall of the Sorbonne, before more than 2,000 persons, belonging mostly to the high schools and learned professions. The only reference made to political matters by the lecturer related to the funeral of Claude Bernard, which took place at the expense of the Government. M. Paul Bert reminded his hearers that it was the first time such an honour had been paid to a man of science. Up to that time they had been exclusively reserved for men who had earned their reputation on the battle-field, or who belonged by blood to the reigning family.

IN his lecture on Claude Bernard, M. Paul Bert narrated a singular stratagem which was invented by Bernard during the last Franco-German war, and might be utilised without difficulty, under similar circumstances. It was proposed to re-victual Paris, which was strictly blockaded by German forces. A large number of cattle had been collected, waiting for an opportunity to cross the German lines. But a difficulty was to silence these animals, as their cries would attract the attention of the enemy. Claude Bernard proposed to practise upon them the section of the nerve which enables them to emit their usual cries. The operation is so easy that it could be executed in a few seconds by an ordinary butcher. None of the animals appeared to suffer in any way by the mutilation which had made them mute. But the military movement proved a failure, and for other causes the re-victualling could not take place.

SOME of our readers may be interested to know that there exists in Berlin an exceedingly efficient and comprehensive scientific agency, that of Friedländer und Sohn. Not only do they issue, at short intervals, catalogues of works and papers in all departments of science, published all over the world, but they undertake to assist individuals and associations in carrying out almost any scheme of a scientific kind. To any one, *e.g.*, anxious to pursue a particular line of research, they will furnish a methodical list of all the best researches that have been published on the subject; they assist museums, libraries, &c., in

forming collections of scientific specimens and books, and are, in short, the guides, philosophers, and friends of all desirous of accomplishing almost any purpose connected with science. Their "Bücher-Verzeichniss," No. 293 (Physics and Chemistry), is marvellously complete; nothing of any value, published in any country in any form, seems to have escaped the compiler. Friedländer und Sohn have been at this work for twenty-eight years, and their catalogues issued during that time must be of great interest and value to the student of science.

THE *Times* Geneva correspondent, under date February 3, telegraphs that a singular and almost unprecedented meteorological phenomenon has been observable during the past ten or fifteen days in many parts of Switzerland. While the temperature in the valleys and plains has been low, the waters covered with ice, and snow resting on the ground, a warm south wind has prevailed in the uplands and among the higher Alps, where the streams remain unfrozen and the snow has almost disappeared. This has been especially the case in Uri, Schwytz, the Grisons, Neuchatel, and the Bernese Oberland. Mr. Coolidge, an Englishman, with four guides, made the ascent of the great Schreckhorn last week at four o'clock in the afternoon, when the thermometer on the summit of the mountain marked several degrees above freezing-point. The Oberland Alpine Club propose to buy some of the ibex forming part of the collection of the late King Victor Emmanuel, for the purpose of re-stocking the mountains of Switzerland.

A SHOCK of earthquake was felt at Foochow and Amoy on December 17.

A FINE meteor was observed at Prague and many other towns and villages of Bohemia on January 11, at 7.30 P.M. It appeared in the north-western part of the sky and moved towards the south-west, disappearing with a loud report, and leaving a long luminous train behind. The colour of the meteor was white at first and reddish violet at the end; the duration of the phenomenon was ten seconds.

THE project of a canal between the Rhine and the Maas seems at last to approach realisation. The city of Crefeld has declared its readiness to pay the sum of 500,000 marks (25,000*l.*) towards it, and it is confidently hoped that now both the Prussian as well as the Dutch Government will grant the necessary additional funds.

WE believe that the changes in the Government of the French Republic will be favourable to the development of education all over the land. The extension of public instruction is to be a part of the programme of the Ministry, which will not be published before our present impression will be in the hands of our readers.

ANOTHER of the London gas companies has been trying to show what gas-lighting can be made if only the public are willing to go to the necessary expense. On Friday last the Gas Light and Coke Company lit up part of Regent Street in much the same way that the Phœnix Company recently did the Waterloo Road. The result is described as admirable. By the use of Sugg's improved form of burner, a light framework, and the proper adjustment of suitable reflectors, a light was obtained very much brighter than that to which we have been so long accustomed. We believe if some enterprising company undertook to light one of our principal thoroughfares for some months at their own expense by this method, they would most likely be rewarded by a demand on the part of the public that the new form of light should be made general and permanent. Some comparative experiments which have been made at Westgate-on-Sea with the Jablochkoff candles have led the experimenters to the conclusion that this form of electric lighting is much more expensive than gas, and is surrounded with so many difficulties that no amount of improvement is likely to fit it for adoption. It is rumoured that an experiment is likely to be made in lighting the reading-room of the British Museum with the electric light.

THE Austrian Tourist Club has offered two prizes of 100 and 50 florins respectively for the best and next-best monograph of a mountain group or single mountain from the district of the Austrian Alps. Particulars respecting the competition can be learnt upon application to the Committee of the Club, Gusshausstrasse, Vienna.

CONTINUING his researches on the scintillation of stars, M. Montigny has examined the influence of atmospheric temperature and pressure, moisture in the air, fogs, snow, different winds, &c. His observations are detailed in a recent number (11, of 1878) of the Belgian Academy's *Bulletin*. The general conclusion to which the various facts point is thus stated:—It is the presence of water in greater or less quantity in the atmosphere, that exerts the most marked influence on scintillation, and which most modifies the character of it, either when the water is dissolved as vapour in the air, or when it falls to the surface of the ground in the liquid state, or in the solid state, in the form of snow."

IN spectacles designed purely for amusement there occur from time to time exhibitions of muscular dexterity and strength which are highly interesting to the physiologist. *La Nature* mentions that there was lately to be seen at the Hippodrome, in Paris, a gymnast, named Joignerey, who discharged a piece of cannon, not supporting it on the shoulder, as others have done, but like a rifle. The same man, suspended by his legs from a trapeze, raised with his teeth a horse and its rider. About the same time visitors to the skating theatre were astounded by the feats of the juggler Treniz, who entwined himself in a long streamer wound as an aerial helix, a feat which has been peculiar to the Japanese; and, with cubes of wood thrown into the air and caught, sketched the rudiments of unstable architectural forms, modifying their arrangement with unfailing dexterity and certainty.

AT a recent meeting of the French Physical Society M. Benoit showed a thermo-regulator of his invention, based on the increase of maximum tension of a saturated vapour with the temperature. A small vessel, containing methylic ether, is placed in the stove whose temperature is to be kept constant; it communicates with a mercury manometer, the movements of which, again, serve to regulate the flow of the coal-gas which heats the stove. M. Benoit has thus been able to maintain a temperature of 85° C. constant to within one-tenth of a degree. The apparatus owes this rare precision to the smallness of its mass and the rapidity with which the tension of the vapour increases with the temperature. The author showed that after having regulated it for the surrounding temperature, one had merely to blow rapidly on the small vessel of liquid in order to produce the extinction of the gas-burners governed by the apparatus.

SEVERAL Parisian photographers have tried to use electric light for obtaining *clichés*, and have been wonderfully successful. MM. Pierre Petit and Lebert are the most prominent amongst them.

SCARCELY a month passes but we receive the first number of a new journal devoted to science. Last week we referred to a new Italian *Nature*, and we have before us several other journals which are at least new to us. *L'Athénæum Belge*, which has entered on its second year, devotes a portion of its space to science, as well as to literature and art; it seems to us to be well conducted. The first number of the second year of *Le Monde*

de la Science et de l'Industrie is extremely satisfactory, containing much and varied information both in pure and applied science. The *Telephone Journal*, of which also No. 1 of vol. ii. lies before us, we have seen for the first time. It seems to be an organ of the Chicago branch of the Bell Telephone Company, and contains mostly a list of persons and firms telephonically connected with each other through the Central Office in Chicago. The list of names is a long one, and as the "calls" of the Company are stated to average 5,500 daily, we infer they are doing a paying business. We have already referred to the Spanish *Crónica Cientifica*; Nos. 25 and 26 are exceedingly creditable, containing a fair selection from the scientific work being done both in Spain and in other countries. Altogether science has taken a prominent and influential place in the journalism of the day.

"THE Magic Lantern Manual," by Mr. W. J. Chadwick, is a plentifully illustrated little volume likely to be of great service to those, and they are many, who work with this useful apparatus in one or other of its many forms. Warne and Co. are the publishers. Equally useful in its own department is Dr. Sylvester Marsh's little manual on Section Cutting, a practical guide to the preparing and mounting of sections for the microscope, special prominence being given to the subject of animal sections. Messrs. Churchill are the publishers.

SOME excavations made at Merten, near Bolchen, in German Lorraine, have given remarkable results. The remains of a gigantic equestrian statue were found, of which the figure of the rider is particularly well preserved. Investigation of other remains tend to show that the origin of the statue is Roman; parts of mosaic floors, &c., have also been discovered.

A NEW agricultural school is about to be established at Meissen, Saxony.

THE cultivation and consumption of opium continues to increase largely in China, but notwitstanding this extended cultivation, the Persian drug is extensively consumed on account of its comparative cheapness. In a report from Amoy it is stated that the poppy is cultivated in the neighbourhood with the knowledge and sanction of the mandarins; but so far the production of opium appears in no way to affect the foreign produce, as, from the imperfect system of manufacture practised by the natives, they are unable to produce a drug in any way approaching the foreign article, either in quality or flavour. As regards the habit of using opium, Mr. Alabaster says: "It is now so general that I assume there is little probability of much increase in the demand unless the population of Formosa increase, where, as the use of opium is almost a necessity of life in the plantations there, to counteract the malarious influences of the climate there must be a larger export thither. Nor is it to be desired that the consumption should become greater, for although I cannot agree with those who so vigorously denounce the trade as a source of every evil, and am inclined to think from observation that many more lives are annually saved by its moderate use than are sacrificed to inordinate indulgence in it, an increase would now rather mark the spread of the abuse of the drug, than of its employment as a stimulant to counteract the lowering effects of climate, and damp and ill-drained houses."

THE additions to the Zoological Society's Gardens during the past week include two Macaque Monkeys (*Macacus cynomolgus*) from India, presented respectively by Mr. E. E. Barclay and Mr. Eardley Holt; a Weeper Capuchin (*Cebus capucinus*) from South America, presented by Mr. W. Fridrick; two White-Fronted Capuchins (*Cebus hypoleucus*) from South America, presented by Mr. Geo. Backhouse; a Short-Tailed Wallaby (*Halmaturus brachyurus*) from West Australia, presented by Mr. G. Bowen; a Grey Ichneumon (*Herpestes griseus*) from India, presented by Mr. B. Baverstock; a Golden-Naped Amazon (*Chrysotis auripalliata*) from South America, presented by Mrs. H. A. Hopkins; three Canada Geese (*Bernicla canadensis*) from North America, presented by Mr. W. Bonorton; a Black-Winged Pea-fowl (*Pavo nigripennis*) from Cochin China, presented by the Hon. A. S. G. Canning, F.Z.S.; a Giraffe (*Camelopardalis giraffa*) from Nubia, deposited; a Golden-Fronted Parrakeet (*Brotogerys tuipara*), an American Tantalus (*Tantalus loculator*), a Rough Terrapin (*Clemmys punctularia*) from South America, four River Jack Vipers (*Vipera rhinoceros*) from West Africa, received in exchange.

FOREST GEOGRAPHY

SOME months ago Prof. Asa Gray delivered to the Harvard University Natural History Society a lecture on Forest Geography and Archæology, which has been published in two recent numbers of the *American Journal of Science*. The lecture referred mainly to the forests of North America, and in speaking of these, Prof. Gray referred to them not exactly as they are to-day, but as they were before civilised man had materially interfered with them. In the first part of the lecture Prof. Gray showed how the distribution of forests is mostly dependent on the distribution of moisture, and thus explained the great difference which exists in this feature between the eastern and western States. The Atlantic "forest primeval," he stated, a few generations ago covered essentially the whole country from the Gulf of St. Lawrence and Canada to Florida and Texas, and from the Atlantic to beyond the Mississippi. This Atlantic forest of the United States is one of the largest and almost the richest of the temperate forests of the world. Then going westwards from the Mississippi come prairies and open plains; beyond these is the Rocky Mountains, forest again, but only in narrow lines and patches; but after passing the Sierra Nevada, the western rim of the basin, we come to what is in some respects the noblest and most remarkable forest in the world. In the long valley of California it almost disappears again, to resume its sway in the Coast Ranges, with altered features, some of them not less magnificent and of greater beauty. Thus there are two forest-regions in North America—an Atlantic and a Pacific, each dependent on the oceans which they respectively border. Prof. Gray then goes on to show how the distribution and nature of these forests are dependent mainly on moisture and temperature, proceeding to prove that the difference in the composition of the Atlantic and Pacific forests is not less marked than that of the climate and geographical configuration to which the two are respectively adapted.

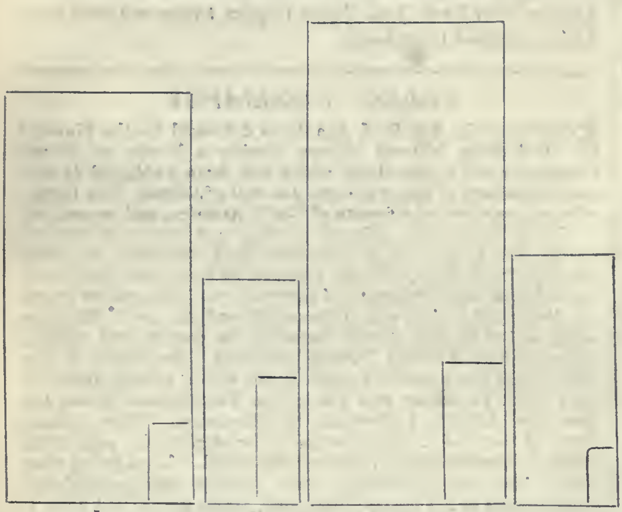
"With some very notable exceptions, the forests of the whole northern hemisphere in the temperate zone (those that we are concerned with) are mainly made up of the same or similar *kinds*. Not of the same species; for rarely do identical trees occur in any two or more widely separated regions. But all round the world in our zone, the woods contain *pines* and *firs* and *larches*, *cypresses* and *junipers*, *oaks* and *birches*, *willows* and *poplars*, *maples* and *ashes*, and the like. Yet with all these family likenesses throughout, each region has some peculiar features, some trees by which the country may at once be distinguished."

With regard to the Pacific forests the greater part of the Atlantic trees are conspicuous by their absence.

"For example, it has no magnolias, no tulip-tree, no papaw, no linden or basswood, and is very poor in maples; no locust-trees—neither flowering locust nor honey locust—nor any leguminous tree; no cherry large enough for a timber-tree, like our wild black cherry; no gum-trees (*Nyssa* nor *Liquidambar*), no sorrel-tree, nor kalmia; no persimmon, or bumelia; not a holly; only one ash that may be called a timber-tree; no catalpa, or sassafras; not a single elm, nor hackberry; not a mulberry, nor planer-tree, nor maclura; not a hickory, nor a beech, nor a true chestnut, nor a hornbeam; barely one birch tree, and that only far north, where the differences are less striking. But as to coniferous trees, the only missing type is our bald cypress, the so-called cypress of our southern swamps, and that deficiency is made up by other things. But as to ordinary trees, if you ask what takes the place in Oregon and California of all these missing kinds, which are familiar on our side of the continent, I must answer, nothing, or nearly nothing. There is the *Madroña* (arbutus) instead of our kalmia (both really trees in some places); and there is the California laurel

instead of our southern red bay tree. Nor in any of the genera common to the two does the Pacific forest equal the Atlantic in species. It has not half as many maples, nor ashes, nor poplars, nor walnuts, nor birches, and those it has are of smaller size and inferior quality; it has not half as many oaks, and these and the ashes are of so inferior economical value, that (as we are told) a passable waggon-wheel cannot be made of California wood, nor a really good one in Oregon."

Prof. Gray then illustrates graphically by diagrams, which we here reproduce, this poverty of the western forest in species in type (of timber-trees); it has only 31 genera and 78 species to 66 genera and 155 species on the Atlantic side. In the appended diagrams the short side of the rectangle is proportionate to the number of genera and the long side to the number of species. The geographical areas of the two forests are not very different, the length of the Pacific forest making up to some extent for its comparative narrowness.



1 2 3 4

1. Atlantic American Forest. 2. Pacific American Forest. 3. Japan-Manchurian Forest. 4. European Forest.

"How can so meagre a forest make so imposing a show? Surely not by the greater number and size of its individuals, so far as deciduous (or more correctly non-coniferous) trees are concerned; for on the whole they are inferior to their eastern brethren in size if not in number of individuals. The reason is, that a larger proportion of the genera and species are coniferous trees; and these, being evergreen (except the larches), of aspiring port and eminently gregarious habit, usually dominate where they occur. While the east has almost three times as many genera and four times as many species of non-coniferous trees as the west, it has slightly fewer genera and almost one-half fewer species of coniferous trees than the west. That is, the Atlantic coniferous forest is represented by eleven genera and twenty-five species; the Pacific by twelve genera and forty-four species. This relative preponderance may also be expressed by the diagrams, in which the smaller inclosed rectangles, drawn on the same scale, represent the coniferous portions of these forests.

"Indeed, the Pacific forest is made up of conifers, with non-coniferous trees as occasional undergrowth or as scattered individuals, and conspicuous only in valleys or in the sparse tree-growth of plains, on which the oaks at most reproduce the features of the 'oak openings' here and there bordering the Mississippi prairie region. Perhaps the most striking contrast between the west and the east, along the latitude usually traversed, is that between the spiry evergreens which the traveller leaves when he quits California, and the familiar woods of various-hued round-headed trees which give him the feeling of home when he reaches the Mississippi. The Atlantic forest is particularly rich in these, and is not meagre in coniferous trees. All the glory of the Pacific forest is in its coniferous trees: its desperate poverty in other trees appears in the annexed diagram. These diagrams are made more instructive, and the relative richness of the forests round the world in our latitude is most simply exhibited, by adding two or three similar ones. Two will serve, one for Europe, the other for North-East Asia . . . .

"Keeping as nearly as possible to the same scale, we may count the indigenous forest trees of all Europe at 33 genera and 85 species. And those of the Japan-Manchurian region, of very much smaller geographical area, at 66 genera and 168 species. I here include in it only Japan, Eastern Manchuria, and the adjacent borders of China. The known species of trees must be rather roughly determined, but the numbers here given are not exaggerated, and are much more likely to be sensibly increased by further knowledge than are those of any of the other regions. Properly to estimate the surpassing richness of this Japan-Manchurian forest, the comparative smallness of geographical area must come in as an important consideration.

"To complete the view, let it be noted that the division of these forests into coniferous and non-coniferous is, for the

European non-coniferous,	26 genera,	68 species.
,, coniferous	7 ,,	17 ,,
	33 ,,	85 ,,
Japan-Manchurian non-coniferous	47 genera,	123 species.
,, ,, coniferous	19 ,,	45 ,,
	66 ,,	168 ,,

In other words, a narrow region in Eastern Asia contains twice as many genera and about twice as many species of indigenous trees as are possessed by all Europe; and as to coniferous trees, the former has more genera than the latter has species, and over twice and a half as many species.

"The only question about the relation of these four forest regions, as to their component species, which we can here pause to answer, is to what extent they contain trees of identical species. If we took the shrubs, there would be a small number, if the herbs a very considerable number, of species common to the two New World and to the two Old World areas respectively, at least to their northern portions, even after excluding arctic-alpine plants. The same may be said, in its degree, of the North European flora compared with the Atlantic North American, of the North-East Asiatic compared with the northern part of the Pacific North American, and also in a peculiar way (which I have formerly pointed out and shall have soon to mention) of the North-Eastern Asiatic flora in its relations to the Atlantic North American. But as to the forest trees there is very little community of species. Yet this is not absolutely wanting. The Red Cedar (*Juniperus Virginiana*) among coniferous trees, and *Populus tremuloides* among the deciduous, extend across the American continent specifically unchanged, though hardly developed as forest trees on the Pacific side. There are probably, but not certainly, one or two instances on the northern verge of these two forests. There are as many in which eastern and western species are suggestively similar. The hemlock-spruce of the Northern Atlantic States, and the yew of Florida are extremely like corresponding trees of the Pacific forest; indeed the yew-trees of all four regions may come to be regarded as forms of one polymorphous species. The white birch of Europe and that of Canada and New England are in similar case; and so is the common chestnut (in America confined to the Atlantic States), which on the other side of the world is also represented in Japan. A link in the other direction is seen in one spruce tree (called in Oregon Menzies spruce) which inhabits north-east Asia, while a peculiar form of it represents the species in the Rocky Mountains."

Prof. Gray then asks why the Pacific forest region, which is rich and in some respects unique in coniferous, should be so poor in deciduous trees. And how came California to have the monopoly of the two *Big-trees*, Sequoias, which have no near relatives anywhere? "Such relatives," he goes on to say, "as the Sequoias have are also local, peculiar, and chiefly of one species to each genus. Only one of them is American, and that solely eastern, the taxodium of our Atlantic States and the plateau of Mexico. The others are Japanese and Chinese. Why should trees of six related genera, which will all thrive in Europe, be restricted naturally, one to the eastern side of the American continent, one genus to the western side and very locally, the rest to a small portion of the eastern border of Asia? Why should coniferous trees most affect and preserve the greatest number of types in these parts of the world? And why should the north-east Asian region have, in a comparatively small area,

not only most coniferous trees, but a notably larger number of trees altogether than any other part of the northern temperate zone? Why should its only and near rival be in the antipodes, namely, here in Atlantic North America? In other words, why should the Pacific and the European forests be so poor in comparison, and why the Pacific poorest of all in deciduous, yet rich in coniferous trees?"

Prof. Gray ventures to conclude that this richness is normal, and that what we really have to explain is the absence of so many forms from Europe on the one hand, from Oregon and California on the other. He shows that most of the forms, even of shrubs and herbs, which are peculiar to the Atlantic forest, have their close counterparts in Japan and North China. Prof. Gray noticed the feature long ago, and evidences of the remarkable relationship have multiplied year after year.

"The result, as to the trees, is seen in these four diagrams. As to number of species generally, it cannot be said that Europe and Pacific North America are at all in arrears. But as to trees, either the contrasted regions have been exceptionally favoured, or these have been hardly dealt with. There is, as I have intimated, some reason to adopt the latter alternative.

"We may take it for granted that the indigenous plants of any country, particularly the trees, have been selected by climate. Whatever other influences or circumstances have been brought to bear upon them, or the trees have brought to bear on each other, no tree could hold its place as a member of any forest or flora which is not adapted to endure even the extremes of the climate of the region or station. But the character of the climate will not explain the remarkable paucity of the trees which compose the indigenous European forest. That is proved by experiment, sufficiently prolonged in certain cases to justify the inference. Probably there is no tree of the northern temperate zone which will not flourish in some part of Europe. Great Britain alone can grow double or treble the number of trees that the Atlantic States can. In all the latter we can grow hardly one tree of the Pacific coast. England supports all of them, and all our Atlantic trees also, and likewise the Japanese and North Siberian species, which do thrive here remarkably in some part of the Atlantic coast, especially the cooler-temperate ones. The poverty of the European sylva is attributable to the absence of our Atlantic American types, to its having no magnolia, liriodendron, asimina, negundo, no æsculus, none of that rich assemblage of leguminous trees represented by locusts, honey-locusts, gymnocladus, and cladrastis (even its cercis, which is hardly European, is like the Californian one, mainly a shrub); no nyssa, nor liquidambar; no ericaceæ rising to a tree; no bumelia, catalpa, sassafras, osage orange, hickory, or walnut; and as to conifers, no hemlock spruce, arbor-vitæ, taxodium, nor torreya. As compared with north-eastern Asia, Europe wants most of these same types, also the ailantus, gingko, and a goodly number of coniferous genera. I cannot point to any types tending to make up the deficiency, that is, to any not either in east-north America or in north-east Asia, or in both. Cedrus, the true cedar, which comes near to it, is only north African and Asian. I need not say that Europe has no sequoia, and shares no special type with California.

"Now the capital fact is, that many and perhaps almost all of these genera of trees were well represented in Europe throughout the later tertiary times. It had not only the same generic types, but in some cases even the same species, or what must pass as such, in the lack of recognisable distinctions between fossil remains and living analogues. Probably the European miocene forest was about as rich and various as is ours of the present day, and very like it. The glacial period came and passed, and these types have not survived there, nor returned. Hence the comparative poverty of the existing European sylva, or at least, the probable explanation of the absence of those kinds of trees which make the characteristic difference."

Before answering the question as to why these trees perished out of Europe but survive in America and Asia Prof. Gray inquires how these American trees came to be in Europe. From certain considerations he is led to the inference that all species closely related to each other have had a common birthplace and origin. So that when we find individuals of a species or of a group widely out of range of their fellows, we wonder how they got there. When we find the same species all round the hemisphere—and a very considerable number of species of herbs and shrubs, and a few trees are so found—we ask how this dispersion came to pass. Prof. Gray goes on to say:—

"I take it that the true explanation of the whole problem comes from a just general view, and not through piecemeal suppositions of chances. And I am clear that it is to be found by looking to the north, to the state of things at the arctic zone first, as it now is, and then as it has been. North of our forest-regions comes the zone unwooded from cold, the zone of arctic vegetation. In this, as a rule, the species are the same round the world; as exceptions, some are restricted to a part of the circle. The polar projection of the earth down to the northern tropic, as here exhibited, shows to the eye—as our maps do not—how all the lands come together into one region, and how natural it may be for the same species, under homogeneous conditions, to spread over it. When we know, moreover, that sea and land have varied greatly since these species existed, we may well believe that any ocean-gaps, now in the way of equable distribution, may have been bridged over. There is now only one considerable gap.

"What would happen if a cold period were to come on from the north, and were very slowly to carry the present arctic climate, or something like it, down far into the temperate zone? Why, just what has happened in the glacial period, when the refrigeration somehow pushed all these plants before it down to southern Europe, to middle Asia, to the middle and southern part of the United States; and at length receding, left some parts of them stranded on the Pyrenees, the Alps, the Apennines, the Caucasus, on our White and Rocky Mountains, or wherever they could escape the increasing warmth as well by ascending mountains as by receding northward at lower levels. Those that kept together at a low level, and made good their retreat, form the main body of present arctic vegetation. Those that took to the mountains had their line of retreat cut off, and hold their positions on the mountain-tops under cover of the frigid climate due to elevation. The conditions of these on different continents or different mountains are similar, but not wholly alike. Some species proved better adapted to one, some to another, part of the world; where less adapted, or less adaptable, they have perished; where better adapted, they continue—with or without some change;—and hence the diversification of alpine plants, as well as the general likeness through all the northern hemisphere.

"All this exactly applies to the temperate zone vegetation, and to the trees that we are concerned with. The clue was seized when the fossil botany of the high arctic regions came to light; when it was demonstrated that in the times next preceding the glacial period—in the latest tertiary—from Spitzbergen and Iceland, to Greenland and Kamtschatka, a climate like that we now enjoy prevailed, and forests like those of New England, and Virginia, and of California, clothed the land. We infer the climate from the trees; and the trees give sure indications of the climate.

"I had divined and published the explanation long before I knew of the fossil plants. These, since made known, render the inference sure, and give us a clear idea of just what the climate was. At the time we speak of, Greenland, Spitzbergen, and our arctic sea-shore had the climate of Pennsylvania and Virginia now. It would take too much time to enumerate the sorts of trees that have been identified by their leaves and fruits in the arctic later tertiary deposits.

". . . . Long genealogies always deal more or less in conjecture; but we appear to be within the limits of scientific inference when we announce that our existing temperate trees came from the north, and within the bounds of high probability when we claim not a few of them as the originals of present species. Remains of the same plants have been found fossil in our temperate region, as well as in Europe.

"Here, then, we have reached a fair answer to the question how the same or similar species of our trees came to be so dispersed over such widely separated continents."

Prof. Gray then shows what would naturally follow from a gradual pushing of the Arctic vegetation southwards, and that the modifications resulting from differences of climate in the divergent continents, and on their different sides, might well account for the present diversification. The siftings and resiftings which have since taken place from changes of climate, submergence, and re-emergence, and other causes, have left their impress on the actual vegetation, especially on the trees. They furnish probable reason for the loss of American types sustained by Europe.

"I conceive that three things have conspired to this loss. First, Europe, hardly extending south of latitude 40°, is all within the limits generally assigned to severe glacial action.

Second, its mountains trend east and west, from the Pyrenees to the Carpathians and the Caucasus beyond, near its southern border; and they had glaciers of their own, which must have begun their operations, and poured down the northward flanks, while the plains were still covered with forest on the retreat from the great ice-wave coming from the north. Attacked both on front and rear, much of the forest must have perished then and there. Third, across the line of retreat of those which may have flanked the mountain-ranges, or were stationed south of them, stretched the Mediterranean, an impassable barrier. Some hardy trees may have eked out their existence on the northern shore of the Mediterranean and the Atlantic coast. But we doubt not, taxodium and sequoias, magnolias and liquidambars, and even hickories and the like were among the missing. Escape by the east, and rehabilitation from that quarter until a very late period, was apparently prevented by the prolongation of the Mediterranean to the Caspian, and thence to the Siberian ocean."

Prof. Gray shows that on the American continent on the other hand the trees, when touched in the north by the incoming refrigeration, had only to move their southern border southward, along an open way, as far as the exigency required; and there was no impediment to their due return. The still greater richness of north-east Asia in arboreal vegetation may find an explanation in the prevalence of particularly favourable conditions, both anteglacial and recent.

"The case of the Pacific forest is remarkable and paradoxical. It is, as we know, the sole refuge of the most characteristic and wide-spread type of miocene coniferæ, the sequoias; it is rich in coniferous types beyond any country except Japan; in its gold-bearing gravels are indications that it possessed, seemingly down to the very beginning of the glacial period, magnolias and beeches, a true chestnut, liquidambar, elms, and other trees now wholly wanting to that side of the continent, though common both to Japan and to Atlantic North America. Any attempted explanation of this extreme paucity of the usually major constituents of forest, along with a great development of the minor, or coniferous, element, would take us quite too far, and would bring us to mere conjectures."

Prof. Gray concludes his interesting lecture by saying:—

"I have done all that I could hope to do in one lecture if I have distinctly shown that the races of trees, like the races of men, have come down to us through a prehistoric (or prenatural-historic) period; and that the explanation of the present condition is to be sought in the past, and traced in vestiges, and remains, and survivals; that for the vegetable kingdom also there is a veritable archæology."

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

THE Cambridge Smith's Prizes have been awarded to Micaiah John Muller Hill, B.A., St. Peter's College, and Arnold Joseph Wallis, B.A., Trinity College, bracketed equal. These gentlemen were also bracketed equal as fourth wranglers in 1879.

A UNIVERSITY for ladies will be opened shortly in Odessa. It will have three faculties—History and Literature, Mathematics, and Natural Science. The programme will be the same as in the other Russian Universities for male students, with a few changes. Greek will not be obligatory in the Historico-Literary Faculty; there will be in the same faculty a Chair of Political Economy and Statistics. Pedagogy and hygiene will be obligatory in all faculties.

SCIENTIFIC SERIALS

Annalen der Physik und Chemie, No. 12, 1878.—In an inaugural dissertation here given, Herr Nahrwold studies atmospheric electricity; his method of experiment having been to electrify air in a cylindrical vessel fitted with a (mercury) dropping collector. His first attempts, with points, convinced him that only the dust, not the air, could be thus electrified; he then successfully used a fine platinum wire kept glowing with a battery (the air having been first freed from dust), and a condenser or galvanic element connected with the circuit. Interesting data are furnished with regard to the charge of the air, the ratio of this to the source of electricity used, and the decrease of the charge. Some of the observations seem to throw doubt on Thomson's conclusions as to the distribution of electricity in the upper regions of the atmosphere.—Herr Wiedemann offers a theory on the nature of spectra, deduced from the kinetic theory of gases. Line-spectra are attributed to oscillatory motions of atoms, isolated at high temperatures; band spectra of elements and spectra of compounds to vibrations of atoms in the molecule, or of the ether-envelopes. —A quantitative verification of the electrodynamic law, regarding the reciprocal action of closed circuits, for the case in which the circuit suffers deformation, is furnished by Herr Niemöller.—Herr Korteweg discusses the velocity of propagation of sound in elastic tubes, and Herr Rühlmann gives formulæ for measurement of ocean depths with the manometer. —There are several notes on crystallography.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, January 23.—"Researches on Lactin," by Edmund J. Mills, D.Sc., F.R.S., "Young" Professor of Technical Chemistry in Anderson's College, Glasgow, and James Hogarth.

The authors have investigated lactin with the aid of polarised light, their object being to gain further insight into the chemical nature of that compound. Their conclusions are as follows:—

1. The initial specific rotation of lactin is $92°\cdot63$.
2. The permanent specific rotation of lactin is $59°\cdot17$.
3. The change of rotation of a solution of lactin can be expressed by a mathematical equation.
4. When the specific rotation $64°\cdot8$ is reached, the law of change must be expressed by a different equation.
5. The initial solubility of lactin is one part lactin in 10·64 parts water.
6. The permanent solubility is one part lactin in 3·23 parts water.

"Researches on Chemical Equivalence." Part II. Hydric Chloride and Sulphate. By Edmund J. Mills, D.Sc., F.R.S., and James Hogarth.

While carrying out their researches on lactin, it struck the authors that use might be made of it to compare the dynamical equivalents of acid bodies. They accordingly selected hydric chloride and hydric sulphate for the measurements in question.

The results show that though $2HCl$ may be the "equivalent" of H_2SO_4 in weight for saturation (*i.e.*, in the ordinary sense), it certainly is not the equivalent in the dynamical sense. They also render it highly probable that HCl is equal dynamically to H_2SO_4. Ostwald, by a method based on the alteration of the specific volume of solutions, has shown that the ratio $\frac{2HCl}{H_2SO_4} = 1\cdot93$, a result which their numbers, though not as perfect as the authors could wish, nevertheless strongly confirm.

"Limestone as an Index of Geological Time," by T. Mellard Reade, C.E.

January 30.—"On Certain Means of Measuring and Regulating Electric Currents." By C. William Siemens, D.C.L., F.R.S.

The dynamo-electro machine furnishes us with a means of producing electric currents of great magnitude, and it has become a matter of importance to measure and regulate the proportionate amount of current that shall be permitted to flow through any branch circuit, especially in such applications as the distribution of light and mechanical force.

On June 19 last, upon the occasion of the *soirée* of the President of the Royal Society, was exhibited a first conception of an arrangement for regulating such currents, which the author has since worked out into a practical form. At the same time a method has been realised by which currents passing through a circuit, or branch circuit, are measured, and graphically recorded.

It is well known that when an electric current passes through a conductor heat is generated, which, according to Joule, is proportionate in amount to the resistance of the conductor, and to the square of the current which passes through it in a unit of time, and advantage has been taken of this well-established law of electro-dynamics, in order to limit and determine the amount of current passing through a circuit.

The paper refers to three instruments, in the first of which one end of a thin strip of metal is attached to a screw, by which its tension can be regulated; it then passes upwards over an elevated insulated pulley, and down again to the end of a short

lever working on an axis, armed with a counter-weight and with a lever whose angular position will be materially affected by any small elongation of the strip that may take place from any cause. The apparatus further consists of a number of prisms of metal, supported by means of metallic springs, so regulated by movable weights as to insure the equidistant position of each prism from its neighbour.

A series of comparatively thin coils of wire of German silver or other resisting metal, connect the alternate ends of each two adjoining springs, the first and last spring being also connected to the lever and terminal respectively.

The strip is put under a glass shade, and the instrument itself should be placed in a room where a tolerably uniform temperature of say 15° C. is maintained.

When the minimum current is passing, the thin metallic strip is at its minimum working temperature, and all the metallic prisms are in contact, this being the position of least resistance. As soon as the current passing through the apparatus shall increase in amount, the thin metallic strip will immediately rise in temperature, which will cause it to elongate, and will allow the lever to recede from its extreme position, liberating one contact piece after another. Each such liberation will call into action the resistance coil connecting the spring ends, and an immediate corresponding diminution of the current through the additional resistance thus thrown into the circuit.

Suppose that the current intended to be passed through the instrument is capable of maintaining the sensitive strip at a temperature of say 60° C., and that a sudden increase of current takes place in consequence either of an augmentation of the supply of electricity or of a change in the extraneous resistance to be overcome, the result will be an augmentation of temperature, which will continue until a new equilibrium between the heat supplied and that lost by radiation is effected. If the strip is made of metal of high conductivity, such as copper or silver, and is rolled down to a thickness not exceeding 0·05 millim., its capacity for heat is exceedingly small, and its surface being relatively very great, the new equilibrium between the supply of heat and its loss by radiation is effected almost instantaneously. But, with the increase of temperature, the position of the regulating lever is simultaneously affected, causing one or more contacts to be liberated, and as many additional resistance coils to be thrown into circuit: the result being that the temperature of the strip varies only between very narrow limits, and that the current itself is rendered very uniform, notwithstanding considerable variation in its force, or in the resistance of the lamp, or other extraneous resistance which it is intended to regulate.

The resistance coils, by which adjoining contact-springs are connected, may be readily changed, so as to suit particular cases; they are made by preference of naked wire, in order to expose the entire surface to the cooling action of the atmosphere.

For feeble currents, disks of carbon are substituted for the wire rheostat, the electrical resistance of carbon varying inversely with the pressure to which it is subjected. A steel wire of say 0·3 millim. diameter is drawn tight between the end of a bell-crank lever and an adjusting screw, the pressure of the lever being resisted by a pile of carbon disks placed in a vertical glass tube. The current, passing through the steel wire, through the bell-crank lever, and through the carbon disks, encounters the minimum resistance in the latter so long as the tension of the wire is at its maximum; whereas the least increase in temperature of the steel wire by the passage of the current causes a decrease of pressure upon the pile of carbon disks, and an increase in their electrical resistance; it will thus be readily seen that, by means of this simple apparatus, the strength of small currents may be regulated so as to vary only within certain narrow limits.

The apparatus first described may be adapted also for the *measurement* of powerful electric currents. The variable rheostat is in this case dispensed with, and the lever carries at its end a pencil pressing with its point upon a strip of paper drawn under it in a parallel direction with the lever by means of clockwork. A second fixed pencil draws a second or datum line upon the strip, so adjusted that the lines drawn by the two pencils coincide when no current is passing through the sensitive strip. The passage of a current through the strip immediately causes the pencil attached to the lever to move away from the datum line, and the distance between the two lines represents the temperature of the strip. This temperature depends, in the first place, upon the amount of current passing through the strip, and, in the second place, upon the loss of heat by radiation from the strip; which two quantities balance one another during any interval that the current remains constant.

In order to facilitate the process of determining the value of the diagram produced by motion of pencil in Weber's or other units of current, it is only necessary, if the variations are not excessive, to average the ordinates, and to determine their value from a table prepared for that purpose. The error committed in taking the average ordinate instead of the absolute ordinates, when the current varies between small limits, is evidently small, the variation of the ordinates above their mean value averaging the variations below the same.

The thin sensitive conductor may thus be utilised either to restrict the amount of electricity flowing through a branch circuit, within certain narrow limits, or to produce a record of the amount of current passed through a circuit in any given time.

Physical Society, January 25.—Prof. G. C. Foster, vice-president, in the chair.—Prof. E. Ray Lankester and Mr. Alex. Macdonald, B.A., were elected Members.—Dr. Erck exhibited a constant bichromate of potash battery. The ordinary bichromate battery soon loses power when in use, and in order to secure a powerful constant battery to drive a small astronomical clock, Dr. Erck devised the modified form shown. It consists of a narrow lead trough 12 inches long by 3 inches wide and 1 inch deep, lined along both sides with two carbon plates. The zinc plate 10 inches long is immersed in the solution to the depth of an inch midway between the two carbons. A continual circulation of the bichromate solution is kept up by allowing fresh solution to drop into the cell at one end, and the exhausted solution to drop away by a tap at the other end. As the space between the two carbons is only about half an inch wide, there is merely a thin layer of solution between the positive and negative poles. The internal resistance of the cell is, therefore, very low, when short circuited only about $\frac{1}{4}$ ohm. To obtain the maximum current about 8 oz. of solution per hour should be applied. Dr. Erck also showed a battery formed of zinc and carbon circular plates mounted on an axle which is rotated by wheelwork, thus mechanically stirring the bichromate solution.—Dr. F. Guthrie, F.R.S., described some of the results he had obtained from experiments on the vibration of metal rods or lathes fixed in a vice at one end and free to vibrate at the other. The experiments were carried on by dusting sand on the rod and observing the nodal lines formed by it when the rod was vibrated, so as to give out notes determined by a monochord. Dr. Guthrie's results show that the two final segments at the free end are together equal in length to the inner segment at the fixed end. It appears from these experiments that if a free lathe vibrating with a node in the middle, but having an even number of segments, be clamped at where there is a node, we alter its conditions of vibration. When the lathe is half free, the end segment breaks up into two parts together equal to the segment at the fixed end. In the case of a torsional vibration of the lathe, the position of the longitudinal nodal lines depended to some extent on the clamping of the lathe in the vice. Prof. Foster pointed out that in a natural node the direction of the tangent is varying, whereas in an artificial node it is always horizontal. Prof. Unwin explained that the sand accumulated at nodes because the particles, when thrown off the lathe, make certain horizontal excursions which tend to move them nearer the points of repose of the lathe.—Messrs. Elliot Brothers exhibited sundry electric commutators and resistance boxes.

Anthropological Institute, January 21.—Mr. John Evans, D.C.L., F.R.S., president, in the chair.—The Director read a communication from Dr. Paul Topinard on resemblances between a Galtcha and a Savoyard skull. The similarity between these skulls is such that the author is inclined to regard the Galtchas of Eastern Turkistan and the Celts of Western Europe as branches of one common stock, of which the Slavs of Eastern Europe are also members.—M. Elie Reclus read a paper on circumcision, its significance, its origin, and its kindred rites. The practice of this custom was traced over a large portion of the inhabited globe, including Australia and South America, though among the nations of antiquity the Egyptians and Jews are those among whom it is best known to have prevaile·.

Photographic Society, January 14.—James Glaisher, F.R.S., in the chair.—Capt. Abney, R.E., F.R.S., read a paper on the fading of the undeveloped photographic image, and on soluble bromide in emulsions; and Col. Wortley explained a new instantaneous shutter, designed by him. Capt. Abney, in his paper, stated that one cause of the fading arose from impure

pyroxyline, which, during decomposition, liberated nitrous acid; and that this acid would destroy (before development) a photographic image on collodion, made from such pyroxyline.—Capt. Abney then discovered that as an excess of alkaline bromide would not diminish sensitiveness, or rather not prevent an image being formed, consequently, if a nitrite of some alkali, in conjunction with an excess of bromide, were added, the formation of any acid would be prevented, so that by the application of an alkaline carbonate to the film, all nitrous acid liberated from pyroxyline is absorbed to form an alkaline nitrite, and the destruction of the photographic image avoided.

CAMBRIDGE

Philosophical Society, December 2, 1878.—Prof. Liveing, president, in the chair.—Dr. G. W. Royston-Pigott made a communication to the Society on a new method of determining the limits of microscopic vision. The author referred to his method of forming miniatures by reversing an object-glass which has been described in the *Philosophical Transactions*, and showed how he had applied it to determine the limit of smallness of objects that could be detected by the microscope. The process employed was to form a miniature of an object such as a spider-line, and then examine the miniature with the microscope. In this manner Dr. Royston-Pigott had found that objects even as small as the millionth of an inch in diameter could be seen, contrary to the generally received view of opticians that it was useless to attempt to perfect the microscope further, as it could not show objects smaller than the hundred-thousandth of an inch in diameter. Dr. Jurin found that with the naked eye he could discover a pin fixed in a window forty feet away from him, subtending an angle of two or three seconds, but if he placed two pins together he could not distinguish them as separated except they were so far apart as to make an angle of forty seconds. Thus a bright interval could not be discovered unless it were ten or fifteen times larger than the objects forming it; but Dr. Royston-Pigott found that the excellence of modern objectives was such as to enable the eye to discern an interval only four times larger than the diameter of the web miniature, reckoned at one millionth of an inch. The microscopes and apparatus employed to produce the miniature were exhibited to the Society, and the precautions to be taken in the use of the method were explained.—Mr. W. M. Hicks communicated some results of an investigation on the motion of two cylinders surrounded by fluid.

PARIS

Academy of Sciences, January 27.—M. Daubrée in the chair.—The following papers were read:—Third reply to M. Berthelot, by M. Pasteur.—On the development of the perturbative function where, the excentricities being small, the mutual inclination of the orbits is considerable, by M. Tisserand.—On a formula giving approximately the moment of torsion, by M. de Saint-Venant.—Researches on the relations of spectrum analysis to the spectrum of the sun, by Mr. J. Norman Lockyer.—On the electric clutch-gear on board ships, by MM. Trève and Achard. An arrangement for managing marine engines or helms at a distance electrically.—On the composition of banana and attempts at utilisation of this fruit, by MM. Marcano and Muntz. The banana keeps the ground moist round it, and this property is utilised in Venezuela to help the coffee-plant in dry weather. But only a little of the banana's fruit is there used, and the authors call attention to the flour and the alcohol obtainable from it, recommending exportation. The flour is a food essentially feculent.—On the application of his atomic theory to various minerals, by M. Gaudin.—On the diameters of the sun and of Mercury, deduced from the transit of May, 1878, by M. Cruls (Rio de Janeiro). The solar semi-diameter is found 15′ 59″·982, agreeing nearly with Leverrier's 16′ 0″·0 (deduced from previous transits). The value for the planets' diameter, got from observations of ingress, was 10″·78, by another method 10″·74.—Hydro-electricity and hydro-magnetism; analytical results, by M. Bjerknes.—On a development in series, by M. Picard.—Displacement of spectral lines due to motion of rotation of the sun, by M. Thollon. His experiments on this with his new prism convince him that with a suitable arrangement the displacement may be produced in an incontestable manner. The telluric lines did not show any change, and some of them, near those of nickel, enabled one to see very distinctly how the latter were displaced.—On the radiation of incandescent platina, by M. Violle. He measured this from 900 to 1,775 degrees. The intensity of a given radiation does not increase indefinitely with the temperature, but passes through a maximum and then decreases to a point, where it becomes insensible. The luminous heat of fused platinum transmitted through alum is $\frac{1}{4·5}$ of the total heat transmitted through rock-salt.—On the illumination of lines of molecular pressure, and on the trajectory of molecules, by Mr. W. Crookes. M. Du Moncel said the dark space is not only manifested in vacuo; it is distinctly seen round the negative electrode, on sending an induction spark between two plates of glass, and examining it with a microscope. (A figure is given.)—On electrodynamic phenomena, and especially on induction, by M. de Meaux. In a closed circuit, you do not change the intensity of the current produced by induction of an indefinite cylindrical conductor on another of the same form, by surrounding one or other, or even both, of these conductors with a concentric metallic envelope, communicating with the ground throughout its length.—On a new Bell telephone speaking with loud voice, by M. Gower. The two magnet poles are placed opposite each other; the diaphragm is thick, large, and tense; the inclosing case is metallic and sonorous, and a speaking trumpet is added.—On the amalgams of chromium, manganese, iron, cobalt, and nickel, and on a new process of preparation of metallic chromium, by M. Moissan. This method is, stirring a concentrated solution of protochloride of chromium in water with pasty sodium-amalgam; the amalgam of chromium obtained is then heated to 350° in a current of hydrogen. Amalgams of the other metals named may be had similarly.—On a preparation of methylformic ether and of pure methylic alcohol, by MM. Bardy and Bordet.—On the principles which give *Sarracenia purpurea* its therapeutic properties, by M. Hetet.—On the termination of the visceral arterioles of *Arion rufus*, by M. Jourdain.—Researches on the action of *grenat*, or the residue of the manufacture of fuchsine, by M. Jousset de Bellesme. This is used to colour wines. It may be taken in large quantities without causing death; but it is hurtful, producing uræmia, &c.—On the quantity of light lost in actuating the visual apparatus, and its variations under different conditions, by M. Charpentier. A light being gradually increased from zero, you note when the eye perceives it; it may then be reduced considerably without the eye ceasing to perceive it. This difference is much greater, if the eye have been kept in the dark five minutes or more. But this effect of rest in the dark does not apply (or very little) to chromatic sensibility. The author considers the sensation of light wholly independent of that of colour.—On the phosphorescence of the lobster's flesh, by MM. Bancel and Husson. They consider it due to a kind of fermentation.—M. Mége Mouris presented a note on the properties of marine salt; and MM. Nasse and Decharme, notes on a liquid rain which lately covered the ground with a thick surface of ice.

THE "THUNDERER" EXPLOSION

NOW that the Committee appointed to inquire into the cause of the bursting of one of the 38-ton guns on board the *Thunderer* have made known the substance of their report, it is no longer necessary to suspend judgment and withhold comment for fear of prejudicing the case. The abstract only of the report of the Committee, which has reached us by telegram, states that the explosion was due to a cause, which, as far as we are aware, was not anticipated by any one of the numerous writers who have made suggestions or advanced theories on the subject. They simply report that the gun having missed fire when loaded with the battering charge, was again loaded with a full charge, and fired with both of the charges in the gun at the same time. We are bound to assume that conclusive evidence of this extraordinary occurrence has been obtained by the Committee, or the statement would be simply incredible. Cases are recorded in volley-firing of a soldier loading charge after charge into his musket or rifle in the days of muzzle-loaders, being unaware that the first had missed fire until the violent explosion, and perhaps bursting of his piece, or the apparent growth of his ramrod showed that something unusual was taking place, but that a squad of blue-jackets serving a 38-ton gun should be unaware, or even uncertain, if the 110 lb. of powder they were supposed to be firing had exploded or not is beyond comprehension. Even if the two guns in the fore turret were being fired simultaneously by electricity, the absence of recoil would have alone been sufficient to indicate that the gun had missed fire. That the rammer did not pass home might, it is conceivable, have escaped notice in loading the second round with the hydraulic gear, but we must look to the report of the Committee for some explanation of the first miss-fire having escaped notice.

In the many suggestions that have been made respecting the probable cause of the disaster by the writers of letters to the daily and weekly papers, it appears to us that a too low estimate has generally been made of the strength of the gun. It has been assumed by many that if it could be shown that the projectile slipped forward in the bore on the withdrawal of the rammer, a sufficient cause for the accident had been discovered. Experiments were at once tried at Woolwich which established the fact that when no ring-wad was used the shot frequently followed the rammer on its withdrawal for a distance of three or four feet. Instances have also been given of the bursting of fowling-pieces through an accidental stoppage of the muzzle by snow or a wad, and it was thought by many that a clear case had been made out for the cause of the explosion. Sir William Palliser's experiments, however, disprove the truth of this suggestion, for, many years ago, in firing an experimental 8-inch gun with various air spaces up to four feet between the powder charge and the shot, he found that there was no dangerous pressure in the bore. The gun made use of in this experiment was an old cast-iron 68-pounder which was converted into an 8-inch rifled gun, on Sir William Palliser's system by the insertion of a coiled wrought-iron tube $2\frac{1}{2}$ inches thick. This gun was fired with 22 lbs. of powder and a shot of 180 lbs. weight, with successive air spaces of 10 inches, 20 inches, up to 50 inches between the powder and the shot, and sustained no damage. Sufficient experiments have not yet been made to indicate accurately all the variations of pressure that would be introduced by an air-space between the powder charge and shot, but the only cause which would tend to raise the gas pressure, and in particular the longitudinal and twisting strain on the gun, above that due to an ordinary discharge is the fact that the pitch of the rifling would be sharper where the projectile started in the former case than in the latter. In the case of a fowling-piece the cause of bursting with a slight stoppage at the muzzle is probably due rather to the weakness of the barrel at that part than to the excessive pressure. In the 38-ton gun, with the heaviest charges employed on service, the central part of the length of the gun known as the 1 B coil is probably amply strong enough to resist the pressure brought to bear upon it, even if the shot was in this part of the bore and the maximum gas-pressure exerted. Although it has been shown by the report of the Committee that none of the conjectures as to the cause of the accident is correct, there is still utility in examining them, for, if valid, they might bring about a similar accident at some future time, and should therefore be provided against. Though the running forward of the shot when the gun is much depressed for loading with the hydraulic gear would cause but a small risk of explosion to the gun, it is so undesirable for many other reasons, that means should be taken to render it impossible, or at least render its detection a certainty. The means at present employed to obviate the shifting of the shot when once rammed home, consist of a ring wad which fits round the pointed head of the shot, and is firmly wedged in between it and the bore. Here again we are provided with a very possible chance of an accident. The two letters of Sir William Palliser published in the *Times* pointed out what appeared to us, before the publication of the report, by far the most probable solution of the problem: it consisted simply in the employment at the same time of a gas-check and a ring-wad. As clearly pointed out by Sir William, it is merely a question of the relative coefficient of friction between the shot and the wad and between the wad and the surface of the bore, which has to decide whether the wad is forced along the bore when the shot commences to move, or whether the head of the shot is forced further into the wad, wedging it tightly against the surface of the bore. This action would be impossible without the employment at the same time of a gas-check, as the gas rushing past the shot would inevitably dislodge the wad. The gas-check consists of a cupped disk of copper with the periphery turned down so as to form a flange; this is fitted to the base of the projectile, and, when fired, the pressure of the gas causes the flange to expand and press firmly on the surface of the bore, both in the grooves and in the lands between them, thus preventing the passage of the gas past the shot. Sir William says: "With regard to the friction between the wad and the gun, it is a fact that when the atmosphere is moist the residue of the powder deposits itself upon the surface of the bore in a black, greasy substance which reduces friction to a very low point. On a dry day, however, this deposit assumes the

form of a hard, dry, and rough coating like emery paper, and the friction in the bore is increased to a very large extent." Thus it may readily be seen that under varying circumstances the requisite conditions are very likely to occur, and experiments should most undoubtedly be undertaken to test the validity of this source of accident, and we think that great credit is due to Sir William Palliser for having been the first to point it out. Yet another cause has been insisted on as likely to bring about the destruction of some of our Woolwich rifled guns. In a paper read by Prof. Osborne Reynolds at the meeting of the British Association at Bradford, it was shown that the system of rifling employed at Woolwich, giving a gradually increasing twist to the grooves, threw a much greater strain on the gun than a uniform twist, and rendered it impossible for the studs on the shot to fit the grooves with accuracy throughout the whole length of the bore. The objections raised by Prof. Reynolds have, we believe, remained unanswered and perhaps unnoticed now for five or six years by the departmental officers, and during this time many hundreds of guns have been constructed on the condemned principle. Now that so much public attention is being directed to the whole system of gun manufacture as carried on at Woolwich, and the criticisms adverse to its merits are so numerous it would be well that the country should have further assurance that the system is founded on a safe scientific basis, or that the errors, if they exist, should be admitted and rectified.

It is admitted that with the increasing twist in the rifling the shearing of the studs has frequently shown that the projectile has some difficulty in centring itself in the bore while the great wear in the steel tubes of the guns occasionally used for practice on board ship points to a short life for the gun, but we are not aware that the destruction of a gun has hitherto been traced with certainty to the jamming of the studs between two grooves. In the event of this occurring it is shown conclusively by Mr. Longridge, in a letter inserted in *Engineering* last week, that the strain would be far more than sufficient to burst the gun. The bursting pressure of the gases would easily split the tube and coils, or the energy of the shot if only moving with a moderate velocity would cause a longitudinal stress which the steel tube would be quite unable to resist.

It may appear to some useless to draw particular attention to the various causes of this terrible accident that have been suggested now that the report of the Committee has been made known and has shown that all the suppositions are equally erroneous, but in our opinion it is of the utmost importance that these dangers to which we direct attention and which might at any time cause a similar accident, should not be passed over and forgotten.

CAPTAIN COOK

IT seems on first thoughts rather a strange proceeding to publicly celebrate the centenary of the death of a great man, especially when that death was a murder. But this is what the Paris Geographical Society have arranged to do to-morrow in the case, not of any of their own explorers or navigators, but in the case of England's greatest exploring navigator, Captain James Cook, who was murdered 100 years ago to-morrow by the natives of the Sandwich Islands. But we know that the generous-minded Frenchmen do not intend to rejoice at the death of this great man, as they would do were it his birth they intended to commemorate. Cook, they know, was one of the greatest of geographical explorers, and it is quite natural and commendable that the Society, in their enthusiasm for their science and its promoters, should wish in some way to show their reverence for a man like Cook on the centenary of his remarkable death. Cook, and with him England, owed some gratitude to the French, whose government of the time, though at war with this country, generously gave instructions to their war-ships and colonial governors, not only not to molest Cook in his pursuit of knowledge, but to render him all reasonable assistance. It is obvious that only about every third generation can take part in celebrating the centenary of a man's birth, and it is natural, therefore, that those of the intermediate generation who count him among their heroes, should take advantage of the occurrence of the centenary of his death to show their appreciation of his greatness. In Cook's case birthday and death-day were only about half a century apart, the date of the former being October 27, 1728.

Why our own Geographical Society should have left it to our French neighbours to commemorate so remarkable an event in the history of geographical discovery, we cannot undertake to say, though it seems to savour somewhat of dog-in-the-manger that they have declined the invitation to send an official representative. It would surely have been easy for them to have organised some kind of demonstration that would both have honoured the memory of one of our greatest naval heroes and most scientific of navigators, and at the same time have proved both interesting and instructive to the public. However, England will not be entirely unrepresented to-morrow, as we understand the Admiralty are contributing several original charts to the exhibition of the Paris Society. Mr. Brassey, who has visited the spot where Cook was killed, has sent to the Society a number of views and documents to be exhibited. Mr. Jackson has also promised to send valuable maps and manuscripts from Cook's own hand. Researches will be executed in the Archives to discover the original of the *Ordre du Roi*, forbidding French cruisers to molest Captain Cook's expedition, and in spite of the declaration of war, to assist him if necessary for the fulfilling of a mission interesting the whole of mankind.

We need not recount the claims of Captain Cook to be regarded as one of the greatest, as he was one of the most scientific, of navigating explorers; probably there are few of our readers who have not at one time or other read some account of the voyages of Captain Cook. The son of a peasant, he rose to his honourable position by sheer force of genius and its invariable accompaniment, hard work. To him we owe the discovery of the Sandwich, and many other Pacific Islands. His enthusiasm on behalf of science was manifested in his work at Tahiti in connection with the memorable transit of Venus of June 3, 1769. He gave certainty to our knowledge of New Zealand, and left not much to be done to fill up with accuracy an outline of the coast of Australia. He proved

that that continent was unconnected with New Guinea, and above all, dispelled the long-lived illusion of a great southern continent, having been the first to cross the Antarctic Circle. At high south latitudes he sailed nearly all round the confines of the Antarctic, adding greatly to a knowledge of the geography of this unknown region, and proving once for all, as we have said, that a "great southern continent" was a delusion, at least outside the Antarctic Circle. A comparison of the maps of 1762 and 1785 will serve to show how much was accomplished by Cook in this direction. In his second voyage of three years, 1772-75, Cook sailed over 20,000 leagues in the Pacific and Southern Oceans. And it was not only geographical knowledge that was thus advanced by his skill and determination. He was always accompanied by a staff of scientific specialists, to whom he gave every opportunity of pursuing research in their own departments, and thus of adding enormously to a knowledge of the natural history (in its widest sense) of great tracts of our globe. In the Transit expedition, for example, he was accompanied by the young Joseph Banks as naturalist. His third, and fatal voyage, was undertaken mainly for the discovery of a North-West Passage, Cook and Capt. Clarke sailing in the *Resolution* and *Discovery* from Plymouth in July, 1776, and after a roundabout voyage by the South Pacific, the Sandwich Islands were discovered on January 18, 1778. After attempting to penetrate the Arctic Ocean, he was compelled to turn back, and resolved to spend the winter in completing the survey of the Sandwich Islands. Here, as almost everywhere else that he went, Cook won the hearts of the natives by his gentle, firm, and perfectly upright dealing, in this respect being a pattern to all explorers. The end is too well known, and we need not repeat the details of the sad event which happened at Karakakooa Bay, on the south side of Hawaii, on February 14, 1779. No blame can be attributed to Cook, and, probably, very little to the natives themselves. Had the lieutenant who accompanied Cook on shore, and the sailors themselves, possessed a little of his tact and true bravery the catastrophe might have been prevented. There is reason to believe that the islanders regarded Cook as a sort of superior being, a kind of heaven-sent messenger whom they half-expected, and that they actually worshipped him as a god. Indeed it has been said that it was only when the first stunning blow from a club proved him human that their chagrin and disappointment vented themselves in barbarous massacre. There seems no doubt that the natives were sincerely sorry for what had occurred, and continued to worship his memory, if not his bones, for long after. It is commonly stated that his remains were obtained and buried in the sea, but we would refer our readers to a remarkable story published in NATURE, vol. viii. p. 211. From this it would seem that the large bones of Cook's body had been retained by the islanders, and tended and enshrined as those of a hero, if not of a deity. Whatever amount of truth there may be in the details of this story, it, along with other evidence, tends to prove that the catastrophe was a sad mistake, regretted by none more than the natives themselves.

Cook's instincts were thoroughly scientific, and he did all that his circumstances would admit of to qualify himself to carry on his great and important work on the basis of scientific principles. The results show that all things considered science profited largely by his labours, and that to-morrow a foreign society will strive to keep green the memory of one of England's most scientific navigators, one of her ablest and most lovable sons.

THE SAMOAN LANGUAGE

A Grammar and Dictionary of the Samoan Language. By the Rev. George Pratt. Second Edition. Edited by the Rev. S. J. Whitmee, F.R.G.S. (Trübner and Co., 1878.)

THIS is perhaps as complete a guide to the study of the Samoan language as could be expected under the circumstances. It consists, properly, of four parts: a grammar, which, for obvious reasons, is necessarily disappointing; a chapter on the native poetry, which would be much more useful were the specimens given accompanied by a translation, or at least by more copious notes; an English-Samoan vocabulary of about 4,500 fairly well-selected words, and a Samoan-English dictionary of more than double that number of terms. The editor informs us that many of the names of the indigenous flora and fauna collected by him still remain to be published. They will doubtless be embodied in the large "Comparative Polynesian Dictionary" he is now preparing, and when this is done we shall have at last a well-nigh complete dictionary of the most typical of the eastern Polynesian languages.

The grammatical portion of the work, notwithstanding the many extremely useful and suggestive additions of the editor, still leaves so much to be desired that we cannot but regret he did not re-cast this whole section, and give us a treatise more in harmony with the present state of linguistic studies. When we read in Mr. Pratt's preface that he was led to prepare a Samoan syntax "by observing, while reading Nordheimer's Hebrew grammar, that the Samoan in many points resembled the Hebrew," we feel at once that it would be hopeless to expect from him a sound exposition of the structure of this language, and the most cursory glance fully confirms this anticipation. Hebrew is a member of the Semitic family of languages, and is consequently an inflecting tongue. Hence it can have nothing beyond mere coincidences in common with the Eastern Polynesian group, which has scarcely yet got much beyond the isolating state, of which Chinese is typical. Its position, in fact, is quite unique, and until its true character is thoroughly realised we shall never get a rational treatment of the subject. This obvious truth was largely recognised by Gaussin, which at once explains the satisfactory nature of his work. Had it been based on the Samoan instead of on the Tahitian and Marquesan dialects, the result would doubtless have been still more satisfactory, and he would have avoided some of the misconceptions which detract from the value of that treatise. Yet even so it incidentally throws more light on the real genius of the Samoan itself than does the present work. Here the treatment of the verb is especially meagre and irrational. The schemes of tense and mood occupy less than two pages, and each tense is illustrated by a different verb, *pule* (rule) for the present, *alofa* (love) for the imperfect, *sao* (escape) for the perfect,

&c. The consequence is, that we get no general scheme at all of any given verb, which, however, is perhaps the less to be regretted, inasmuch as there are no true verbs at all in the language. These Eastern Polynesian tongues have certainly got beyond the purely isolating state of the Chinese, in which each root passes in its unmodified state directly into the sentence, where it becomes a true word only in virtue of its position. But they have not yet reached the next, or agglutinating state, because in them all parts of speech are not yet clearly differentiated. The so-called verb is merely a nominal predicate with the various temporal, personal, and modal relations more or less clearly expressed by determining particles. Hence the so-called second person present *e pule 'oe*, here rendered "thou rulest," is made up of the enunciative *e* equally applicable to present and future time, to the infinitive and to other words such as all the numerals (*e tasi* = one, *e lua* = two, &c., with which cf. *a* hundred, *a* thousand, &c.), of the noun *pule* = order, command, rule, and of the pronoun *'oe* = thou. Thus, the whole expression merely attributes the rule or command, that is, *the thing* in a vague way to the subject, and seems scarcely to convey the idea of action, that is, of the use of the thing as does the true verbal form *regis*, thou rulest, in which the original nominal conception is completely absorbed in the idea of action. We thus see that the verb, as a distinct part of speech, is not yet developed, though there is an evident tendency towards its evolution. Hence these so-called verbs are incapable of any change to express mood, tense, person, and even the plural forms, in which reduplication plays such a large part, are adjectival, as may be seen by comparing *sisina*, the plural of *sina* = white, with *nonofo*, the plural of *nofo* = to sit. On these plural forms the editor supplies some excellent supplementary matter at pages 13–16, which throws a strong light on the great influence of euphony in the development of language in its earlier stages. His remarks on the subtle distinction between the particles *a* and *o*, roughly corresponding to our possessive, are also very good. If to the active or transitive and passive or intransitive notions obviously involved in the use of *a* and *o* respectively, we add those of the *voluntary* and *involuntary* states, nearly all the difficulties will be removed, and the law may be confidently laid down that *a* is used with objects over which we have *free control*, *o* with those we possess, so to say, independently of ourselves, and which we must use in a definite way. Thus: *lona fale* = his house, *i.e.*, which he needs must use as a place of refuge or shelter; but *lana va'a* = his canoe, which he can apply to twenty different purposes. So also in the Tahitian: *ta'u va'a* = my canoe; *to'u fare* = my house; for such is the amazing homogeneity of these eastern Polynesian languages that the most delicate distinctions are often found to pervade the whole group from New Zealand to Hawaii, or from Samoa to Easter Island after a separation in some cases of certainly not less than six hundred years.

Mr. Whitmee's notes betray altogether such a deep insight into the true genius of this linguistic family that we earnestly hope, when another edition of this work is called for, he may be induced to suppress the author's grammar, and give us in its stead a thoroughly rational treatment of the subject. It will then be also very desirable in all cases to give a literal, or at least a close, translation of the examples quoted in illustration of the various rules and principles laid down. Many phrases are given in the present edition which may be useful to those already acquainted with the language, but which, for want of such a translation, it is to be feared will be thrown away upon the ordinary student, who may not have the opportunity of consulting a teacher. In the actual condition of these languages particles necessarily play a very large part, and are constantly heaped up in the sentence to a degree that must be very perplexing to the beginner. Where possible these particles should be translated, and when this cannot be done, which is very often the case, their various functions in the sentence should always be carefully indicated. This may, no doubt, demand more space, but the space can be saved by giving fewer examples and explaining them thoroughly. A comparative table of Eastern Polynesian alphabets, illustrating the interchange of letters between the various dialects, and throwing some light on their peculiar phonetic system, would also be a desirable addition, and might be brought within the compass of one or two pages.[1] But the essential point will always be to treat the language from a rational standpoint, independently of all fanciful Semitic, Aryan, or other affinities. The eastern Polynesian group has only just emerged from the isolating or lowest stage of human speech, and still hovers on the verge of the agglutinating or next stage, and must be dealt with accordingly. Hebrew, the classical tongues, English, French, and all others familiar to us, have passed upwards from the isolating through the agglutinating to the inflecting state, and have, therefore, little in common with Samoan, Maori, Tahitian, &c., beyond the faint reminiscences, still lingering on, of their former condition. When these simple truths are fully recognised grammarians may be expected to treat languages with some regard to their individual character.

A. H. KEANE

COAL AND IRON

Coal and Iron in all Countries of the World. By M. Pechar. (Manchester and London: John Heywood, 1878.)

AMONG the results of the International Exhibition at Paris which has just closed its doors, the reports and other permanent records of the actual condition of the great industries of the world are certainly not the least valuable. Even where, as in the case of the work now under review, the materials of comparison are not wholly or mainly derived from the Exhibition itself, still from it have been derived the desire and perhaps the opportunity to execute the work on so complete a scale.

The international character of the book is obvious from every part, even of the title-page; this is the authorised English edition; the subject it professes to treat is Coal and Iron in all Countries of the World; its author, M. Pechar, is a railway director in Teplitz, Bohemia. And it must be confessed that the contents of the book do not belie the title-page. Indeed, the first page of the General Remarks which introduce us to them would lead us to suppose that we were going to be treated to a

review not merely of all terrestrial space but of all terrestrial time as well, we are carried back "over an incalculable number of thousands of years" to the prehistoric time of crude tools of flint, bone, horn, and the like, and so by rapid strides through stone and bronze and iron to these last days, on which the age of steel is dawning.

This, however, is only by way of prelude, and the author straightway settles down to his facts and figures. These latter are naturally so numerous that the general reader will hardly find the book as a whole a light or entertaining one; yet apart from the very high value of the statistics for purposes of reference, there is much in the book to interest every one who cares for his country's or the world's welfare.

First, a few words with respect to the character of the statistics. These of course vary in completeness and in accuracy with the respective development or otherwise of the countries concerned; or of these special industries. With respect to our own country tabular statements are given of the number of pits for certain years between 1854 and 1876; of the production in each coal-district for the year last named; of the total produce in each year since 1854 as well as for certain years previously; of the percentage of increase in production and in value; of the chemical constituents of all the more important coals (sixteen in number); of the comparative heating power and general utility of certain English and Westphalian steam-coals used by the German navy; of the average price of coal for each year from 1865 and for certain years before; of the chief purposes to which the coal is applied and in what proportions; of the growth of British railways, and of the coal traffic thereon as well as by sea and canal; of the growth of British shipping; of the coal exports, and of the chief countries importing these, with the weight and value of their respective amounts. Add to these similar tables for the iron and steel industries of Great Britain; and multiply the total by a similar number of tables according to their degree for other great coal and iron producers such as Germany, United States, Belgium, and France; add also every available form of statistics for other parts of the globe, from the Arctic Circle to the Cape of Good Hope, and from Japan to Morocco, and one will readily admit that as a book of reference the work must be invaluable.

But the book is no mere statistical abstract. These tables, numerous as they are, are only scattered here and there throughout a very full and valuable text. The history of the rise and development of the great coal and iron industries here and elsewhere is stated briefly but sufficiently: the relative advantages and disadvantages of the several competing countries in their material and social aspects are well indicated: such questions as those of labour, increased or improved means of transport, the near prospects of such inventions as the Siemens-Martin and Bessemer steel processes, Barff's process for preventing iron from rusting, electric lighting, &c., are also discussed; and finally, the *literature* of the subjects dealt with is shown under each head at length, so that those whose special requirements demand more than even this work can give them, are at least shown where they may find the information they desire.

At a time of such profound depression in both these important industries, one naturally is eager to discover any rift among the clouds which the large accumulation of facts here contained, or the conclusions of so wide and an accurate an observer, may disclose. There is doubtless a consolation of a selfish kind to be got from observing that the state of affairs as to depreciation in the value of collieries and ironworks, in the prices of iron and coal, and in the wages of the workmen, is apparently quite as bad among our competitors as among ourselves. Thus the average price of coal in Germany was, in 1873, 10*s.* 9*d.*, and in 1877, 5*s.* 7*d.*; the wages, after rapidly rising, have now fallen back to the rates prevalent ten years ago, while the character of the workmen has deteriorated, and their relations to their employers have been changed in every way for the worse. In the iron trade the 125 joint-stock companies lost in 1877 alone a sum equal to 8·9 per cent. of their aggregate capital, which amounts to £24,335,709; and this capital at present represents, according to the quotation of the Berlin share-market, a current value of about £7,335,000 only. One regrets to notice that M. Pechar's chief remedy for these evils appears to be a return to protective tariffs so far as they have been abolished, and an aggravation of them where they exist. He is profoundly convinced that for many years to come no country in the world can hope to compete in the world's markets or even in their respective home-markets, with Great Britain in any but minor special products.

M. Pechar, however, has good hopes for the iron industry generally and consequently for the coal industry, whose fortunes depend so closely on those of iron. He expects that in most of the *present* applications of iron, steel will shortly supplant it, but that the iron industry will not therefore perish, but on the contrary will find new and larger spheres, partly as subsidiary to steel, partly by in its turn ousting wood and other substances from many of their present uses, as for example in buildings.

But it is unfair to summarise M. Pechar's conclusions apart from the many considerations by which he supports them, and we must therefore refer the reader on this and other points to the book itself. It will amply repay his perusal.

J. MARSHALL

OUR BOOK SHELF

Natural History, Sport, and Travel. By Edward Lockwood. (London: Allen and Co., 1878.)

MONGHYR is a large district in Bengal, divided into two nearly equal portions by the Ganges. Here Mr. Lockwood has spent many years as magistrate, and during that period had the inclination and the capacity to gather much knowledge of the district and its people. He laments in his preface that during twenty years' service he met only one Englishman (a Professor of Botany) who could identify the most common trees and plants. This is certainly lamentable, especially for the ignorant themselves, who thus miss a great and constant source of enjoyment and a fine opportunity of adding to a knowledge of the productions of one of our most important dependencies. This modest little volume is a good example of what may be done by a man who makes no pretensions to have more than a "desultory" knowledge of natural history. Mr. Lockwood is a very good observer, and his book contains many valuable notes on the animals and plants to be met with in the district of Monghyr. He has much

also to tell us about the people and their mode of life, the places of interest in the district, sporting experiences, and the various kinds of culture carried on. Altogether his volume is interesting and a distinct addition to our knowledge of the district over which its author ruled.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

Weather, Past and to Come

SIMULTANEOUSLY with the appearance of some important remarks by Mr. Hyde Clarke, in the article "Sun-Spots and the Nile," NATURE, vol. xix. p. 300, I have been called up by a London clergyman of inquiring mind to answer the charge that a paragraph which he cut out of the *Times* last year, declaring on my alleged authority that that winter was to be severer in cold than any known for generations had been totally falsified by the event. I would request, therefore, Mr. Editor, a little space in your valuable pages for the following explanations:—

I give priority to Mr. Hyde Clarke, on account of his early labours in demonstrating a periodicity in human affairs, somewhat of the type of the sun-spot period subsequently discovered elsewhere. His remarks, too, now, of the probability of the existence of other periods of about 26 and 104 years, and that they "interfere," or mix up, with what he considers a ten-year period, are also worthy of note. In fact, they are the first public consent I have yet seen to my often insisted on conclusion from the Edinburgh earth thermometers, that the explanation of the eleven-year wave of heat exhibited there, being both immediately preceded and immediately followed by the deepest trough or wave of cold, for each whole eleven-year cycle on either side of it, was precisely caused by the near concurrence just there of two sets of waves of different periods of undulation. But when he goes on to say (line 38, p. 300) that such interference of two or more sets of undulations "prevented any absolute calculation as to the future," I object to the ruling of that sentence.

The complication may make the matter more difficult. It may oblige the State at last to set apart some good men for professionally prosecuting that subject, and to put them into a dungeon if they attend to anything else. But that is all! Two or three, even six or seven planets, pulling away at the earth and the earth at them in periods of different lengths and with different degrees of energy, do not prevent physical astronomers predicting the final outcome of it all on the earth's motion from day to day, and even minute to minute, and the alleged case of impossibility is only one of like kind.

But to the clergyman with the inquiring mind I would answer as follows:—

1. What I *did* write, in the summer of 1877, on the future weather is to be found at p. "25" of vol. xiv. of the "Edinburgh Astronomical Observations," a volume so liberally distributed by H.M. Government to scientific societies and libraries in London that no one there need have any difficulty in referring to my exact words if they are thought of consequence by any body.

2. Those words are, at all events, as to their general scope and bearing, widely different from the newspaper cutting alluded to. For while that treats only of a cold winter, my first and leading contention in the book was not about cold at all, but about heat. Namely, that the Edinburgh earth-temperature measures for forty years past show that a great *heat*-wave comes upon the earth from without, presumably from the sun, every eleven years, nearly; and that the date of the next such heat-wave was "1879·5, within limits of half a year each way." According to which the coming summer and autumn of this year may prove glowingly hot, and next winter unusually mild, in obedience to a grand cosmical action upon the earth as a whole. And who has yet disproved that?

3. My second, but only second and inferior, contention was, that such eleven-year heat-wave, of solar origination—contrary to the usual ideas of the learned as to the crest of a wave being removed from its trough or lowest point by about half of its length—was, in this case, both *immediately* preceded and *immediately* followed by a trough of extreme cold; the extremest cold, or lowest trough of each whole eleven years period on either side of the heat-wave's crest. Wherefore I contended (in 1877) that we had then still, between us and the good, warm time coming, a trough of extreme cold to wade through; and I did say that that preliminary cold-wave might be expected about 1878·0 "within limits of three-quarters of a year."

4. Because the winter of 1877-78 was not cold, and the winter of 1878-79 is now very cold, *in Great Britain*, the clergyman holds that my prediction was totally falsified. But to that conclusion I oppose the following consideration:—Is the surface of Great Britain large enough to be taken as expressing the condition of the whole globe under a cosmical influence from space without? Is not China much larger than the so-called Great Britain, and was not last winter preternaturally cold in China, with snow and ice down to the sea-coast even in lat. 29°, and inland such long-continued frosts and dry weather, that thence no crops, and the dreadful famine with depopulation of whole provinces?

Is not also the surface of North America larger than that of Great Britain; and at a central station of the former, Manitoba (as worthily reported and notified by Prof. E. D. Archibald in NATURE, vol. xix. p. 266) was not the December of the present winter astonishingly warm, almost hot, or no less than 25° above the mean temperature of former Decembers there?

5. Hence, if we look beyond our own immediate coasts, I suspect that the deficiency of radiation from the sun, called the cold trough, may have occurred, in reality, not far from the date I suggested in 1877, viz., in 1878·0. But as such influence from without has to act on the solid earth practically through the medium of an absorptive, locomotive, double revolving atmosphere, its full and extremest effects are experienced in different manners and at different dates in different parts of the earth.

Wherefore the "meteor" then becomes an affair for terrestrial meteorologists, not for astronomers, to follow up and explain; though the former may glean some useful hints from what the latter have long since ascertained as to the lunar tide-wave: viz., that it is raised, or coincides most nearly with a meridian full moon, near the middle of the Pacific; but at far different and later dates at other places, according to the length and difficulty of the path by which the tide-wave, once raised, has to travel to reach them. Sun-Spots and the Plague

Apropos of the plague—I do not know whether the following curious coincidence has been noticed. In that admirable work, John Graunt's "Natural and Political Observations upon the Bills of Mortality" (second edition, London, 1662), which is probably the earliest treatise on vital statistics, I find the following statement (p. 31):—"There have been in London, within this age, four times of great mortality, that is to say, the years 1592 and 1593, 1603, 1625, and 1636." He shows that large numbers died of the plague in each of these years. Now, if we take the solar period to be 10½ years, nearly in accordance with Dr. Lamont's and Mr. J. A. Broun's estimates, we get the subjoined table, which sufficiently explains itself.

Corresponding solar years.		
1592·5	... Plague in London	1592–3.
1603	... ,, ,, ...	1603.
1613·5		
1624	... ,, ,, ...	1625.
1634·5	... ,, ,, ...	1636.
1645		
1655·5	... Great Plague in Naples	1656.
1666	... ,, of London	1665.
⋮		
1718·5	... ,, at Marseilles ...	1720.

If this particular coincidence has not already been pointed out, it deserves notice as supporting the theory that the rate of mortality is remotely connected with the solar period. There may be several chains of causation leading to the increase of mortality, but one chain is doubtless through the Asiatic famines, which would naturally develop the worst forms of germ disease.

W. STANLEY JEVONS

On the Combustion of Different Kinds of Fuel

I HAVE read with interest the criticism of Mr. I. Lowthian Bell (NATURE, vol. xix. p. 175) on my paper on the mode of combustion in the blast furnace hearth. You say with truth that the question is not simply technical, but is one of scientific importance. The prevailing opinions, which Mr. Bell has expressed with his usual force, rest upon experimental determinations of the gases in the hearth. I have never felt that trustworthy results have been obtained in any of the published analyses, and with your permission I would like to state the case, and see if my difficulties are removable by the wide experience of Mr. Bell or other investigators.

The blast-furnace hearth is a cylinder, closed at the bottom, but perforated near the top by a number of openings in which the tuyeres, or ends of the air blast-pipes are closely fitted. The air enters at a pressure which usually varies in anthracite practice between four and seven pounds to the square inch. As the discharge is at the top of the furnace, many feet higher, the air must describe a curved path from the point of entrance to the centre of the furnace, being acted upon continuously by a horizontal and a vertical force. It is evident that the level of the tuyeres is not the place to obtain the first products of combustion unless they are drawn through a tuyere in action. Elsewhere the samples would not be taken from the path of the air, which is upward from the tuyere from the instant it enters the hearth.

Mr. Bell and other investigators have analysed gases drawn from the hearth by means of porcelain tubes introduced through a closed tuyere aperture, or through holes drilled between the tuyeres. It seems to me these analyses are vitiated by the mode of drawing off the gas, and since this criticism applies to the experimental basis of existing views of combustion in confined spaces and with limited supplies of air, I will give a few details to show the scope of my objection.

At the Wear furnace Mr. Bell drew off gas through a tuyere that was closed for the purpose, but air was entering at other tuyeres on each side and four feet distant. Certainly this did not represent the product of that active combustion which takes place in the path of the air, but of these products after they had filtered through nearly four feet of glowing fuel. What the exact distance was depends upon the velocity of gas in the crucible of the Wear furnace and the inner diameter of the hearth, but was probably over three feet.

The quantity drawn off is not mentioned, but as it was taken for eudiometric analysis, the amount was probably less than five litres, and the movement of the gas through this glowing coal to the sample tube must have been extremely slow. Under these circumstances, whatever the product of combustion in the path of the air may have been, there could be only one gas drawn into the sample tube, and that would be carbonic oxide mixed with nitrogen. Even if we assume that the product of combustion in the furnace is carbonic anhydride alone (which is not true), this would be completely reduced to carbonic oxide by passing through the hot coal.

The experiments made on gas which was drawn through tubes in holes inserted between the tuyeres do not impress me more favourably. There the tubes were thrust "a little way into the contents of the furnace." That description does not apply to the mode in which gas samples were drawn off for analysis, but to experiments for testing the reducing powers of the gas by submitting pieces of ore to its action. Still it is probably also the mode in which samples were obtained, and the object of this note is to ascertain whether more careful means of sampling the unchanged products of combustion were used. If not, I submit that the analyses which form the basis of all modern reasoning on this subject must be rejected. The rapidity with which red hot carbon reduces carbonic anhydride, and produc s just the gas which experimenters find in their sample tubes, is well known, and methods of sampling which take no precautions to guard against this change cannot be accepted. I think the investigators owe it to science to give the world some hint of the means they have used to prevent this action, and to obtain the gas as it is formed. In the case of one of our American furnaces—a small on —the blast has an upward velocity of twenty feet per second at the level of the tuyeres, without considering the increase of volume by its rise in temperature in the furnace, and also allowing it to penetrate *instantly* to the centre, so as to cover the whole ar-a of the crucible. That cannot be true, and on the other hand the withdrawal of gas from the walls at the tuyere level, while the air is entering with great velocity four feet away, can hardly give a fair sample of the unaltered result of immediate combustion.

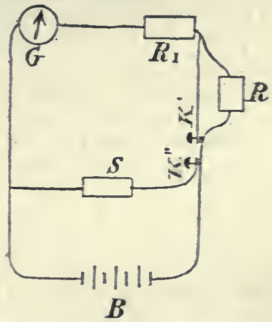
Internal Resistance

THE following method of measuring the internal resistance of a battery was devised some two years ago by Lieut. A. R. Conden, United States Navy, then attached to this station as Instructor in Electricity. It fulfils quite closely the conditions indicated by Clerk Maxwell on p. 412, vol. i. of his treatise on Electricity and Magnetism. As it is not generally known, I venture to call your attention to it.

In the figure, B is the battery, G a galvanometer, R and R_1 resistances, K″ a key for introducing the shunt S, and K′ another key for shunting out the resistance R.



When both keys are open the current through the galvanometer is—

$$S_1 = \frac{E}{B + G + R + R_1}.$$

When both keys are closed the current from the battery divides, part going through G and R_1, part through S. The current through the galvanometer is now—

$$S_2 = \frac{E}{B + \frac{(G + R_1)S}{G + R_1 + S}} \times \frac{S}{G + R_1 + S}.$$

If $S_1 = S_2$, then—

$$\frac{E}{B + G + R + R_1} = \frac{E}{B + \frac{(G + R_1)S}{G + R_1 + S}} \times \frac{S}{G + R_1 + S}.$$

Solving for B—

$$B = S\frac{R}{G + R_1}.$$

Finally, if R have been adjusted equal to $G + R_1$, then—

$$B = S \text{ directly.}$$

In practice R is a rheostat unplugged to equal $G + R_1$, and the two keys are combined in one. If the current be small enough with $G + R$ then R_1 may be omitted and R made equal to G. S is adjusted until, upon closing the double key, the deflection of the needle remains unchanged. The resistance of the battery is then the resistance of the shunt.

The case and concordance of the results obtained in this way through long series of measurements are no less striking than the rapidity with which the observations may be made.

Torpedo Station, Newport, R.I., January 12 — C. F. GOODRICH

The Formation of Mountains

MR. G. DARWIN has shown that, on the supposition that the earth is a cooling solid, the depth at which the maximum cooling and consequently, in all probability, the maximum contraction takes place, moves downwards, and, taking Sir W. Thomson's values of the constants, has not yet got down so far as 100 miles.

This shallowness of the layer hitherto chiefly affected is alone sufficient to prove how small an effect can be attributed to such a cause.

He inquires whether I may not have under-estimated the contraction of rock in cooling. In my calculation I put it at ·00007 linear for one degree Fahr. I derived this estimate from

the consideration of Mr. Mallet's experiments on cooling slag run from an iron furnace.[1]

This coefficient is somewhat larger than the mean of those obtained by Mr. Adie[2] for much lower temperatures. The mean of six of his values, half of them being for moist rock and half for dry, I find to be ·0000057.

Mr. Darwin recalls attention to M. Favre's experiments (out of which the present correspondence arose). M. Favre's experiments illustrate well the structure of an alpine district. But I would observe that, if ours is a cooling solid globe, and if that would give rise to such surface structure, we ought to find it everywhere, and not confined to definite geographical areas, as we do. O. FISHER

Harlton, Cambridge, February 8

Concerning the Colour of Eyes

MAY a portrait painter be allowed to remark that there are two kinds of green eyes, and the poets have duly appreciated both. The eye of the "green-eyed monster" is, no doubt, the cold grey, or stony blue eye, overspread with the yellow of biliousness, hence green; but when Dante called the eyes of the beatified Beatrice *emeralds* he did not mean to insult her. The image called up by his ecstatic words is that of those deep, soft eyes which are a warm brown in some lights—for instance with the light falling on them from one side only—and take a grey tint when facing the light of the sky, and green tints at other times, according to the lights that fall upon them; and are therefore sometimes a puzzle to portrait painters. Eyes, like the sea and precious stones, catch lights and transmute them. The sea is only green from the meeting of sunlight and blue sky light in it. J. M. H.

P.S.—Has it been remarked that the distinction between yellow and blue tints—the only one made by the colour-blind, according to Dr. Pole—is precisely the same as that made by the sun in photography: all the warm tints (as an artist—who makes the same distinction—would call those partaking of yellow) coming out darker, and all the cold ones—or those partaking of blue—lighter than in the object photographed?

Intellect in Brutes

A CORRESPONDENT in NATURE, vol. xix. p. 268, describes the actions of a water-rat which, he says, climbed up to a window-sill, inconvenient of access, and thirteen feet from the ground, in order to get some bread which was habitually put there for the birds during the cold weather. As the rat had never found food there before, the writer concludes that his conduct cannot be attributed either to instinct or to experience, but must be ascribed to a process of reasoning based on the observation of the flocking together of the birds, and the inference that they must be attracted by food. Now it seems to me that before we ascribe to a rat such complicated reasoning powers it is necessary to ask if there is no other, simpler, way of accounting for the phenomenon. I think there is. It is well known that different species of animals vary greatly in the acuteness of their senses. To man, sight is the most important sense, and the same is true of many other animals, and most birds. The cat is a representative of another, smaller, class of animals, whose most perfect organ of sense is the ear; while the dog lives in a world of sensations, the most important of which are contributed by the sense of smell. To this last class belongs the rat, which is noted for the acuteness of its scent. It is evident, therefore, that the water-rat in question was led to the window-sill by his nose, which, in his case, was a more trustworthy guide than his eyes would have been. I do not wish to deny, by any means, that animals have reasoning powers. On the contrary, I am convinced that human and brute intellect differ only in degree, not in kind; and I even adopt Haeckel's "cellular psychology," which attributes the elements of intellectual life—sensation and volition—to infusoria and organic cells in general, in opposition to the older "neural psychology," according to which psychic activity begins with the nervous system in the scale of animal life. But what we have to guard against is not to ascribe to animals reasoning powers of a higher type than is consistent with the development of their brain, especially when the actions which seem to postulate such powers can be readily accounted for by simply bearing in mind the extraordinary acuteness of one or more of their senses. We are altogether too prone to judge the intellectual life of animals by the human standard, to imagine that the eye is everywhere, as with us, the leading source of knowledge; and the neglect of the important *rôle* which the sense of smell plays in animal life has been particularly fruitful of errors in philosophical speculation. It has, among other things, helped to give a longer base of life to the old theory of instinct, regarded as a mysterious power of nature.

Ear Affection

THE remarkable phenomenon described by your correspondent "P," in NATURE, vol. xix. p. 315, induces me to bring to your notice that precisely the same effect was produced in my own case a month ago, when partial deafness came on in both my ears, whilst suffering from congestion of the mucous membrane of the nasal passage and eustachian tube. Not being aware that any prior case had occurred of a distinct difference of a semitone, as indicated by the alternate application of a tuning-fork to the two ears, I at once drew up a memorandum on the subject, and handed it to Dr. Urban Pritchard, who was advising me. Like your correspondent "P," I have also noticed the double sound produced when I whistle, and more particularly when I close both ears with my fingers. G. L. WALLICH

February 11

Bees' Stings

THE American *Quarterly Microscopical Journal*, published last October in New York, contains an elaborate article on "The Sting of the Honey Bee," by J. D. Hyatt. Mr. Hyatt's experience does not tally with that of your correspondent, R. A. He says: "By allowing the bee to sting a soft piece of leather an excellent opportunity is offered for studying the action and mechanism, for the whole apparatus will be beautifully dissected, the *bee not appearing to be seriously injured by the loss*." I should be happy to send the journal to R. A. if I knew his address. W. RADFORD

Sidmouth

Electric Lighting

I NOTICE in an article in NATURE, vol. xix. p. 262, the following reference made to our electric light that it "does not appear to give very great satisfation through its fluctuation." It is true that at first we were caused some trouble owing to the Serrin lamp not working properly, but having overcome the difficulty we find it in our business, where it is necessary to show colours correctly, a very great improvement on all our former trials of lighting, and moreover, in its use we are not troubled in our galleries and upper floors with the heat and fumes which with gas alight no amount of ventilation seemed to remove.

It is not a pleasant light to read or write by owing to a certain flicker which seems common to all the regulators, but in warehouse or show-room use this does not cause any inconvenience, and we think in large places, especially those already having motive power, that it must eventually supersede gas.

Regent Street H. J. NICOLL

RELATION OF METEORITES TO COMETS[1]
II.

THERE are two classes of shooting stars which have been sometimes spoken of as unlike, but which are now admitted on all hands to be of common origin and character, namely, those which come in quantities on certain nights of the year, and give what is called a star shower, and the sporadic meteors, such as we can see on any clear night.

In November, 1799, von Humboldt saw during his travels in South America, a shower of shooting stars, and he has given a glowing description of the sight. These came on the morning of November 12. In 1832, November 13, there was seen in Europe a display of less brilliancy. It, however, attracted not a little atten-

[1] A lecture delivered in the Mechanics' Course at the Sheffield Scientific School of Yale College, U.S., by Prof. H. A. Newton. Continued from p. 317.

tion, as descriptions and newspaper notices show in every country in Europe. But no person seems to have connected it with any previous shower, nor does it appear that any one gave a hint of the true nature of the phenomenon.

The next year there appeared in this country, on the morning of November 13, a more brilliant shower, which some present doubtless witnessed. Through the morning hours of that day the stars shot across the sky like the flakes of snow in a snowstorm. Not a little difference was there in the way people looked at it. The negroes at the south thought the day of judgment had come. The owner of a plantation told me that his negroes had gathered in the "praise-house," and that he on being waked went down to quiet their fears. They had concluded not to call "Missus," as she would soon hear Gabriel's trumpet, and they well knew that she was ready to go. A student here in College was going to prayers, and saw a ball of light pass across the half lighted moving sky. He rubbed his eyes, thinking that something was the matter with them. A second flight made him sure that his eyes were troubled, and he looked down and hurried on to chapel. A servant girl by chance returning home in the early morning, saw it, but said nothing until it was talked of the next day. "Oh," said she, "I saw that." "Did you? Why did you not call us?" "Really, I didn't know but that the stars went out that way every morning." Prof. Twining saw it, and observing that all the flights were away from one point in the heavens, and that that point moved along with the stars as they rose in the morning sky, he said, "These are not, as some say, meteorological phenomena; they are not, as others say, electric; these are bodies coming to us from beyond the air, and they belong to astronomy." This was the first definite proof of the cosmic origin of meteors.

Nine hundred and thirty-one years earlier, that is, in the year 902, there was a like brilliant shower of fire. A cruel Aghlabite king then reigned at Tunis. He had driven the Christians out of Sicily, penning up the Bishop of Taormina and the remnant of his people in the church, and burning it and them together. He had crossed to the mainland, and was besieging Cosenza, then an important city of Calabria. He suddenly died, and the flying monks were relieved of their terrors. They connected his death with the star-shower which occurred at or near the same time, and in all the annals it is repeated in varied phrases that on the night when King Ibrahim Bin Ahmad died an infinite number of stars scattered themselves like rain to the right and left.

Between the years 902 and 1799 the November meteors were seen in unusual numbers in at least nine different years. The showers in the table which I show you are not selected out of an indefinite number in our histories. On the contrary, they are nearly all which we have found in the records as having occurred near that time of year.

Epochs of November Star-Showers

Year.	Day.
902	October 13
931	„ 16
934	„ 14
1002	„ 15
1101	„ 17
1202	„ 19
1366	„ 23
1533	„ 25
1602	„ 28
1698	November 9
1799	„ 12
1832	„ 13
1833	„ 13
1863–68	„ 14

Notice now in this table that the showers came either near the beginning or near the end of the first third, or else near the end of the second third of the century. In other words, they all come near the end of a cycle whose length was 33¼ years. Again, notice that the day of the month advanced with slight irregularity about three days in the century. The large advance of twelve days between 1602 and 1698 is due to the change of ten days in the reckoning in passing from old style to new style.

I have added, as you see, the six years from 1863 to 1868, in each of which, but especially in the latter three, these meteors came, as we had expected, on the morning of November 14. They seemed in all these years to pass, as they did in 1833, across the sky, as though going away from the constellation Leo, or rather from the sickle in Leo. This means that the small bodies really came into the air in parallel lines, the apparent radiation being the way in which parallel lines appear to us. There can be no doubt that there was the same parallelism of paths in all the earlier star-showers.

Here we have a group of solid bodies coming into the air all moving in one given direction. They come to us only on a particular time in the year, for the slow change from the middle of October to the middle of November can be explained. They come to us only at intervals of about a third of a century. These facts can only be satisfied by supposing that vast numbers of these small bodies are moving in a long thin stream around the sun, and that the earth, at the proper times, plunges through them taking into the air each time some scores of millions of them. Each of them must be moving in an orbit having the same period as every other, and approximately the same path.

Now it may be shown that there are but five orbits about the sun that can meet these conditions. Further than that, there is but one of these five that can explain the change of date from the middle of October to the middle of November, and this fifth one does explain the change perfectly. I cannot in the time you kindly grant me give in such detail that you can clearly understand them, the reasons for thus limiting the path of the meteoroids first to five possible orbits, and then to one of these five. I must ask you to accept the statement in view of the fact that no astronomer has, so far as I know, ever questioned the proofs of it.

That orbit is one which is described in 33¼ years. The meteoroids go out a little further than the planet Uranus, or about twenty times as far as the earth is from the sun. While they all describe nearly the same orbit they are not collected in one compact group. On the contrary they take four or five years to pass a given place in the orbit, and are to be thought of as a train several hundred millions of miles long, but only a few thousands of miles in thickness.

Now right along with this train of meteoroids travels a comet. It passed the place where we meet the meteoroid stream nearly a year before the great shower of 1866, and two or three years before the quite considerable displays of 1867 and 1868. It was therefore well towards the front in the great procession.

How came it that this comet and the meteoroids thus travel the same road—the comet with the meteroids and the meteoroids with each other? The plane of the comet's orbit might have cut the earth's orbit to correspond with any other day of the year than November 15. Or cutting it at this place the comet might have gone nearer to the sun or farther away. Or, satisfying these two conditions, it might have made any angle from zero to 180° instead of 167°. Or, satisfying all these, it might have had any other periodic time than 33¼ years; even then it might have gone off in any other direction of the plane than that in which the meteoroids were traveling. All these things did not happen by chance; there is something common.

The comet which I have named is not the only one that has an orbit common with meteoroids, though it is the only case in which the orbit of the meteoroids is

completely known aside from our knowledge of that of the comet. Every August, about the tenth day, we have an unusual number of meteors—a star-sprinkle, as it has been called. A comet whose period is about 125 years moves in the plane, and probably in a like orbit with these meteoroids.

So near the first of December we have had several star-showers—notably one in 1872—and these meteoroids are travelling nearly in the orbit of Biela's comet. In April, too, some showers have occurred which are thought to have had something to do with a known comet.

Thus much as to the meteors of the star-showers. The sporadic meteors are with good reason presumed to be (and observed facts prove some of them to be) the outliers of a large number of meteoroid streams, and the leading problem of meteor-science to-day is to find these streams so faintly shown, and, if possible, the comets they belong to.

Come back with me to the November stream and its comet. The several bodies move along a common path not at all by reason of a present physical connection. They are too far apart, in general a thousand times too far apart, to act on each other so much that we can measure the effect. No; their connection has been in the past. They must have had some common history.

Looking now at the comets, we see that they have been apparently growing smaller at successive returns. Halley's comet was much brighter in its earlier than in its later approaches to the sun. Biela's comet has divided into two, if not more than two, principal parts, and seems to have entirely gone to pieces. It could not be found in 1872, when and where it ought to have been visible. Several comets have had double or multiple nuclei. In the year 1366, in the week after the star-shower, a comet crossed the sky exactly in the track of the meteors. A second comet followed in the same path the week after. Both belonged no doubt to the November stream, and one of them may perhaps have been the comet of 1866.

This stream of meteoroids is a long thin one. In miniature it would be perhaps a mile long to an inch in thickness. We have crossed the stream at many places along a length of a thousand millions of miles, sometimes in advance of, and sometimes behind, the comet, and all along this length have found fragments, sometimes few, sometimes many. This form of the stream suggests continuous action producing it. A brief violent action *might* give this form, but a slowly acting cause seems more natural.

Again, in the history of Biela's comet we have distinct evidence of continued action. The comet divided into two parts not long before 1845, and yet in 1798 fragments of it were met with so far from the comet, that they must have left the comet long before, probably many centuries ago.

Thus are we led to say, *first*, that the periodic meteors of November, of August, of April, &c., are caused by solid fragments of certain known or unknown comets coming into our air; *secondly*, that the sporadic meteors such as we can see any clear night are the like fragments of other comets; *thirdly*, that the large fireballs are only larger fragments of the same kind; and *finally*, that this stone, which was broken off from one of those large fragments in coming through the air, must once have been *a part of a comet*.

Here I should naturally close, yet I am sure that you will ask, How came the comet to break up? Perhaps the prior question would be, How came the comet together? In its history there is much that we cannot yet explain, much about which we can only speculate. Thus, how came this stone to have its curious interior structure? As a mineral it resembles more the deepest fire-rocks than it does the outer crust of our earth. It seems to have been formed in some large mass, possibly in one larger than any of our existing comets. Some facts show that the comets have almost surely come to us from the stellar spaces. Out somewhere in the cold of space a condensing mass furnished heat for the making of this stone. The surrounding atmosphere was unlike ours, since some of these minerals could hardly have been made in the presence of the oxygen of our air. Either in cooling, or by some catastrophe, the rocky mass may have broken to pieces, so as to enter the solar system, having little or no cohesion, like a mass of pebbles; or, it may have come and probably did come, a single solid stone. In either case, as it got near to the sun, new and strong forces acted on it. The same heat and repulsion that develops and drives off from a comet in one direction a tail, sometimes a hundred millions of miles long, may have cracked off and scattered in another direction solid fragments. One of these contained in it this stone, and it wandered in its own orbit about the sun, itself an infinitesimal comet, how many thousands or millions of years we know not, until three years ago it came crashing through the air to the earth in Iowa. Thence this fragment came here to serve as a text to my discourse.

METEOROLOGICAL STATION ON BEN NEVIS

WE are glad to learn that the Scotch Meteorological Society's scheme of a station on Ben Nevis is evoking cordial support from those who have the administration of Government funds available for such objects. The London Meteorological Council, of which Prof. Henry Smith is chairman, has unanimously agreed to offer to the Scotch Society 100*l.* yearly towards the support of the station, provided a copy of the observations is sent regularly to London. This is at once testimony by the most competent judges to the importance of the scheme, and a proper encouragement to the Scotch Society to proceed in its spirited enterprise. We understand that to uphold the station and induce two competent observers to take it by turns to live on the top of the mountain with an assistant will cost about 300*l.* yearly. It is estimated that to purchase a full stock of instruments and erect a building for them and the observers a capital sum of 800*l.* will be required. The Scotch Society has applied for a grant of 400*l.* towards this expenditure from the Committee appointed by Government to distribute 4,000*l.* annually to encourage scientific research. We believe the Committee has not yet met to consider the various claims which are, no doubt, as usual made on the funds.

RESEARCH UNDER DIFFICULTIES

THE following short preface to a very valuable account of the stages of development from the egg of one of the centipedes (Geophilus), no member of which group had been studied previously to this account, gives so convincing a picture of the enthusiasm for investigation which may animate the modern naturalist, that it is worthy of a place in NATURE for the encouragement of the "craft." Elias Metschnikoff has during the past fifteen years worked more assiduously with the microscope at the observation of the minute details of embryology than any other student. To him we are indebted for our first accurate knowledge of this subject in the case of many important animal forms, *e.g.*, sponges, various jelly-fishes, marine worms, the scorpion, and the book-scorpions, various insects, crustaceans, starfishes, and ascidians. One result has been the injury of his eyesight. In reading to-day his memoir on Geophilus, published in 1875 (*Zeitschr. für wiss. Zoologie*), it occurred to me that the following passage has more than technical interest:—

"After having for many years sought in vain for material suited for the investigation of the embryology of the centipedes, I chanced to obtain a quantity of the eggs of

Geophilus. My find, however, took place under such circumstances, and these interfered so much with my investigation, that I feel justified in describing them more minutely. For some considerable time I had been afflicted with a chronic affection of the eyes, and consequently commenced in the spring of the present year a journey to our south-eastern steppes in order to turn my attention to anthropological studies. Instead of taking with me as in previous years all the apparatus necessary for microscopical research, I took this time on my journey only anthropological measuring instruments. When, then, I was in the neighbourhood of Manytsch, nearly in the heart of the Kalmuk steppes, and was visiting a small forest plantation, I discovered quite unexpectedly a number of eggs of Geophilus which had been deposited under the bark of a rotten tree-stem where the females were watching over them. I gathered up the precious material, and having packed it carefully in two bottles, set off with all speed to Astrachan, in order there to set about the microscopic investigation of the eggs. But when, after four days' travelling I arrived in a Russian village, Jandiki, near the shore of the Caspian Sea, and inspected my two bottles, I found in them only a couple of dead, opaque eggs, all the others having entirely disappeared. Fortunately I succeeded in Jandiki, where there is also a small plantation, in obtaining fresh material of the same kind, and this I brought in good condition to Astrachan, making the journey by steamboat. In the town of Astrachan I was able to borrow a Hartnack's microscope from a medical man practising there, and on a second journey took it with me to Jandiki. In this way I was enabled to make out the chief features of the developmental history of Geophilus by the use of my less seriously affected left eye. At the same time, in spite of the very favourable character of the Geophilus-eggs for microscopic research, I could not bring my work to the desired degree of completeness."

Determination and pluck have their scope in embryology! E. Ray Lankester

---

ON THE RECENT ERUPTION AND PRESENT CONDITION OF VESUVIUS

At the end of the great eruption of 1872 the crater of Vesuvius was left as a wide and deep abyss, the floor of which did not possess a very high temperature, and was free from fumarole. Gradually, however, fumarole appeared, the temperature increased, and large quantities of steam and carbonic acid were evolved. The temperature continued to increase and sulphurous acid made its appearance, finally in 1875 the evolution of carbonic acid diminished, and that of hydrochloric acid commenced. This is always the commencement of the highest stage of fumarole activity. In January, 1875, when I ascended the mountain, large quantities of sulphurous acid were being evolved, and it was quite impossible to descend into the crater. On December 18, 1875, a deep chasm opened in the bottom of the crater, at the bottom of which glowing lava could be seen. This was the commencement of a new period of eruption, which Palmieri predicted would last a long time, and which is still going on. The lava gradually rose to the top of the chasm, and a new eruptive cone was soon afterwards formed on the floor of the great crater. Small quantities of lava issued from time to time from the new cone, and spread over the interior of the crater, until on the night of November 1, 1878, it rose to the lowest portion of the edge of the crater, and began to flow down the great cone of Vesuvius in a north-westerly direction. The lava continued to flow in a somewhat intermittent manner until nearly the end of the year, but it did not go beyond the foot of the cone.

On December 29 last I visited the new cone. I left Naples at 8.45 A.M., drove to Portici, and walked to Resina. Left Resina on foot at 10 A.M., came upon the lava of 1451 (according to the guide, but I suspect it was lava of 1631) at 10.30, then bore somewhat to the west, and struck the lava of 1858. Reached the observatory at 11.15 A.M., the foot of the cone at 11.45, and the summit of the cone at 12.40 P.M. Thus the ascent of the cone occupied fifty-five minutes, including about ten minutes of rest. The angle is approximately 32°, and the ash of which the cone is composed is very loose. On arriving at the summit we turned to the west, and walked along the edge of the great crater, until we came to its south-western extremity, beyond which it is broken down by the recent flow of lava. Then we descended the crater by a very precipitous path, and presently found ourselves upon the new lava, surrounded on three sides by precipitous walls of apparently not more than 100 feet in height. Facing due north-east, we had on our right the new cone of November, 1878, and on our left the stream of lava which had issued from it, and which was still very hot, and in some places could be seen to be red hot a little distance beneath the surface. Occasionally a puff of very hot air was blown into our faces from the hotter portions of the lava. In many places hot fumes of hydrochloric acid escaped from the lava, and great cavities (in one or two cases small caverns), from whence the hot acid vapours issued, were coated with brilliant red and yellow sublimates of sesquichloride of iron. These sublimates are constantly spoken of as sulphur. I am inclined to assert that in more than ninety-nine cases out of a hundred, they are sesquichloride of iron formed either by direct sublimation of previously formed chloride from lower recesses in the lava bed, or by the action taking place then and there of the hot hydrochloric acid upon the exposed surfaces of the lava. Sublimations of salt were also apparent in certain portions of the lava bed. Prof. Palmieri informs me that he has detected sulphates in the sublimates, also lithium and boracic acid. I have not yet had time to examine various specimens of sublimates, which were collected from the new lava, and were placed in a dry bottle as soon as I reached Naples.

Prof. Palmieri has kindly furnished me with a MS. account of "Il Vesuvio dopo la grande eruzione del 1872," from which some of the above facts were derived. My own recent experience on the mountain does not, however, allow me to agree with him when he says: "Comunque sia, in tutto il tempo trascorso il cratere ha di mostrato poca attivita dinamica. Pochi brani di lava gettati fino all' altezza di 20 o 30 metri, soffii piu o meno vigorosi e qualche rara detonazione han rappresentato il vigore della forza eruttiva." The new cone, when I saw it, was pouring out vast volumes of smoke and steam, detonations occurred at frequent intervals, and loud noises as if of the lava surging within the crater. At intervals, also, the smoke was intensely illuminated as if the lava had leapt up within the cone. The cone discharged a perpetual shower of red-hot pieces of lava of a more or less cindery character, and certainly to a height far exceeding the "20 o 30 metri" of Prof. Palmieri. It is difficult to judge of heights under such circumstances, but many of the fragments appeared to be projected to a height equal to that of an ordinary sky-rocket. The ejected masses nearly all fell on one side of the cone, and helped to raise it. Occasionally, however, a sudden burst would come which scattered the red-hot masses in all directions. We approached as near as we could to the cone, and stood upon the bank of cinders (*vide* the accompanying woodcut) in immediate contact with it, and not a dozen yards from its vomiting crater. Showers of red-hot stones were projected from the crater, many of which fell into it again, and the rest for the most part on the side remote from us. There came a sudden burst, however, which shook the ground under our feet, and scat-

tered red-hot masses in all directions. A piece weighing four ounces fell within six feet of where I was standing, and the guide ran up to it and pressed a copper coin upon its still soft surface. A few minutes later a piece of red-hot lava, weighing at least seven times as much as the preceding, fell within four feet of me, and I promptly retired to a safer distance. Fifteen days before a guide had been killed by a falling red-hot stone from the crater. The projectiles from the crater are doubly dangerous, because you cannot "dodge" them. They do not come down straight like a cricket-ball, but waver in their flight like a boomerang. In the case of the larger of the two masses which fell so near to me, I had not only time before it fell to watch it in the air above my head, but also to speculate as to where it would fall. Judging by its position when about forty feet from the ground, it would certainly, I thought, fall behind me; a moment later it swerved, and fell about four feet in front of me. The cone, with its lurid smoke, and loud detonations, and showers of red-hot stones, presented a most fascinating spectacle. What, then, must be the effect when the whole great cone of Vesuvius is in a like condition?

The new lava is very leucitic, and does not resemble that of 1872. When in a viscous state it can easily be drawn into threads, and when cold it is jet-black and possesses a fine lustre.

Chloride of ammonium does not appear to have been at all a common product in this eruption, although it was conspicuously present during the eruption of 1872. Great differences of opinion still exist as to the formation of sublimates of chloride of ammonium in lavas. Bunsen considers that it is mainly formed by the action of the hot lava upon vegetable soil, and he has proved that "a square metre of meadow land yields on dry distillation a quantity of ammonia corresponding to 223·3 grammes of chloride of ammonium." Palmieri, while he admits that he has found more chloride of ammonium in those portions of lavas which have passed over cultivated ground, asserts that he has also found it high upon Vesuvius far above the range of vegetation, and in localities where the new lava has simply flowed over older and perfectly barren lava fields. He accounts for its formation by supposing that aqueous vapour undergoes dissociation in the heated crevices of the lava, and that the nascent hydrogen combines with the nitrogen of the air to form ammonia. We do not know what chemists will have to say to this theory.

New Eruptive Cone within the Crater of Vesuvius, which opened on November 2, 1878, and is still active.

Not far from the active cone I found a very interesting specimen of volcanic cinder which had obviously been exposed to the action of hydrochloric acid at a very elevated temperature, and had then probably been ejected before the action was complete. The central portions consisted of undecomposed cinder, and this was surrounded by a thick layer of perfectly white decomposed substance consisting chiefly of silicate of alumina and silica; the hot hydrochloric acid having formed sesquichloride of iron with the iron in the superficial layers of the mass, which sesquichloride had been afterwards volatilised out of the mass. By passing hydrochloric acid over lava heated to redness in a porcelain tube, the same effect was produced, the portions of lava most strongly heated, and longest submitted to the action of the hydrochloric acid, became perfectly white, while a copious sublimate of chloride of iron and chloride of aluminium passed into the receiver.

I ascended from the new lava (viz., from the bottom of the great crater of Vesuvius, *vide* the foreground of the accompanying woodcut) at 1.30 P.M., ran down the sides of the great cone, which had taken fifty-five minutes to climb, in seven minutes, reached the observatory at 2.30 P.M.; Portici, by a roundabout way to the west near Monte Somma, whither we went to search for minerals, at 4.30 P.M.; and Naples at 5.40. The next evening

while steaming out of the bay, *en route* for Tunis, I noticed that the smoke at the apex of the mountain was ruddy from the reflection of the lava within the small crater of 1878, and then for many days after, the summit of the mountain was obscured by clouds, and snow lay upon it when I next saw it towards the middle of last January. G. F. RODWELL

POPULAR NATURAL HISTORY[1]

VOLUME II. of this handsomely illustrated work on natural history is equally well got up as the first, which we noticed some months ago; it contains brief histories of the Carnivora, Cetacea, Sirenia, Proboscidia, Hyracoidea, and Ungulata.

The terrestrial, or on-the-land-living Carnivores, are described by Mr. Kitchen Parker, assisted by his son Jeffery. The father's pleasant style and his power of apt illustration will be recognised in the too few pages introductory to this group, and some of the woodcuts are from drawings made by the author. The marine Carnivora, the Whales, and the Sirenia, are described by Dr. Murie, while the editor, with the assistance of Prof. Garrod and Mr. Oakley, describes the Proboscidia, the Hyracoidea, and the Ungulata.

The land carnivora are, undoubtedly, as Mr. Parker tells us, one of the most compact as well as one of the most interesting groups among the mammalia. So many of the animals contained in it have become "familiar in our mouths as household words," bearing as they do an

FIG. 1.—The Binturong (*Arctictis binturong*).

important part in fable, in travel, and even in history. Many of them are of wonderful beauty, and many of them are of terrible ferocity. Two she-bears out of the wood tore up the forty and two naughty mocking little children near Bethel, and the narrative thereof frightens our own little children to this day. Packs of enraged lions, "fierce with dark keeping," were by the noble Romans let loose to mangle and devour helpless men and women in the arena, and as for the wolf, what terrible stories are not told about him? He was the very dread of the shepherd in the far distant times. As Mr. Parker reminds us, his bad character for ferocity was so well known in the early days, that "a very old sheep-master, addressing his sons on his death-bed, these sons being eleven out of twelve of them shepherds, said, knowing they would understand him, of the youngest, 'Benjamin shall raven as a wolf: in the morning he shall devour the prey, and at night he shall divide the spoil.'"

And with all this ferociousness of character, it is from among the number of the land carnivora that man has selected his faithful and devoted follower the dog. For a wonderfully interesting account of this friend of our race, a friend in whom, as Mr. Darwin observes, it is scarcely possible to doubt but that the love of man has become an instinct, an instinct, as Mr. Parker naively observes, not as yet certainly developed in man—there is a pleasant chapter, one that tells of what is known of prehistoric dogs, of the origin of the dog, and of the many varieties of the dog.

As an illustration of the general character of the woodcuts which so profusely adorn the volume, we have

[1] "Cassell's Natural History." Edited by P. Martin Duncan, M.B., F.R.S., Professor of Geology, King's College, London. Vol. ii. Illustrated. (London, Paris, and New York: Cassell, Petter, and Galpin.) 4to.

selected one of an interesting animal which has been a great puzzle to the systematic zoologist (Fig. 1).

"The Binturong (*Arctictis binturong*) is a curious little animal of a black colour, with a white border to its ears; it has a large head and a turned-up nose; its tail is immensely long, thick, and tapering, and which is very remarkable, it is prehensile, like that of a new world monkey. It is from twenty-eight to thirty inches in length from the snout to the root of its tail, and the tail itself is nearly the same length. It is quite nocturnal, solitary, and arboreal in its habits. In creeping along the larger branches, it is aided by its prehensile tail. It is omnivorous, eating small animals, birds, insects, and fruits. Its howl is loud. It walks entirely on the soles

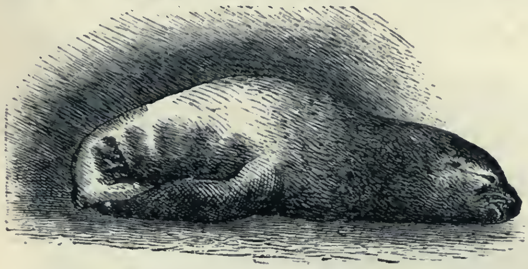

FIG. 2.—The Seal asleep.

of its feet, and its claws are not retractile. While it is wild and retiring in its manner, it is said to be easily tamed. It is placed by Mr. Parker among the group of the civets."

In his description of the fur and hair seals, Dr. Murie, as was to be expected, is quite at home, and we have, among other accounts of these wonderful creatures, a long one of that sea lion which lived so long in the London Gardens. This animal seemed to pass its time between sleeping and eating, and we give two out of a series of illustrations which depict its habits—one of it when fast asleep (Fig. 2), the other when it is in "a watchful attitude," waiting to be fed (Fig. 3); it was well known to all visitors to the gardens. It was in the habit of devouring upwards of twenty-five pounds' weight of fish every day, and not thinking this too much. It was originally captured in

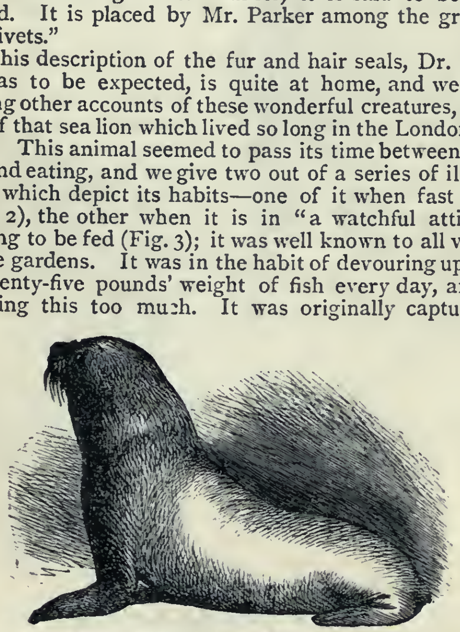

FIG. 3.—Waiting to be fed.

the neighbourhood of Cape Horn; and François Lecomte, the French sailor into whose possession it fell, exhibited the animal for a short time at Buenos Ayres before bringing it to London, where for a short time he earned a living by showing it off. By kindness and dint of training he taught it to become quite a performer in its way. It mounted a ladder with perfect ease, and it could descend either head or tail foremost, so that it seemed a marvel of docility, and its appearance in London seems to have created quite a general interest in the group hitherto so little studied of the eared seals.

The volume concludes with an account of the non-ruminating members of the even-toed sub-order of the Ungulates, embracing the pigs of the Old World, the peccaries of the New World, and the hippopotami. The next volume will contain a description of the Ruminants, a large and very interesting group. E. P. W.

THE KEITH MEDAL OF THE ROYAL SOCIETY OF EDINBURGH.

ON the 3rd inst., at a meeting of the Royal Society of Edinburgh, the President, Professor Kelland, in presenting the Keith Medal which had been awarded by the Council to Professor Heddle, of St. Andrews, delivered the following address:—"Professor Heddle—I am here to-night to exemplify a remark which is often made, that to insure success in an address, such as I am about to deliver, the best way is to commit the charge of it to one absolutely ignorant of the subject. No false pride will then stand in the way of the best sources of information, nor will any undue admixture of half knowledge clog and darken the truth. For every particular contained in these remarks, then, I at once unhesitatingly acknowledge myself indebted to Professor Geikie. When I first became acquainted with this Society, forty years ago, there used to frequent our meetings men who had the reputation of being mineralogists rather than geologists—Lord Greenock, Allan, and perhaps Jameson himself. That race has now died out, and with them mineralogy, as a distinct science, has all but lain dormant amongst us. During the preceding quarter of a century that science had flourished nowhere more vigorously than in Edinburgh. Professor Jameson introduced the definiteness of system of the Freyberg School, and infused into his pupils such a love of minerals that numerous private cabinets were formed; while under his fostering care the University Museum grew into a large and admirable series. One of my first acts as Professor in the University was to vote out of the Reid Fund, which had just come into our hands, a large sum (some thousands) to pay back moneys expended on minerals throughout a series of years preceding. During these years, Geology, as the science is now understood, hardly existed. For, as the nature and importance of the organic remains embedded in rocks became recognised, their enormous value in the elucidation of geological problems gradually drew observers away from the study of minerals. Consequently, as Palæontology increased, Mineralogy waned among us. To such an extent was the study of minerals neglected, that geologists, even of high reputation, could not distinguish many ordinary varieties. But, as a knowledge of rocks presupposes an acquaintance more or less extensive with minerals, the neglect of mineralogy reacted most disadvantageously on that domain of geology which deals with the composition and structure of rocks. The nomenclature of the rocks of Britain sank into a state of confusion, from which it is now only beginning to recover. To you, Professor Heddle, belongs the merit of having almost alone upheld the mineralogical reputation of your native country during these long years of depression. You have devoted your life to the study, and have made more analyses of minerals than any other observer in Britain. You have not contented yourself with determining their composition and their names; you have gone into almost every parish in the more mountainous regions, have searched them out in their native localities, and, by this means, have studied their geological relations, treasuring up evidences from which to reason regarding their origin and history. After thirty years of continuous work, you have communicated the results of your labours to this Society. For the first two of these papers on the Rhombohedral Carbonates and on the Feldspars, in which you have greatly extended our knowledge of pseudomorphic change among minerals, enunciating a law of the shrinkage so frequently resulting therefrom, the Society proposes now to express its gratitude to you. The value of your papers is undoubted.

Through the kindness of Mr. Milne Home, I have been favoured with the sight of letters addressed to you by four eminent mineralogists, Dana of America, Rammelsberg of Berlin, Szabo of Buda-Pesth, and King of Queen's College, Galway. Szabo states that the notice of your paper on the Feldspars, which appeared in Groth's *Zeitschrift für Mineralogie*, greatly interests him, and makes him desirous of placing himself in direct communication with the author. Dana says, 'I have read your paper on the Feldspars, in the Transactions of the Royal Society of Edinburgh, with great satisfaction. Your thorough method of work leads towards important results of great geological, as well as mineralogical value.'

"I have the satisfaction, in the name of the Council of this Society, of presenting you with the Keith Medal. It is hoped that this recognition of your labours will not be without encouragement to you in the arduous researches in which you are engaged."

OUR ASTRONOMICAL COLUMN

TEMPEL'S COMET, 1867 II.—Now that Brorsen's comet of short period is again under observation, the next comet of the same class to be sought for, is that discovered by Dr. Tempel at Marseilles, on April 3, 1867, which was also observed at its next appearance in 1873; it is probable there may be greater difficulty in recovering this object, than appears to have been the case with Brorsen's comet, the reason for which may be made clearer if we briefly detail its history since the year 1867. Less than a month after it was discovered in that year the deviation of the orbit from a parabola became evident, and several of the German astronomers, Prof. Bruhns, now Director of the Observatory of Leipsic, in the first instance, deduced elliptical orbits, with periods of between five and six years. The most complete investigations on the motion of the comet in this year were due to Dr. Sandberg and Mr. Searle. The comet was observed by Dr. Julius Schmidt at Athens till August 21, and the perihelion passage having taken place on May 23, a considerable arc of the orbit was included within the limits of visibility. Dr. Sandberg, after taking into account the effect of planetary perturbations during the comet's appearance, found the period of revolution 2,080 days. On examining the track of this body with reference to the orbits of the planets, it was seen that near the aphelion it must approach very near to the orbit of Jupiter, the least distance being within 0·37 of the mean distance of the earth from the sun, and from the position of this great planet near the time of aphelion passage of the comet early in 1870, it was obvious that great perturbations in the elements of the latter must ensue, and without at least an approximate knowledge of their amount, there might be difficulty in recovering the comet at its next return to perihelion. The first publication of results in this direction was by Mr. W. E. Plummer, from Mr. Bishop's observatory, Twickenham, in February, 1873, followed shortly afterwards by particulars of similar independent investigations undertaken by Dr. Seeliger, of Leipsic, and the late Dr. von Asten, of Pulkowa. It was found that the effect of the attraction of Jupiter, which planet was only 0·32 distant from the comet on January 20, 1870, caused a retrograde change in the longitude of the node to the amount of 22½°, and increased the inclination of the orbital plane to the ecliptic nearly 3°; the period of revolution was lengthened by more than three months, and the point of nearest approach to the sun was removed further from him by upwards of 0·2 of the earth's mean distance. Changes in the elements to this amount would of course entirely alter the track of the comet in 1873, but they had been so closely determined, that immediately after receiving an ephemeris in which their effect was included, M. Stephan re-detected the comet at Marseilles, and as early as April 3, or five weeks before the perihelion passage, and it was observed until the last week in June. We subjoin Dr. Sandberg's elements for the two appearances:—

	1867.	1873.
Perihelion passage	May 23·9204 G.M.T.	May 9·0134 G.M.T.
	° ′ ″	° ′ ″
Long. of perihelion ...	236 9 24	237 38 42
,, ascending node	101 10 10	78 44 39
Inclination to ecliptic...	6 24 36	9 44 13
Angle of excentricity...	30 38 39	27 30 58
Log. semi-axis major ...	0·503658	0·517057
Revolution	2080·1 days.	2178·6 days.

The longitudes are reckoned from the mean equinox of the commencement of the respective years. The period of revolution applies to the ellipse which the comet was describing at perihelion passage.

With regard to the length of the actual revolution, it is certain that no very material perturbation can result from known causes: Jupiter, the great disturber of the cometary motions, was at almost his greatest possible distance from the comet when the latter passed nearest to his path about May, 1876. A recent investigation by M. Raoul Gautier, of which, however, no details are yet published, assigns a longer period of revolution corresponding to the perihelion passage in 1873 than was given by Dr. Sandberg, the difference being about 10½ days, so that if the mean motion at the last appearance does not, as M. Gautier implies, admit of exact determination, there will be an uncertainty in the date of the approaching perihelion passage, which will necessitate a pretty extended and careful search in order to detect the comet. It belongs to the fainter class, and although in 1867 and 1873 it appeared under rather favourable circumstances for observation, and is likely to do so to a certain extent this year, it has never been a good telescopic object. When at its greatest intensity of light early in May, 1867, its nucleus, which was stellar, had not the brightness of a star of the ninth magnitude. At the last observation at Athens, in that year the theoretical intensity of light was 0·21, and the comet would have the same degree of brightness about March 27 next, whether we assume the time of perihelion passage (perturbation neglected) from the orbit of Dr. Sandberg or M. Gautier, but the uncertainty of position may probably delay its rediscovery till some time later. We may hope that the publication of the further results of M. Gautier, who mentions being engaged on the calculation of perturbations during the present revolution, will not be long deferred. It is desirable the comet should be under observation as long as practicable at this return, since the period being now nearly equal to half that of Jupiter, the two bodies will come into proximity again towards the month of November, 1881, though their mutual distance may not be less than 0·55. This will involve a new, strict investigation similar to those undertaken in 1873, to enable the epoch of ensuing perihelion passage to be ascertained.

Using Dr. Sandberg's orbit of 1873, the comet's place at Greenwich midnight, on March 27, would be in R.A. 253°·9, N.P.D. 103°·7, or, if the perihelion passage be assumed ten days later, which would more nearly accord with M. Gautier's calculation in R.A. 247°·0, N.P.D. 101°·0.

THE INTRA-MERCURIAL PLANET QUESTION.—It appears that this subject has lately engaged the attention of that excellent practical astronomer Dr. Oppölzer, of Vienna, who has communicated to the *Astronomische Nachrichten* some curious results of his examination of the records of rapidly-moving dark spots upon the sun's disk. His inquiry resolves itself simply into the conclusion, that even introducing rather more extended data than were used by Leverrier, who, it will be remembered, found several possible periods of revolution for the hypothetical planet, they may all be represented so far as regards the necessity of a transit across the sun's disk on

the days named, by an orbit, the elements of which Dr. Oppölzer gives as follows :—

Epoch 1850, January 1·0, Paris M.T.

Mean anomaly	356° 0′	
Longitude of perihelion	27 45	Equinox of 1850.
,, ,, ascending node	178 0	
Inclination to ecliptic	7 0	
Angle of excentricity	14 13 or $e = 0·2456$	
Log. semi-axis major	9·0906	
Mean diurnal motion	22°·789529	

The period of revolution would therefore be 15·797 days. Comparing with the observations employed the following are the differences shown by the above orbit in geocentric longitude; the calculated geocentric latitude is annexed :—

	Diff. longitude.	Latitude.
1800, March 29, Fritsch	+ 0°·6	+ 14′
1802, Oct. 10, ,, ...	+ 0·4	− 14
1819, Oct. 9, Stark	+ 0·2	− 13
1839, Oct. 2, Decuppis	+ 0·5	− 7
1849, March 12, Sidebotham ...	− 0·8	− 7
1857, Sept. 12, Ohrt	+ 0·1	+ 7
1859, March 26, Lescarbault ...	0·0	+ 10
1862, March 20, Lummis	+ 0·1	+ 2

But it is unfortunate that notwithstanding this almost perfect representation of the longitudes assumed and the circumstance that the latitudes point to a transit across the sun's disk on every date, there are apparently fatal objections to our admitting the existence of a planet with these elements, several of which are pointed out by Dr. Oppölzer. It may be sufficient to mention here the first of them :—With so short a period and small inclination, a transit across the sun's disk would occur every year, and we know that observation by no means supports such a condition. However, the existence of a body moving in this orbit will admit, as Dr. Oppölzer states, of very early decision :—On March 18 a nearly central transit should occur—

Ingress at 18h 8m Berlin M.T. ...	Angle of position	74°
Egress at 23 15 ,, ...	,,	254

We give these particulars as affording another illustration of the difficulties attending any trustworthy inferences from the observations of suspicious spots upon the sun's disk. The above orbit, it should be mentioned, will not accord with either of Prof. Watson's presumed planets, though possibly, by increasing the excentricity, elements might be found which would agree with one or other of his positions, while representing most of the observations used by Dr. Oppölzer. We ignore the idea of a want of *bona fides* on the part of the observers on so many occasions, but there is still to be remembered the fact that comets have traversed the sun's disk, and with small perihelion distances might do so without our discovering them except in the course of transit, supposing them to possess the degree of condensation which some have indicated. The object observed by M. Coumbary at Constantinople in May, 1865, could only have been a comet, with a perihelion distance so small as, like the great comet of 1843, almost to graze the sun's surface.

GEOGRAPHICAL NOTES

AT the meeting of the Geographical Society on Monday, when the Earl of Dufferin occupied the presidential chair for the second and last time, Mr. T. J. Comber, of the Baptist Missionary Society, who is about to lead an expedition above the Yellala Falls of the Congo, gave some account of his explorations inland from Mount Cameroons, in the course of which he visited a district of country previously unknown, and discovered a small lake to the northward of the mountain; he also ascertained that there was a broad valley there instead of a continuous mountain range. He mentioned one fact with regard to Mount Cameroons, which goes far to show that there may be some difficulty in finding a suitable spot for the proposed missionary sanatorium. When at an elevation of 2,000 feet there were such heavy mists, that, although he slept between two fires, his blanket was wet through. It is, of course, possible that here, as in the Neilgherry Hills, and other places, positions may be found to which the miasmatic influences do not extend. Mr. Comber next gave some brief and interesting notes of a journey which he made through Congo to Makuta, the place which Lieut. Grandy saw from the brow of a neighbouring hill, but was not allowed to enter. Sir Henry Barkly afterwards read some observations on the Bamangwata country in South Africa, to which a melancholy interest attached from the fact of their having been drawn up by the late Capt. R. R. Patterson, who recently met with his death by poison when some three days' journey from the Victoria Falls of the Zambesi. The country would appear to be of a not very promising nature, for its soil is sand, covered with stunted bush, and there are few mountain fastnesses, except those near Shoshong, the capital; in the winter it is badly watered, as the Limpopo, Zambesi, and Zouga (or lake river), are the only rivers which run continuously, while the Tati, Shasha, and Makalapogo, are sand rivers. The open country is sparsely inhabited by Veld-people of two classes, the Bakala and Masarwa, of whom the former enjoy the right of possessing cattle and gardens, but the latter neither; they are, in fact, slaves, living on game and roots. The Bamangwata country is ruled by a chief named Khame, whom Capt. Patterson described as a very good man, an opinion in which Sir H. Barkly concurred.

IN connection with the meeting on Monday at Preston in reference to a Central African railway, the letter in yesterday's *Times* from the Alexandria correspondent of that paper is of interest. It seems that the Khedive had some time ago devised an excellent scheme for bringing the riches of the great lake district to the outer world by way of the Indian Ocean, at the mouth of the Juba river. The distance between that point and Victoria Nyanza is only 280 miles, and McKillop Pasha was instructed to work gradually from the coast, planting colonial stations at regular distances, while Gordon Pasha was to cooperate from the lake side. Though the plan seems to have been ably, but too secretly devised by the Khedive, it rather unfortunately fell through, we think on account of the jealousy of the Sultan of Zanzibar and his friends. There is no talk by the Khedive of a railway, and we think with the *Times* correspondent, that something more elementary should be attempted, with a country so totally undeveloped as that of Africa. That it will be opened to trade soon by some nation is evident. English, Germans, Italians, French, Portuguese, are all striving from various points. There is plenty of room for all.

A LARGE amount of material for arriving at some approximately correct notion of the mean depth of the sea, has accumulated in recent years. In a note to the Göttingen Academy, Dr. Krümmel has lately attempted this, in view of the vague and variable statements on the subject in text-books. Soundings were wanting for the Antarctic and a part of the North Polar Sea, *i.e.*, about 475,000 square miles, or 7 per cent. of the entire sea-surface, so that he gives his estimate only as a closer approximation. He estimates, then, the mean depth of the sea as 1,877 fathoms, or 3,432 metres, or 0·4624 geographical miles. It was natural to compare the mean height of dry land above the sea-level. Humboldt's estimate of 308 metres is regarded as quite out of date. Leipoldt has since estimated the mean height of Europe as 300 metres. Accepting this number for Europe, 500 for Asia and Africa, 330 for America, and 250 for

Australia, Dr. Krümmel obtains the mean of 420 metres, or 0·0566 miles. The surface-ratio of land to water being considered 1 : 2.75, the volume of all dry land above the sea-level is inferred to be 140,086 cubic miles, and the volume of the sea 3,138,000 cubic miles. Thus the ratio of the volumes of land and water is 1 : 22·4. That is, the continents, so far as they are above the sea-level, might be contained 22·4 times over in the sea-basin. Reckoning, however, the mass of solid land from the level of the sea-bottom, the former would be contained only 2·443 times in the sea-space. Dr. Krümmel also compares the masses (taking recent data); he finds that of the sea 3,229,700 cubic miles, and that of the solid land 3,211,310 (a small difference). If the specific gravity of the land were raised merely from 2·5 to 2·51432, we should thus have perfect equilibrium. Such equilibrium is probably the fact.

NEWS has been received from Moscow that Colonel Grodekoff, of the Russian general staff, has returned to that place from a somewhat venturesome expedition in Central Asia, during which he travelled in European clothes, and without any attempt at disguise. He was accompanied by a Kirghiz and two Persians, and traversed the northern part of Afghanistan, reaching Persia by way of Herat.

IN connection with the Russian scheme for a railway from Orenburg to Tashkent, it is stated that the Grand Duke Nicholas is preparing a third expedition for 1879, which is to set out in the end of March. After having passed Tashkent and Samarkand, it will cross the Amu and pursue its researches to the defile of Bamian, in Afghanistan, in the direction of Kabul. The explorers will then descend the Amu in a native boat, from the meridian of Balkh to Khiva, for the purpose of investigating the navigation of that river. From Khiva they will follow the ancient bed of the river to its old mouth in the Caspian.

CAPT. HOWGATE has presented to the United States Congress a supplementary note on the advantages arising from the creation of a polar colony on the border of the great palæocrystic ocean. The whaling interest is fast on the decrease in the States; the total value of imports being only two million dollars instead of ten millions twenty years ago. This deficit has been attributed by Agassiz and other competent authorities to the whales taking refuge in that almost inaccessible polar basin, to which, by the creation of a civilised station at Lady Franklin Bay, access might be gained.

THE Conference on the civilisation of Africa held a meeting recently at Brussels under the presidency of the King of the Belgians. It is stated that Mr. Stanley, who was present, "will be placed at the head of the approaching Belgian Exploring Expedition to Africa."

PETERMANN'S *Mittheilungen* for February contains a detailed account, with map, of Dr. Woeikoff's travels through central and southern Japan in 1878. In connection with a narrative of the discovery of the island Einsamkeit to the north-east of Novaya Zemlya is a map of the island showing its configuration and relative position. Prof. Hann contributes a short paper on the climate at the Victoria Nyanza on the basis of data collected by Dr. Emin Bey and the Rev. Mr. Wilson.

THE January number of the *Bolletino* of the Italian Geographical Society contains a long letter from Lieut. Bové, who accompanies Nordenskjöld's expedition; it was written from the mouth of the Lena, and gives many important details of observations made up to that point.

THE December *Bulletin* of the Paris Geographical Society contains a valuable sketch of the work done in Sumatra by the Dutch expedition, which started in the beginning of 1877 under the late M. Santwoort, and of which we have from time to time given news. The sketch is by Col. Venteggio. The number contains also the addresses by M. Huber in presenting the medals for 1878 to Mr. Stanley, M. Vivien de St. Martin, and Dr. Harmand.

A YOUNG Austrian painter, Herr Joseph Ladein, of Mödling near Vienna, has recently started for a tour through Central Africa. In a letter dated from Oran he states that his intention is to proceed through Marocco, to cross the Great Desert to the Senegal River, then to turn eastward to Haussa and the Nile Lakes, and to return to Europe along the course of the Nile.

A BRANCH of the new Berlin "Society for Commercial Geography and the furtherance of German Interests Abroad" has been established at Leipzig.

M. L. BABÉ has announced to the Paris Geographical Society that he proposes to explore the globe by means of an improved Montgolfier balloon, capable of storing heat in all regions and of maintaining a sufficient height for several weeks.

BAD news has been received from Zanzibar by the French Geographical Society. It appears that two of the French missionaries who were exploring this part of Africa have died, one of them by illness, and the other having been killed by a lion.

NOTES

AT a full meeting of the Council of the Zoological Society, held on the 5th inst. at the Society's office, in Hanover Square, Prof. William Henry Flower, F.R.S., Conservator of the Museum of the Royal College of Surgeons, was unanimously elected president of the Society, in succession to the late Marquis of Tweeddale. The new president, who, we need hardly inform the readers of NATURE, is one of the most learned zoologists and anatomists of the present day, has been for some years on the Council of the Society and one of its vice-presidents, and has communicated many valuable memoirs to its *Transactions* and *Proceedings*. Prof. Flower is the seventh president elected since the foundation of the Society in 1826. Sir Stamford Raffles, the first president, who died a few months after the foundation of the Society, was succeeded by the Marquis of Lansdowne, who resigned in February, 1831, in favour of the thirteenth Earl of Derby, then Lord Stanley. He held the presidentship for upwards of twenty years, and on his death, in 1851, was succeeded by the late Prince Consort. On the death of the Prince Consort, in 1861, Sir George Clerk, of Penicuik, was chosen as his successor, and retained the presidentship until his death, in 1867. He was succeeded in January, 1868, by the late Lord Tweeddale, then Viscount Walden, whose death has caused the vacancy to which Prof. Flower has succeeded.

THE Chemical Society have received from the executors of the late Mr. Sydney Ellis a legacy of 1,000*l*. free of duty.

THE friends of Prof. Clifford, who has been compelled by ill health to relinquish active work and reside in Madeira, are anxious to present him with a substantial testimonial in public recognition of his great scientific and literary attainments. At a meeting held at the Royal Institution, Albemarle Street, on Friday, January 31, Dr. William Spottiswoode, President of the Royal Society, in the chair, it was resolved that a fund should be raised for the above-mentioned purpose, and that the sums received should be placed in the hands of trustees, for the benefit of Prof. Clifford and his family. Contributions may be paid to the account of the "Clifford Testimonial Fund," with Messrs. Robarts, Lubbock, and Co., or to either of the Honorary Secretaries. Among the gentlemen who have kindly consented to act on the General Committee are the following:—Dr. William Spottiswoode, Dr. Andrew Clark, Prof. R. B. Clifton, F.R.S., Prof. T. H. Huxley, Prof. Henry Morley, Prof. A. Newton, F.R.S., Sir Fred. Pollock, Bart., Prof. Roscoe, F.R.S., Prof. H. J. S. Smith, F.R.S., Hon. Mr. Justice Stephen, Sir Henry

Thompson, Prof. John Tyndall, D.C.L., F.R.S., Prof. Alex. W. Williamson, Ph.D., F.R.S. Dr. William Spottiswoode, Pres. Roy. Soc., and Sir John Lubbock, Bart., M.P., F.R.S., are Joint Hon. Treasurers and Trustees.

A GRANT of 75*l.* has been made from the Worts (Cambridge) Travelling Scholars' Fund to John Edward Marr, B.A., St. John's, to enable him to travel in Bohemia and collect evidence and specimens bearing upon the question of the classification of the Cambrian and Silurian rocks, with the understanding that specimens be sent by him to the University, accompanied by reports which may be hereafter published.

WE have already referred to the fact that the inhabitants of Heilbronn, desirous of paying due respect to the memory of Dr. Julius Robert Mayer, who was born there, have resolved to erect a suitable memorial on the spot where he lived, laboured, and died. They invite co-operation, and, with the view of enabling the admirers of Dr. Mayer in England to join in this tribute of recognition, some of the most eminent men of science in England have agreed to form a Mayer-Memorial Committee; the list is headed by Dr. William Spottiswoode, Pres. R.S. Subscriptions exceeding 1*l.* may be sent by cheque to Messrs. Robarts, Lubbock, and Co., 15, Lombard Street. Smaller sums may be sent by Post Office Order to the Hon. Secretary, T. Archer Hirst, Royal Naval College, Greenwich.

M. LÉON LALANNE, Director of the School of Ponts et Chaussées, has been elected to fill the place of the late M. Bienaymé, in the Paris Academy of Sciences.

WE are glad to see that several important and much-needed reforms are being introduced into the British Museum. The Museum is now open free to the public on every week day—Monday till Friday from 10 o'clock, and on Saturday from 12 o'clock till the ordinary hour of closure. Special arrangements have been made to enable students to carry on their work without interruption. Students of natural history will have Tuesday and Thursday reserved for their studies, students of archæology Wednesday and Friday. On Monday and Saturday the public will be able to view the whole of the collections; on Tuesday and Thursday, all except the natural history specimens; and on Wednesday and Friday, all except the Greek and Roman sculptures, and antiquities in the upper gallery. Persons holding tickets of admission to the reading-room, the department of prints and drawings, the sculpture galleries, and the departments of natural history will not be required to renew them every six months, as the tickets will be granted to readers and students without limit of term, but subject to withdrawal. The actual presentation of the ticket will not be considered necessary for entrance into the reading-room. These and several other new arrangements seem to show that the Museum powers have at last come to the conclusion that the institution exists for the benefit of the public, and that their convenience ought to be made paramount in all arrangements.

THE obituary list of foreign men of science is heavy this week. We much regret to announce the death, on January 24, of Dr. Heinrich Geissler, the celebrated inventor in the field of physical mechanics. Dr. Geissler died at Bonn at the age of sixty-five years. Amongst his inventions are the well-known Geissler tubes, the vaporimeter, the mercury-pump, &c. We regret to have to record the deaths of two other eminent German men of science, viz., that of Dr. Eduard Lösche, Professor of Physics at the Royal Polytechnic Institution of Dresden, and well known naturalist, who died on January 25, aged fifty-eight; and that of Dr. Benedikt Stilling, of Cassel, whose name was but recently mentioned as one of the hon. secretaries at last year's meeting of the German Association. Dr. Stilling was an eminent anatomist; he was born at Kirchheim, near Marburg, on February 22, 1810, and died at the same place on January 28, aged sixty-nine years. The death is announced of Dr. Steinheil, the eminent optician of Munich. M. Paul Gervais, the distinguished palæontologist and Professor at the Paris Jardin des Plantes, died on Monday in his sixty-third year.

Apropos of the statue to Gauss, the following extracts from a Brunswick correspondent may interest some of the readers of NATURE. The sum collected, including contributions of 3,000 marks each from the Emperor of Germany and the Duke of Brunswick, promised subscriptions and interests, has now reached 41,000 marks. Herr Schaper has almost, if he has not quite, finished the statue; the casting in bronze is then to be superintended by Prof. Howaldt of Brunswick. A Berlin firm will provide the pedestal of red granite from Sweden. The statue will be one and a half life size, standing eight feet four inches (Rhenish measure), and the pedestal will be of about the same height. It is hoped that the unveiling of the statue will take place on April 30, 1880—the anniversary of Gauss's birth.

A CONCURRENT resolution of thanks to Prof. Hayden for his "accurate and comprehensive survey of the State of Colorado" passed the Colorado legislature, January 14. Senator Gaussion, who is himself an eminent mining engineer, remarked—"These reports, coming from a scientific and authoritative source, do more to answer and satisfy the inquiries of capitalists than everything else. They tell the world what the great western country is made of. The western domain of the United States is to-day the glory of the nation."

WE are asked to state that supplemental meetings, for the reading and discussion of papers by students of the Institution of Civil Engineers, have been appointed for the following Friday evenings:—February 14, 21, 28, and March 7. The papers to be read on these evenings are respectively: "The Excavating of a Tunnel in Rock by Hand Labour and by Machinery," by John C. Mackay: "The Design and Construction of Wrought-Iron Tied Arches," by Percy W. Britton; "The Cost and Construction of a Cheap Light Railway," by Alfred W. Szlumper; and "The Interlocking of Points and Signals and the Electric Block System," by George D. Marston. The chair will be taken at 7 o'clock on each evening, and successively by Mr. Hayter, Mr. Barlow, F.R.S., Mr. Bruce, and Mr. Woods, Members of Council.

SOME recent experiments by Herr Holmgren in Prof. Kühne's laboratory in Heidelberg seem to prove that the variations of the retina current through the action of light have no essential relation to the blanching and regeneration of the so-called "visual purple," thus increasing the difficulty of regarding that purple as directly connected with vision. In one experiment an eye of a newly killed frog was kept half an hour to an hour in sunlight, till all the visual purple was blanched. Variations of the retina current on incidence of light were found to occur in the ordinary way. Again, one eye of a rabbit was protected against the action of light by sewing the ear over it, while the other eye was exposed to the light. The animal showed normal variations of the retina current, and when the eyes were examined, with the necessary precautions, the normal amount of purple was found in the covered eye, while the other, which gave variations of the current, was quite without purple. Conversely, eyes of frogs and rabbits were taken out and treated with alum solution in the dark. The visual purple was thus maintained twenty-four hours, and it was then exposed to light. The light blanched it, like that of a fresh eye, but there was no trace of variation of current in consequence of this action. The author's conclusion regarding vision finds support in the facts that visual purple is wanting in some animals, which must be supposed capable of sight, and that it is absent from the yellow spot in man, and so from that part of the retina in which vision is most distinct.

IN a recent series of demonstrations at La Salpêtrière, Paris, Prof. Charcot has shown, *inter alia*, that it is possible to produce in one subject a state of catalepsy on one side of the body, and a simultaneous state of lethargy on the other. The patient is first thrown into catalepsy by looking at the electric light (in this state the limbs are supple and will retain any position one chooses to give them). To produce the state of lethargy or somnambulism on one side, it is sufficient to close the corresponding eye, or shut off the light with a screen; the two states are then co-existent on the two sides of the body.

WE learn from the *North China Herald* that at the December meeting of the Shanghai branch of the Royal Asiatic Society, a paper was read by M. A. A. Fauvel, on the alligators of China, on which occasion the author exhibited a live specimen obtained last October from Chinkiang, on the Yangtsze-kiang, as well as a cranium and skeleton, and a stuffed crocodile for comparison. The paper commenced with a philological dissertation on the names by which the saurians of China have been known at various times, and the specimen exhibited (between 5 and 6 feet long) was identified with the *t'o* or *ngo* of the old writers. Among modern writers, the late Mr. Swinhoe seems to have been the first to allude to its existence, and in 1869 a specimen was exhibited in the Chinese city of Shanghai. Père Heude more recently nearly became the possessor of a specimen which he only lost through his servant haggling over the price. At various times reports have reached Shanghai of crocodile-like animals being seen in the Yangtsze-kiang, but Mr. L. E. Palm, of the Chinese Customs' service, was the first to obtain a genuine specimen, which was presented to the Society last year. A careful examination soon showed, according to M. Fauvel, "that it was no crocodile, but a genuine alligator, a most interesting fact, as hitherto no alligator has been met with in the Old World, the genus being supposed to be confined to the rivers of America." M. Fauvel then explained from the specimens, and by means of careful drawings, the peculiarities of the genus. The Chinese animal seemed to resemble most the *Alligator lucius* of the Mississippi, but, as it seemed to belong to a distinct species, he proposed for it the specific title of "*sinensis*," until further research should establish or disprove the distinction.

THE *North China Herald* publishes some notes of a journey made during last October by the Rev. J. S. Crossette, in the northern part of the Chinese province of Shantung, in the course of which he visited a cotton-growing district. His account of this industry is not very encouraging. The scraggy little shrub, he writes, not as high as the knee, black as if blasted by mildew or killed by frost, looks very different from that in the cotton-fields of the United States; and in his opinion the introduction of some foreign cotton-seed would effect a great improvement.

ACCORDING to the *Democrat*, San Francisco is to be the first city whose streets are to be lighted entirely by the electric light. It is proposed to divide the city into districts, varying in extent from one to three miles, each of which will be fed by a sufficiently powerful Gramme machine. The machines have already arrived at New York, and arrangements have been made for adopting two or three different patents. The *Electrician* says:—"The experimental trial of the electric light at the works being executed at the port of Havre has given complete satisfaction. Without waiting for the report of the committee nominated by the French Board of Works, the Chamber of Commerce has authorised the establishment of ten lights in the outer port."

IN his last report to the Foreign Office, H.M.'s Consul at Tamsui, Formosa, calls attention to one or two features of interest in connection with the camphor trade there, which is assuming considerable proportions. Formosa, it is well known, is one of the very few districts in the world which produce camphor, the others being Japan and some parts of the Malay Archipelago. The tree from which it is obtained (*Camphora officinarum*), is said not to be known on the mainland of China; camphor, at any rate, is not extracted from it there. The camphor-producing tree of the Malay Archipelago differs from that growing in Formosa and Japan, and, in addition to the crude camphor, produces a valuable medicinal gum, known to merchants as "camphor baroos," the duty on which in China is about 6*s*. per pound. The Formosan tree, on the contrary, does not produce this gum.

AS showing the much greater attention gradually being directed to Singapore and the Malay Peninsula, to which we have from time to time alluded, it will not be uninteresting to record that some land at Tanjong Pagar, which, not a great number of years ago, was bought from the East India Company at the rate of 1 rupee for fifteen acres, was recently sold at prices ranging from 20,000 dols. to 30,000 dols. per acre.

OWING to the melting of mountain snows and torrential rains, the Lake of Geneva reached a higher level last month than it has been known to attain at this season in the forty-one years during which its fluctuations have been noticed.

IT is rumoured that M. Ferdinand de Lesseps will be appointed Governor-General of Algeria.

M. MAURICE SAND has discovered and published an account of a "pre-historic flint-implement workshop" near the village of Loges, on the frontier of the Indre and the Cher. On the summit of a heath, almost on a level with the surface, he has picked up hundreds of fragments of flints, convex on one side, concave on the other; also lanceolated axe-heads, arrow-heads, a jasper axe, and many scrapers in red and white cornelian or sardonyx. The flint-layers cropping out to the surface bear marks of human labour.

THE collection of maps, plans, and views of London and Westminster, made by the late Mr. Frederick Crace, and lent to the South Kensington Museum by his son, Mr. J. G. Crace, is now on view from 10 to 4 daily, in two of the upper rooms in the galleries on the west side of the Horticultural Gardens. The plans and views selected from the collection for exhibition are 3,085 in number. A complete catalogue, compiled from Mr. Crace's larger work, has been issued by the Stationary Office.

NEW GUINEA is rapidly ceasing to be *terra incognita*. Thanks to both scientific and missionary enterprise we have lately learnt much both of its geography and ethnology. Recently, and in this country alone we have had the results of the experience of D'Albertis, Comrie, Kiehl, Lawes, Moresby, Stone, and Turner. In the *Chronicle of the London Missionary Society*, October, 1878, we have, under the title "New Guinea," an account of the journeys made by the Rev. Jas. Chalmers. He is stated to have visited one hundred and five villages on the south coast of the mainland during the spring of last year, and ninety of these villages are reported as being visited for the first time by a white man. From Mr. Chalmers's general ethnological notes we learn that these natives cook the heads of their slain enemies to secure clean skulls to place on sacred places. Each family has a sacred place where offerings are carried to the spirits of deceased ancestors. This ancestor worship seems to be carried on with great fear. The spirits of their dead are invoked at the commencement of planting, at starting on trading expeditions, &c. They have one great spirit—Palaku Bara, who dwells in the mountains. Pigs are always killed in the sacred place and offered to the spirit, after which the carcase is carried back to the village to be divided and eaten. During this expe-

dition the entire coast line from Keppel Point to McFarlane Harbour was traversed on foot.

PERHAPS no branch of anthropology has been more cultivated or yielded larger results during the last few years than that relating to prehistoric man. At the same time no inconsiderable part of the evidence has been derived from the examination of osseous and other remains in caves both in England and on the continent. The greatest interest has always been felt in the revelations that might accrue to the science of anthropology by an investigation of the bone-caves of Borneo, situated as that island is on the confines of the lost continent Lemuria, where Dr. Peschel thinks it possible that the first appearance of man may have taken place. In his late presidential address to the Anthropological Institute, Mr. Evans referred to the fact that Mr. Everett, a well-known naturalist, had undertaken to devote a twelvemonth to the prosecution of cave-researches in Borneo. Mr. Everett commenced his researches in October last, and the principal proceeds from more or less extensive excavations in several caves are now on their way to this country. Mr. Everett's first quarterly report had just been received by Mr. Evans, in which the discovery is reported of numerous mammalian remains, the age of which has still, of course, to be determined, and also of remains of a race of men of whom no local tradition seems to be extant, and who habitually used the caves of Upper Saráwak either as domiciles, or as places of sepulture, or possibly for other purposes. Though unknown to history or tradition, this race of men appear to have been acquainted with the use of manufactured iron, so that, probably, no great antiquity is to be assigned to the remains already discovered. Mr. Evans stated that at least 100*l*. has still to be forthcoming for the exploration fund, in addition to what has been already subscribed, and that he would be happy to receive subscriptions.

THE magnetic behaviour of iron in the form of powder has lately been investigated by Prof. von Waltenhofen, of Prague. Three samples of finely pulverised and chemically pure iron, filling well-closed glass tubes, were magnetised by means of spirals of wire, through which were sent currents of increasing intensity, and the magnetic moments thus produced were measured. A comparison of these with those excited in equally heavy iron and steel bars by equal magnetising forces shows that the specific magnetisability of pulverised iron is not only much smaller than that of coherent iron, but even smaller than that of the hardest kind of steel known, viz., glass-hard Wolfram steel. Prof. Waltenhofen seeks an explanation of this in the circumstance that the magnetic mutual action of the polar molecules, which strengthens the action of exterior magnetising forces, is greatly lessened through the comparatively great intervals between the particles of the powdered iron; and the numbers he obtained led him to the conclusion that the electromagnetism of an iron bar is to be regarded only in the least part as due to direct action of the magnetising current, and mainly due to that reciprocal action of the molecular magnets.

IN his ninth Bridgewater treatise, Mr. Babbage refers to the possibility of constructing an automaton which would play the simple game of tit-tat-to (or "oughts and crosses"). Such a machine (probably the first ever constructed), working on the principle of a mechanical table, has been made by Mr. Freeland of Philadelphia. It is described in the January number of the *Journal of the Franklin Institute*, and was exhibited at the Institute on October 16 last year. It is now at the University of Pennsylvania, where, since its final adjustment, it has played a large number of games without losing a single one.

EARTHQUAKES are reported from Waldkirch and Buchholz, in Baden, on January 26, at 10 P.M. Both villages are situated in the Elz Valley, on the slopes of the Kandel Mountain, which measures 1,380 metres in height. A violent shock was also felt in the Swiss Canton of Uri on January 24, at 2 A.M.

THE Italian Secretary for Agriculture, Industry, and Commerce, has offered a prize of 3,000 lire (about 115*l*.) for the best monograph on the cultivation, growth, and diseases of the species *citrus* (the common lemon-tree). The competition will last until May, 1881, and all particulars may be learnt direct from the Secretary's office at Rome.

A VERY satisfactory Report comes to us from the Free Library Committee of Dundee. Under the care of Mr. Maclachlan, the library, in the quality of its contents and its organisation, is becoming one of the first of the kind in the kingdom, and is evidently well appreciated by the busy and inquisitive workers of Dundee. Scientific works have a large share of attention, and the museum, we are glad to see, is rapidly extending, and is likely ere long to be worthy of one of our great commercial centres. We have received a carefully compiled fourth supplement to the catalogue of the Library.

THE additions to the Zoological Society's Gardens during the past week include two Slender Loris (*Loris gracilis*) from Ceylon, presented by Mr. Leith Bonhâte; a Common Rhea (*Rhea americana*) from South America, presented by Major Venables; a Purple-crested Touracou (*Corythaix porphyreolopha*) from East Africa, presented by the Rev. J. A. Gould; a Geoffroy's Dove (*Peristera geoffroii*), bred in the Gardens.

OXYGEN IN THE SUN[1]

THE paper referred to appeared in the October number of this Journal.[2] A cursory glance at it gives the impression that the methods had been carefully criticised beforehand, that the experiments had been made with minute accuracy and that the results were trustworthy; but closer examination of it raises most serious questions on all the points mentioned. Errors of method and of experiment appear which make it quite impossible to accept the conclusions reached. It is the purpose of this note to point out some of these.

In the first place the author throughout the paper confounds Ångström's scale numbers with wave-lengths. Thus, for example, p. 257, he says, line 18, the photographs were "in sections of eighty to one hundred wave-lengths," line 24, "each wave-length being five millimeters in extent," and line 34, "each section of one hundred or more wave-lengths;" p. 258, line 24, "Error amounting to half a wave-length could therefore exist in the position of a line, according as it fell on one side or the other of a figure on the scale expressing a wave-length;" p. 259, line 18, one iron line "to every eleven wave-lengths was used;" p. 261, line 18, no element gives "a line within two or three-tenths of a wave-length of that position;" p. 264, line 16, "no other element furnishes a line which falls on the same wave-length." In proof that he really means scale divisions, he gives a section of his chart on p. 259, and says, line 38, "On the first space below the line is the scale of wave-lengths, each wave-length being five millimeters in extent;" and p. 260, line 28, "in the eighteen wave-lengths represented in the diagram." There are eighteen scale divisions in the diagram, each scale division being five millimeters long. Again, p. 264, referring to the coincidence of oxygen and solar lines in his table, he says, line 2, "in four, the difference is only five one-hundredths of a wave-length; in twenty-two, ten one-hundredths of a wave-length; in four, fifteen one-hundredths of a wave-length; in eleven, twenty-one one-hundredths of a wave-length; and in the remainder, the greatest difference is only thirty-five one-hundredths of a wave-length." Referring to the table, the four lines first mentioned are given as 3982·75, 4075·50, 4345·15, and 4483·80; the corresponding oxygen lines being given as 3982·70, 4075·45, 4345·20, and 4483·75. The difference is obviously five one-hundredths of a scale division, not of a wave-

[1] Note on J. C. Draper's paper "On the Presence of Dark Lines in the Solar Spectrum which correspond closely to the Lines of the Spectrum of Oxygen." From the *American Journal of Science* for February. Communicated by the Author.

[2] See NATURE, vol. xviii. p. 654.

length. From the fact that this error runs through the entire paper, it would almost seem as if the author was not aware of the distinction between wave-lengths and scale numbers. Using Ångström's scale he confuses wave-lengths with ten millionths of a millimeter; whereas in the case of D for example, the wave-length is nearly 6,000 times greater. If the author really means what he says, he asserts that the wave-length of the mean ray of the spectrum is one two-hundred and fifty-millionth of an inch instead of about one forty-thousandth, as we know it is.

Second, the author deems it of the greatest importance in the preparation of his solar photographs to use reflected rays exclusively; saying, p. 256, last line, "*at no time did the solar rays pass through glass*; all error that might arise during refraction was thus avoided." After this virtual condemnation of the use of refraction at all, he not only uses for comparison Ångström's wave-lengths made with achromatic lenses and a refracting grating, constructing even his chart upon them as a basis, p. 258, line 7, "the values assigned to the wave-lengths in this chart are those of Ångström"; but the very spectrum of oxygen by which the coincidence of the lines of this element with those of the sun spectrum were to be established, was photographed with glass prisms and achromatic lenses.

Third, the author states that the prisms with which the spectrum of oxygen was photographed were adjusted "to the minimum deviation of D'." Supposing D_1 to be meant, this precaution, which gives the appearance of extraordinary accuracy to the adjustment, is practically an impossibility with the apparatus employed. Minimum deviation of the D line as a whole could not under these circumstances be distinguished from that of either of its components, nor could that of D_1 be distinguished from that of D_2. Moreover, it is difficult to understand why he adjusts to minimum deviation for D' and not for G, near which the work is to be done. Instead of D', the line for which his apparatus was adjusted should have been chosen in the photographic portion of the spectrum, for example between G and H.

Fourth, on page 265, line 25, the author says that this "is a problem not to be solved by the comparison of two spectra of small dispersion." Hence it is a matter of some surprise to find that in getting his oxygen spectrum, he uses only "two flint glass prisms of 60," and for objectives, "achromatics of ten inches focus." The bright line spectrum of oxygen taken by Henry Draper, which the author in this paper inferentially attacks, was made, as we find on examination, with a direct vision battery of nine prisms and an observing telescope of forty-two inches focal length. The original negatives taken with the latter apparatus must consequently have been eight or nine times as long as the author's; and even these were none too large for the proper solution of the question.

Fifth, the author seems to have attempted to compare together a diffraction spectrum of the sun with a prismatic spectrum of oxygen. Such a comparison, by the method adopted, is manifestly of no value. Owing to the irrationality of dispersion of various refractive media it is an extremely difficult thing to compare accurately two prismatic spectra of different kinds. But the matter rises to an absurdity when a comparison is attempted between a grating spectrum and a prism spectrum. The graphic method, employed to supplement the direct method, does not appear to help the comparison, since the author nowhere gives both co-ordinates to the curve constructed.

Sixth, it is more than questionable whether the measurements of the solar lines actually made by the author are capable of the accuracy he assigns to them. The values in his table of wave-lengths are given to one hundredth of a division of Ångström's scale. As the author says on p. 257 that each division of this scale, which is one millimeter, was enlarged to five millimeters upon the paper scale on which the photographs were projected, to measure to one hundredth of a scale-division would require the measurements on the screen to be made to one-twentieth of a millimeter or the one five-hundredth of an inch, about; a degree of refinement highly improbable under these conditions. Moreover the accuracy of the results of such measurements is seriously impaired by the variation in the position of the lines on the screen, due to the fact that the large number of negatives (eight or nine apparently), required to give the whole photographic spectrum, must, unless special precaution was taken (of which there is no evidence), have been made with glass of different thicknesses. When projected in the lantern, this variation in thickness would necessitate a change in focus and so cause a change in the magnifying power. The smaller sizes of photographic glass vary in thickness from one to two millimeters. Consequently the displacement of the lines due to the difference of magnifying power arising from this cause would exceed considerably the limit of measurement, which, as above stated, was the one five-hundredth of an inch. But another and a more serious cause of inaccuracy must here be pointed out. From the data given by the author, it may readily be calculated that his original photographs of the oxygen spectrum, taken with two prisms of 60° and with lenses of ten inches focus, could not have been over half an inch long in the region from G to H. Since Ångström's chart from G to H is sixteen inches long, the author's spectrum would have to be magnified thirty-two times to make it the size of this. But as each millimeter of Ångström's scale was made five millimeters on the author's scale of measurement, the original negative as thrown on the screen must have been magnified one hundred and sixty diameters. Any one who has worked at all in spectrum photography, knows that it is utterly futile for purposes of measurement to magnify a photograph taken under these circumstances, as much as this, since then the size of the silver grains becomes larger than the details of the picture. In the absence of any precise statement the reader has to make the calculation for himself; but the figures above given cannot be far astray.

Seventh, there is only an appearance of accuracy when the attempt is made to fix the position of the oxygen spectrum lines to hundredths of one of Ångström's scale divisions. The projection method by which his solar lines were measured, has already been proved inadequate. And as to the method of graphical interpolation, used as auxiliary to the lantern, it does not appear that, as used by the author, it was capable of any such accuracy as that claimed. In constructing the curve, the iron lines are taken with Ångström's values for the wave-lengths; but these, though estimated to tenths, were read only to whole divisions of the scale. Moreover, only forty-seven iron lines were used in all, or one to every eleven scale divisions; the reading being to one one-hundredth of a scale division, or 1,100 numbers to one iron line. Since the author measured no wave-lengths directly, he was obliged to construct a considerable "portion of the curve from the wave-lengths of oxygen and air lines already given by various authorities." These values were taken, p. 258, from Watt's "Index of Spectra." On referring to this book, the values are given only to the units place. And even then, discrepancies amounting to from three to five entire units, or from three hundred to five hundred times the author's limit, appear in the wave-length as given by the various authors relied on for the measurements employed in the paper before us.

Eighth, the author nowhere states the peculiar character of the lines in the oxygen spectrum and appears not to know that they have any. He has apparently taken it for granted that the lines of oxygen are intrinsically as sharp as the lines of the solar spectrum. But this, at least in many instances, is known not to be the case. Consequently it is quite impossible to measure the oxygen lines as accurately as the solar lines, and even these, as has been shown, cannot be measured to the accuracy which the author claims. Ångström himself admits that there may be an error of one-tenth of a division in his scale numbers.

It would seem sufficiently obvious from what has been said that the results given in this paper are entirely vitiated by the errors of method and of experiment which it contains. The author must not be confounded, because of the similarity of initials, with the distinguished investigator, Dr. J. W. Draper.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

UNIVERSITY education for women may be taken as firmly established in England. The names of nine out of eleven female candidates have just been posted at Burlington Gardens as having passed the winter matriculation examination of the University of London, half-a-dozen in the honours division, besides three more in that next below, and are thus now on the high road to its B.A. degree, on the occasion of its first decorating their sex three academical years hence. From two interesting articles in the *Daily News* it is seen that Girton and Newnham Colleges have attained to unexpected success. The former is so much too small for the number of students that yearly flock to it that it is to be nearly doubled in size. At both institutions the students work much more earnestly than the average student of the hitherto privileged sex, and the examinations passed, at least at Girton, would

suffice to give the most successful student a high place in the Cambridge list of Wranglers. No doubt, in the near future, English girls all over the land will have as few obstacles in the way of their higher education as English boys.

MR. H. T. WOOD, of the Society of Arts, writing to Col. Donnelly, of the Science and Art Department, South Kensington, informs him that sufficient funds will be provided by the City Companies for the payment of teachers of classes for instruction in technology, on the same scale as that on which teachers of science classes are now paid by the Science and Art Department, and without any proportionate reduction, as stated in the Society's Programme of Examinations (p. 14), on the ground that all the amount at the disposal of the Society might be insufficient to allow of the full payment in all cases. Mr. Wood asks that this important fact be brought under the notice of the Secretaries of Science Classes and Schools. The arrangement will apply to the examinations held in May next.

DR. T. LAUDER BRUNTON, who was recently appointed to the Thomson Lectureship in the Aberdeen Free Church College, delivered the opening lecture on Monday, the 3rd inst. The course will consist of ten lectures.

THE University Library at Strassburg, founded after the recent Franco-German War, numbered no less than 470,000 volumes at the end of 1878.

WE are glad to see that in the second number of the *University College of Wales Magazine* science finds a corner in the shape of "Museum Notes." One of these, by Prof. Rudler, is a brief *résumé* of what is known of the Moa, *apropos* of a collection of moa-bones in the College Museum.

SCIENTIFIC SERIALS

Journal of the Franklin Institute, January.—The error of some wild statements made about the size and cost of the cable that would be needed to convey the power of Niagara Falls several hundred miles by electricity is here shown by Professors Thomson and Huston, who calculate, *e.g.*, that 1,500 to 3,000 horse-power could be conveyed 1,000 miles (50 per cent. out of 3,000 horse-power) with a copper cable about $\frac{3}{4}$ inch in thickness. Less than $\frac{1}{2}$ inch would suffice for 500 m. For consumption of 1,000,000 horse-power a 3-inch cable would suffice. The same authors describe a curious thermo-magnetic motor, and an induction apparatus for reversed currents.—Dr. Henry Morton finds the coating of the "luminous clocks" sulphide of calcium attached with some resinous medium, and seems hopeful that advances in this direction may by and by give us houses lit at night by phosphorescent walls.—Mr. Huston gets some remarkable effects (needing confirmation from repeated tests) in subjecting iron to a continued and constantly increasing strain.—Dr. Dudley considers toughness, rather than hardness, the essential quality for durability of steel rails.—An automatic machine for playing the game of tit-tat-to is described by Mr. Freeland.

Reale Istituto Lombardo di Scienze e Lettere, vol. xi. fasc. xix., xx.—On some derivatives of ethyl-paraoxybenzoic aldehyde, by S. Corbetta.—The English sanitary laws, by Dr. Zucchi.—On the use of salts of berberine as febrifuge, and on tumours of the spleen from malarian infection, by Dr. Zucchi.—Studies on milk at the Pavian laboratory of cryptogamic botany, by Drs. Pirotta and Riboni.—Value of two meteorological instruments of Bellani, by Prof. Cantoni.—Observations on the seismic microphone of De Rossi, by Prof. Cantoni.

Vol. xii. fasc. i.—Studies on milk (continued), by Drs. Pirotta and Riboni.—New physio-pathological researches on pulmonary phthisis, by Prof. de Giovanni.—First lines of introduction to the study of the Italian bacteria, by S. Trevisan.—On modular equations, by S. Klein.—On pentahedral equations of surfaces of the third order, by Prof. Beltrami.

Bulletin de l'Académie Royale de Belgique, No. 11, 1878.—Besides M. Montigny's paper on variations in the scintillation of stars (referred to last week), this number contains a valuable memoir by M. Fredericq on the organisation and physiology of the poulpe (or octopus), which he studied at the laboratory of Roscoff. The arterial blood yields a blue colouring matter (called *hæmocyanine*), which corresponds somewhat to hæmoglobin, but contains copper, not iron. Both respiration and nutrition of tissues depend on it. The heart has both accelerating and moderating nerves. The blood pressure is considerably greater than in cold-blooded vertebrates; the venous system shows rhythmic contraction; exterior water does not mix with the blood; the urine contains neither urea nor uric acid, but a substance like guanine, &c. M. Fredericq localises the centres of the respiratory movements, and gives some interesting observations on the "chromatic function."—M. Van der Mensbrugghe finds confirmation of his theory of the variations of potential energy of liquid surfaces, in some peculiarities of liquid sheets, which he accounts for on thermodynamical principles.—M. Lienard communicates researches on the structure of the digestive apparatus of Mygales and Nephiles, and M. Longchamps concludes his synopsis of the Gomphines.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, January 30.—"On the Effects of Heat on the Di-iodide of Mercury, HgI_2," by G. F. Rodwell, Science Master, and H. M. Elder, a pupil, in Marlborough College.

The authors, in continuation of experiments of a similar character previously communicated by one of them to the Society, on the anomalous expansion of the iodide of silver, have examined the iodide of mercury with a view to the detection of similar anomalies. This body is dimorphous, existing in the form of yellow prismatic crystals, which change under external mechanical influence, or during the process of cooling, to brilliant scarlet octohedrons with a truncated summit. The mass melts at 200° C. to a red-brown liquid, which volatilizes at a slightly higher temperature. The following volumes were determined at the temperatures given:—

	Volume.		Specific Gravity
Liquid at 200° C.	1·1191147	...	5·286
Solid ,, ,, ...	1·0190453	...	6·179
Yellow prismatic condition at 126° C.	1·0115378	...	6·225
Red octohedral condition at 126° C.	1·0043337	...	6·276
,, ,, ,, at 0° C.	1·0000000	...	6·297

Thus the di-iodide of mercury possesses one coefficient of expansion = ·0000344706 for 1° C. between 0° and 126° C., it then undergoes a sudden expansion = ·00720407 in changing from the red octohedral to the yellow prismatic variety, while between 126° C. and the melting-point (200° C.), it expands under a higher coefficient than before = ·0001002953 for 1° C.

"A Comparison of the Variations of the Diurnal Range of Magnetic Declination as recorded at the Observatories of Kew and Trevandrum." By Balfour Stewart, F.R.S., Professor of Natural Philosophy in Owens College, Manchester, and Morisabro Hiraoka.

1. Generally speaking, maximum points or risings in the one curve must be associated with maximum points or risings in the other, rather than with minimum points or depressions. Indeed, the researches of Broun and others, from a different point of view, strengthen this conclusion, which is, however, abundantly supported by a glance at the curves themselves.

2. The oscillations of the Trevandrum curve are greater than than those of the Kew curve.

3. In many cases where there is a want of striking likeness between the oscillations of the two curves, there are yet noticeable traces in the one curve corresponding to the oscillations of the other. There are, however, a few cases where there is a want of apparent likeness.

4. In general, though not invariably, the oscillations of the Trevandrum curve follow rather than precede the corresponding oscillati ons of the Kew curve.

February 6.—"Absorption of Gases by Charcoal. Part II. On a new Series of Equivalents or Molecules." By R. Angus Smith, Ph. D., F.R.S.

In the *Transactions* of the British Association, 1868, Norwich, on p. 64 of the "Abstracts," there is a preliminary notice of an investigation into the amount of certain gases absorbed by charcoal. I made the inquiry from a belief previously expressed in a paper of which an abstract is in the *Proceedings* of the Royal Society, p. 425, for 1863. I said in that paper that the action of the gas and charcoal was on the border line between physics and chemistry, and that chemical phenomena were an extension of the physical; also that the gases were absorbed by charcoal in whole volumes, the exceptions in the numbers being supposed to be mistakes. The results given were:—

Hydrogen	1
Oxygen	7·99
Carbonic oxide	6·03
Carbonic acid	22·05
Marsh-gas	10·01
Nitrous oxide	12·90
Sulphurous acid	36·95
Nitrogen	4·27

It was remarked that the number for nitrogen was probably too low; I had some belief that the charcoal retained a certain amount which I had not been able to estimate.

For common air, the number 40·065 crept into the paper or abstract instead of the quotient 7·06.

I considered the numbers very remarkable, but was afraid that they would be of little interest unless they could be brought more easily under the eyes of others; my experiments were somewhat laborious; the exact numbers were seldom approached by the single analysis, but were wholly the result of a series of irregular averages and apparently irregular experiments. The cause of this was clear, as I believed, namely, the irregular character of the charcoal with which I had to deal. The experiments were forgotten, I suppose, by most men, but the late Prof. Graham told me that he had repeated them with the same results that I had published. I might have considered this sufficient, but waited for time to make a still more elaborate investigation of the subject, and to take special care with oxygen, in the belief that, the rule being found, the rest of the inquiry would be easy; this was extended to nitrogen, but not by so many experiments as with oxygen. I am now assured of a sound foundation for inquiries, which must take their beginning from the results here given.

It is found that charcoal absorbs gases in definite volumes, the physical action resembling the chemical.

Calling the volume of hydrogen absorbed 1, the volume of oxygen absorbed is 8. That is, whilst hydrogen unites with eight times its weight of oxygen to constitute water, charcoal absorbs eight times more oxygen by volume than it absorbs hydrogen. No relation by volume has been hitherto found the same as the relation by weight.

The specific gravity of oxygen being 16 times greater than hydrogen, charcoal absorbs 8 times 16, or 128 times more oxygen by weight than it does hydrogen. This is equal to the specific gravity of oxygen squared and divided by two $\frac{16^2}{2}$, or it is the atomic weight and specific gravity multiplied into each other, 16×16, and divided by two $\frac{256}{2} = 128$.

Nitrogen was expected to act in a similar way, but it refused. The average number of the latest inquiry is 4·52, but the difficulty of removing all the nitrogen from charcoal is great, and I suppose the correct number to be 4·66. Taking this one as the weight absorbed, $14 \times 4{\cdot}66 = 65{\cdot}3$, or it is $\frac{14^2}{3}$. Oxygen is a dyad; nitrogen a triad.

We have then carbonic acid not divided, but simply 22 squared = 484.

Time is required for full speculation, but the chemist must be surprised at the following:—

Carbonic oxide	6	volumes.	
Carbonic acid, CO_2	6 + 16	,,	= 22.
Marsh-gas, CH_4	6 + 4	,,	= 10.
Protoxide of nitrogen, NO	8 + 4·66 (N) (4·9).		= 12·66.

These four results belong to the early group not corroborated lately, but so remarkably carrying out the principle of volume in this union giving numbers the same as those of weight in chemical union, that they scarcely require to be delayed.

I am not willing to theorise much on the results; it is here sufficient to make a good beginning. We appear to have the formation of a new series of molecules made by squaring our present chemical atoms, and by certain other divisions peculiar to the gases themselves. Or it may be that the larger molecule exists in the free gas, and chemical combination breaks it up. These new and larger molecules may lead us to the understanding of chemical combinations in organic chemistry and whenever there is union not very firm, and may also modify some of our opinions on atomic weights and the motion of gases.

Of course, I cannot pretend to give the result of these results; but as we have here the building up of a molecule by volumes, so as to form an equivalent of physical combination analogous to the chemical equivalent, it is impossible to avoid seeing that it indicates the possibility of our present equivalents being made up in a similar manner.

I did not expect these numbers; but I certainly, as my previous paper showed, had in full view a necessity for some connection between physical and chemical phenomena more decided than we possessed.

Chemical Society, February 6.—Dr. Gladstone, president, in the chair.—This meeting was occupied by the discussion on the processes for determining the organic purity of potable waters, a paper read by Prof. Tidy some time since. Dr. Frankland opened the discussion and criticised at some length the objections urged by Prof. Tidy against his method of estimating the carbon and nitrogen in a water residne by combustion. The discussion was continued by Mr. Wanklyn, Mr. Kingzett, Prof. Bischof, Dr. Voelcker, Mr. Grosjean, Dr. Dupré, Mr. W. Thorp, and Dr. Hake. Prof. Tidy then briefly replied, and the proceedings terminated with a unanimous vote of thanks from a crowded meeting to Prof. Tidy for his paper.

Zoological Society, February 4.—Dr. Günther, F.R.S., vice-president, in the chair.—Mr. Sclater exhibited and made remarks on a specimen of a Curassow, belonging to the Royal Museum of Copenhagen, which he had received from Prof. J. Reinhardt, F.M.Z.S., for examination, and which Prof. Reinhardt had proposed to refer to a new species (*Mitua salvini*).—Mr. R. Bowdler Sharpe exhibited a series of Bulwer's Pheasant (*Lobiophasis bulweri*), from the Lawas River, N.W. Borneo, collected by Mr. W. H. Treacher, Acting-Governor of Labuan. The series represented every stage of plumage of this pheasant, and conclusively proved that *L. castaneicaudatus*, Sharpe, was the immature male of *L. bulweri*.—A communication was read from Prof. A. H. Garrod, F.R.S., containing some notes on certain points in the anatomy of Hoatzin (*Opisthocomus cristatus*).—Mr. Sclater read some notes on the breeding of the Argus Pheasant and other Phasianidæ in the Society's Gardens.—A communication was read from the Rev. O. P. Cambridge, C.M.Z.S., containing the description of a new genus and species of spiders, proposed to be called *Fritzia muelleri*.—Mr. W. Ottley read the firs part of a series of observations on the structure of the eye-muscles in the mammalia.—A communication was read from Mr. Osbert Salvin, F.R.S., on some birds transmitted by the Rev. Thomas Powell from the Samoan Islands, amongst which were two new species proposed to be called *Pinarolestes powelli* and *Fregetta mœstissama*.—A communication was read from Mr. W. H. Dale containing remarks on the use of the generic name *Gouldia* in zoology.—Mr. George A. Shaw read notes upon the habits of four species of Lemurs, specimens of which had been brought alive to England in 1878, from the province of Betsileo in Central Madagascar.—A communication was read from Mr. F. Moore, F.Z.S., containing descriptions of some new Asiatic diurnal lepidoptera.—Dr. A. Günther, F.R.S., pointed out the characters of a new rodent from Medellin, U.S. of Columbia, for which the name *Thrinacodus albicauda* was proposed.

Linnean Society, January 16.—Mr. W. Carruthers, F.R.S., vice-president, in the chair.—Prof. Allen Thomson exhibited and made some remarks on a block of wood, during the growth of which a portion of the shank-bone of an ox had become centrally inclosed; he also called attention to an imperfect frond of a palm (Chæmærops?) asserted to have been discovered within a plank of rosewood.—Mr. Christy in some observations referred to the Chalmugra tree (*Gynocardia odorata*), its therapeutical properties being highly extolled, especially in rheumatism.—Mr. J. G. Baker read a paper on the Colchicaceæ and aberrant tribes of Liliaceæ. Colchicaceæ is the smallest ot the three sub-orders of Liliaceæ, it includes 39 genera and 153 species. Its geographical dispersion agrees completely with true Liliaceæ. In its typical form it is marked by extrorse anthers, a septicidal capsule, and three distinct styles; but as 24 out of 39 genera do not possess all these three characters in combination, but recede more or less decidedly from the type in the direction of true Liliaceæ, it seems injudicious to follow those who have proposed to keep up Colchicaceæ or Melanthaceæ as a distinct natural order. Mr. Baker defines seven tribes, Colchiceæ, Merenderæ, Veratreæ, Anguillareæ, Helonieæ, Uvularieæ, and Tofieldieæ. There are several anomalous genera of the Colchicaceæ, for instance Hewardia, which connects the Liliaceæ with the Iridaceæ. Again, there are three aberrant tribes of Liliaceæ, viz., (1) Conantheræ a connecting link between Liliaceæ and Amaryllidaceæ, (2) Liriopeæ

(formerly Ophiogon) and (3) Gilliesieæ; genera among the two latter receding widely from the liliaceous type and others bridging over the interval between the extreme form and ordinary lilies. The author then enters into lengthened descriptions with ample diagnosis, &c., forming in fact a valuable continuation of his former series of monographs of the natural order of Liliaceæ. —Messrs. G. Brook, A. P. Luff, J. E. Griffiths, C. Sharp, and J. Woodland, were balloted for and elected Fellows of the Society.

Anthropological Institute, January 28.—Anniversary Meeting.—Mr. John Evans, D.C.L., F.R.S., president, in the chair.—The election of Mr. A. H. Keane, B.A., as a Member was announced.—The following gentlemen were elected to serve as officers and council for the year 1879. President—E. B. Tylor, F.R.S. Vice-Presidents—Hyde Clarke, J. Evans, F.R.S., Prof. Flower, F.R.S., Maj-Gen. A. Lane Fox, F.R.S., Francis Galton, F.R.S., Prof. Rolleston, F.R.S. Directors and Hon. Secretaries.—E. W. Brabrook, F.S.A., W. L. Distant, J. E. Price, F.S.A. Treasurer—F. G. H. Price, Esq., F.R.G.S. Council—Lt.-Col. Goodwin Austen, J. Beddoe, F.R.S., Prof. George Busk, F.R.S., C. H. E. Carmichael, M.A., J. Barnard Davis, Esq., F.R.S., W. Boyd Dawkins, F.R.S., Capt. Harold Dillon, F.S.A., A. W. Franks, Esq., F.R.S., J. Park Harrison, M.A., Prof. Huxley, F.R.S., A. L. Lewis, Sir J. Lubbock, Bart., M.P., R. Biddulph Martin, F. W. Rudler, F.G.S., C. R. Des Ruffières, F.R.S.L., Lord Arthur Russell, M.P., Rev. Prof. Sayce, M.R.A.S., Dr. Allen Thomson, F.R.S., C. Staniland Wake, M. J. Walhouse, F.R.A.S. The retiring president delivered his annual address, in the course of which he alluded to the researches now being carried on in the caves of Borneo by Mr. Everett (see p. 352).

Geological Society, January 22.—Henry Clifton Sorby, F.R.S., president, in the chair.—John Edward Marr and Lieut. Henry Tryon Wing were elected Fellows of the Society.—The following communications were read:—On community of structure in rocks of dissimilar origin, by Frank Rutley.—Distribution of the serpentine and associated rocks, with their metallic ores, in Newfoundland, by Alexander Murray.

Institution of Civil Engineers, February 11.—Mr. W. H. Barlow, F.R.S., vice-president, in the chair.—The following papers were read:—On the Geelong water supply, Victoria, Australia, by Mr. Edward Dobson, Assoc. Inst., C.E.—On the Sandhurst Water Supply, Victoria, Australia, by Mr. Joseph Brady, M. Inst. C.E.

Victoria (Philosophical) Institute, February 3.—A paper on the Torquay caves was read by Mr. J. E. Howard, F.R.S., in which he reviewed the reports given by geologists who had excavated and examined the various deposits in these caves. Mr. Howard examined into the nature of these deposits and the conditions under which they must have taken place, and pointed out the peculiar nature of the evidence by which it was possible to arrive at some conclusion as to the age of those deposits. Prof. Challis, F.R.S., and others took part in the discussion, either by sending communications to be read or by attending to do so.

PARIS

Academy of Sciences, February 3.—M. Daubrée in the chair.—The following papers were read:—Remarks on the third reply of M. Pasteur, by M. Berthelot.—On the development of the perturbative function, &c. (continued), by M. Tisserand.—On the fermentation of cellulose, by M. van Tieghem. The author gives observations on amylobacter, the figured ferment of cellulose. It affects different plant tissues differently; only in the young state have all the cells of all plants their membranes equally dissolved by it. The results have a physiological bearing (digestibility of cellulose from different plants), and a palæontological (unequal chances of fossilisation of different plants). The amylobacter first transforms soluble starch into dextrine, then into glucose, and it is really the glucose that ferments. It seems to be by direct contact of amylobacter with cellulose that the latter is dissolved, not through a diastase of cellulose acting without at a distance.—On the construction of the international geodetic scale, by MM. Sainte-Claire Deville and Mascart.—An account of the physical and chemical properties of the scale (of iridised platinum) prepared by Johnston and Matthey, and of experiments to determine the coefficient of dilatation of a thermometric tube made of the material.—On the invention of several arrangements of the heliometer, by M. De la Gourmerie. He attributes the half objectives not to Dollond but to Bouguer, considered the original inventor of the heliometer.—M. Cosson called attention to a case of fire in the laboratory of his herbarium, arising from carbonisation of boards of flooring exposed to hot air from an air-hole fed from a stove 4 m. off on the floor below.—M. de Lesseps presented a fourth volume of his "Letters, Journal, and Documents to serve for the History of the Suez Canal." He quoted a long letter he had addressed to Mr. Layard, vindicating the enterprise against opposition then offered.—M. Lalanne was elected Free Member in room of the late M. Bienaymé.—On the conditions of existence of a determinate number of roots common to two given equations, by M. Simonnet.—On some invariants of linear differential equations, by M. Laguerre.—On the motion of a body which is displaced and deformed while remaining homothetic with itself, by M. Fouret.—Integration, in finite form, of three species of linear differential equations with any coefficients, by M. André.—Extension of the metric system of weights and measures; development of concordant monetary systems in the various states of the civilised world, by M. de Malarce. The metric system of weights and measures is now established obligatorily in eighteen states, with 236·6 millions of inhabitants; it is legally optional in three states with 75·5 millions; and it is admitted in principle, or partially for customs, in five states, with 343·6 millions.—Liquefaction of siliciated hydrogen, by M. Ogier. It is liquid at $-11°$ under 50 atm.; at $-1°$ under 100 atm. At zero it remains gaseous up to 150 and 200 atm.—Memoir on the determination of methylic alcohol in commercial methylenes, by MM. Bardy and Bordet.—Influence of duration and intensity on luminous perception, by MM. Richet and Breguet. A weak light, perceived distinctly when it impresses the retina some time, becomes invisible when its duration diminishes. It may be rendered visible anew by making it more intense, or increasing its duration, or repeating it rapidly. Coloured lights are subject to the same laws, and are always seen with their proper coloration, whether strong or weak, long or short.—On the minute structure of the central nervous system of decapod crustaceans, by M. Yung.—On the Wagnerite of Bamle in Norway, and on a retinite of Russia, by M. Pisani.—The glazed frost of January, 1879, by M. Godefroy.—On the effects of the same at Fontainebleau, by M. Piebourg. This (somewhat rare) phenomenon did great mischief to trees, the greatly increased weight breaking down their branches, &c.

GÖTTINGEN

Royal Academy of Sciences, November 2, 1878.—The following, among other papers, were read:—On a propagation of the growth-stimulus produced by fertilisation on vegetative organs, by Herr Reinke.—Observations on the value of a ligature of the great brain-arteries, for experimental pharmacological researches, by Herr Marmé.

THE COAL MINE COMMISSION

MUCH misapprehension of facts, and much ignorance of scientific principles are, it is to be feared, the most prominent characteristics of the knowledge possessed by most people regarding the nature and mode of occurrence of colliery explosions. Pompous platitudes about the carelessness of the men, and windy panegyrics on the virtues of the safety-lamp have been freely pronounced times without number during the last two generations of mankind. Committees on accidents in mines have met, discussed the question, and separated; inspectors of mines have been appointed, stringent regulations have been framed and enforced which bind both employer and employed, the public have listened to the tale of woe, have wept over the fate of the hapless miner, and have subscribed hundreds of thousands of pounds in aid of his widows and orphans, and yet with all this, and more untold, the history of the past eighteen months would seem almost to indicate that we are as far as ever from a true solution of this much-agitated question.

Can science, then, do nothing? is her hand unable to save even a moiety of the lives that are being constantly cast away before her very eyes? To this question, which is very often asked, the reply is simple. Science can undoubtedly solve the question, but she must do it in her own way; she must approach it with the sap and mine of investigation and research; she must have her own time to do it, and above all, she requires to be encouraged. Scientific men have, no doubt, sometimes turned their attention to the subject without much apparent result, but their efforts have, as a rule, been of short duration, and they have too often met with discouragement, active opposition, and incredulity. We have only to point to Dr. Birbeck's letter to the South Shields Committee (1843) at p. 48 of their report, and to the report addressed to the committee of the coal trade by the special committee appointed to take into consideration the report of Lyell and Faraday on the Haswell Colliery explosion to exemplify what we mean. We wish we could say that there are no examples of the same kind at the present day, but unfortunately we are unable to do so.

Putting aside these gloomy thoughts, however, we are rejoiced to see science so well represented on the Commission just appointed to inquire into and report upon this matter. We had always imagined it to be a purely scientific question, having almost no relation to the art of mining in its stricter sense. We confess that ours is not the common view, but that, on the contrary, it is usually supposed that if practical men, including inspectors of mines, are unable to prevent explosions, nobody else need try to do so. We cannot accede to such a proposition; nay, more, we protest against it. If disasters of this kind could be stopped by hedging round the collier and his employer, with an impenetrable palisade of instructions and restrictions, then we are bound to acknowledge that the practical man with a legal turn of mind could do it effectually. This method has been tried, however, or rather, it is now in force, and we see its results.

The new Commissioners will, no doubt, seek to acquaint themselves to some extent with the work of their predecessors and contemporaries; they will also weigh carefully the opinions that will be expressed before them, and take account more of the facts and reasoning that can be adduced in support of such opinions than of the age and position of those who express them. For example, they will not come to any conclusion regarding the influence of fluctuations of atmospheric pressure and temperature upon the issue of fire-damp from coal until they have obtained a sufficiently large and well-authenticated mass of information to enable them to arrive at sound conclusions. The data which have been collected and tabulated by Messrs. Scott and Galloway and others are amply sufficient to show that the matter is worthy of further careful consideration, but they do not extend over a lengthened period of time, and we venture to say that their weight would be greatly augmented by a further addition of similar facts. As to the use of fire-damp indicators (and by this we suppose are meant instruments for giving notice of the occurrence of outbursts of gas), we fear that their importance has been absurdly exaggerated and that they are brought forward by those who know nothing about mining. It will be for the Commissioners to inquire, however, whether there are any mines in existence in which they could really be of any service. The systematic observation of the air in mines may be taken, we suppose, to apply both as to its quality and quantity. As regards its quality, it will have to be determined whether observations of the height of the cap on the lamp-flame reduced to small dimensions, such as those described by Mr. Galloway in the *Proceedings* of the Royal Society, 1876, are sufficiently accurate and reliable, or whether it will be necessary or expedient to bring into use some kind of instrument like the *grisoumètre*, by means of which a rapid analysis of the air can be made. As regards its quantity, on the other hand, it may be suggested that if the velocity and drag of the currents could be continuously recorded in a manner similar to the pressure and temperature of the air at the meteorological stations, a check might be kept upon the ventilation, and changes in its efficiency could be ascertained by a mere inspection of the curves. Improved methods of ventilation and illumination are important objects. Powerful machines are now being erected at most new collieries, but these alone cannot prevent explosions, if we may judge by the case of Abercarne, which was thoroughly well equipped in that respect. The Commissioners must beware of being drawn into the belief that some advantage can be gained by forcing the air into the mines instead of driving it out by way of keeping the gas in the coal, as it were, and thereby escaping the effect of atmospheric influences. They themselves will be able to balance the slight gain of pressure that could be obtained in this way with the normal pressure of gas in the coal. It will be well worth their while, however, to consider the means that have been suggested of late years for producing an artificial barometric depression in the workings with the view of extracting the gas from the open fissures, old works, and even to some extent from the face of the coal, when the men are out of the mine, and then sweeping it out by admitting air freely through the downcast shaft, and at the same time continuing to work the

exhausting machine. As to ourselves, we thought the idea chimerical when it was first brought under our notice; but after reading a pamphlet on the subject by M. Francis Laur, of Saint-Etienne, we were forced to change our mind. The kind of safety-lamps that ought to be employed will form a subject of warm debate, but we can confidently assure the Commission that if they separate without recommending the universal adoption of lamps that will not continue to burn in an explosive atmosphere, and of more perfect locks than the present ones, they will have failed to satisfy one of the most important requirements of the time. We say this without prejudice to the means that may be thought best for examining the workings for accumulations of gas: we refer to the lamps supplied to the common workmen. The employment of explosive agents in getting the mineral, and other particulars relating to mines and mining operations include, we think, the most important of all the questions that will come before the Commissioners. What is coal-dust? and what bearing has it on the subject? If the presence of coal-dust is, after all, the cause of all these great explosions, and if, as has been once before asserted in these pages, great explosions never happen in damp or wet mines, but always in dry ones containing coal-dust, then surely the Commissioners would be but dallying with the subject if they omitted to carefully weigh all the facts that have been adduced in favour of this hypothesis. They will have to turn to other sources, however, than the reports of the inspectors of mines for information; and they might do worse than consult the report drawn out by M. Haton de la Goupillière of the doings of a similar commission appointed by the French Government in 1878, under the title of *Rôle des Poussières de Charbon*, in which they will find it alluded to, and an historical account given of the steps that have led to our present knowledge regarding it. Otherwise the literature of our own country is not quite so sterile in this respect as it was three years ago; but doubtless the Commissioners will provide themselves with all the most recent information.

The dangers due to the use of explosives in mines are of three kinds: firstly, the shot may ignite an accumulation of gas directly; secondly, it may effect the same thing indirectly by driving the flame of a safety-lamp burning in the accumulation through the meshes of its wire gauze cylinder; thirdly, the sudden rush of flame and the violent disturbance of the air caused by a blown-out shot (that is to say, one which expels its tamping without bringing down or even breaking the rock) may raise and ignite the coal-dust in front of it, and more especially if it is directed towards or parallel with and near to the floor. In the last case the flame has been often known to extend to a distance of thirty, forty, and even eighty yards from its origin, and such a disturbance taking place under favourable conditions is quite sufficient to initiate explosions such as those of Blantyre, Haydock, Abercarne, and Dinas, in which close upon a thousand lives have been lost within the last eighteen months. When we add that each of these mines was very dry and contained plenty of coal-dust, and was not known to contain more than insignificant accumulations of fire-damp, quite insufficient to account for a tithe of the extent and violence of the explosions, we have said enough, we think, to make it apparent how pressing is this matter.

Blasting operations can be safely carried out in any mine if the shots are not fired near explosive accumulations, if the lamps are of such a construction that they cannot burn in an explosive atmosphere, and if the mine is a damp one. It is easy enough to provide the two first requirements, and it is obvious that by plentifully watering the roadways we can turn a naturally dry mine into a damp one and avoid danger such as we have described from blasting, as well as localise explosions of fire-damp. We have seen it stated in a footnote at p. 661 of the last number of the *Bulletin de la Société de l'Industrie Minérale* that dusty mines, which are at the same time well ventilated, may be watered frequently without obtaining permanent humidity. Fortunately, however, we are in a position to point to an example which has come under our own immediate notice, of an extensive mine in which the workings are kept damp throughout their whole extent by a constant application of water. In the case to which we refer the daily output of coal is 800 tons, the temperature of the workings is between 70° and 80° Fahr., and the amount of air passing into and out of the mine is between 80,000 and 90,000 cubic feet per minute.

In conclusion we are eminently satisfied that science is so well represented on the Commission; and if its various members will pull together like a well-balanced team, we anticipate the happiest results from its researches and labours.

KINGZETT'S ANIMAL CHEMISTRY

Animal Chemistry; or, The Relations of Chemistry to Physiology and Pathology. A Manual for Medical Men and Scientific Chemists. By Charles Thomas Kingzett, F.C.S. (London: Longmans, Green, and Co.)

FOR many years the want of a good manual of physiological chemistry or animal chemistry in the English language has been a standing reproach to English science. The causes of this want are not far to seek. Physiology has not many votaries in England, and physiological chemistry, being in interest one step farther than physiology from the verge of medical practice, has still fewer followers. The number of possible writers of a text-book of animal chemistry has, therefore, been small; and, among them, the number of men whose capability and opportunities for such an undertaking might justly have led them to hope for a successful issue to their labours has, it is needless to say, been smaller still. The qualifications to be looked for in one who attempts the task of writing such a manual are indeed not slight. He must be a thoroughly trained chemist whose judgment has been much exercised in the appreciation of chemical questions; he must be a physiologist with a sound and direct knowledge of most of the practical methods of physiology; he must be an anatomist who is fairly well acquainted with the microscopic structure of animal tissues; and he should have some insight, exact if not special, into morbid processes and pathological states. We need not wonder, then, that the labourers have been few.

The absence of any very recent English work of the kind does not lighten the difficulty of writing one; but the disadvantage of this absence is not so great as it might at first sight seem; for on the Continent there are text-books which in case of need might have served as a standard or lay-figure.

The difficulties of the task have, therefore, without a doubt, been many; but the task itself should not have been hopeless or ungrateful. English workers in physiological chemistry have at present to betake themselves to Hoppe-Seyler, Kühne, Gautier, Gorup-Besanez, for the chemico-physiological facts they stand in need of. English students have to make do the brief sections on Animal Chemistry—admirable, but of necessity imperfect and categorical—contained in the English text-books of physiology. Hence an English book specially devoted to animal chemistry, if at all exhaustive, accurate, and modern, would be likely to bespeak for itself a hearty welcome, and a disposition to extenuate its shortcomings.

Such were the prospects, unfavourable and favourable, of an attempt to fill up the book-shelf of English workers in natural science by a manual of animal chemistry. We turn to Mr. Kingzett's book, and, after a careful and reiterated perusal of it, we can say that never was attempt so rashly undertaken. We had expected a sound, if modest, substratum of physiological knowledge, and we find slipshod notions and the speculations of the amateur. We had expected apposite illustrations from pathology, and we find, in most cases, trivial and meaningless references to disease. We had expected a complete and careful account of the more purely chemical portions, and we find a degree of imperfection which sends us back with thankfulness to the chemical sections of Foster and Hermann.

Nor is this all. The book is styled a book of animal chemistry, and we therefore expected animal chemistry; but in addition to the sections so called we find scattered here and there reflections on life, character, and the morals of scientific work which, even were they not mere platitudes, would be utterly out of place in a work like this.

These strictures may seem severe, but they would not be wholly unexpected by any one who had read Mr. Kingzett's preface. He says:—"For four years I was occupied with the practical study of subjects comprehended in the following chapters, and during the whole of that time there were no fluctuations in the success attending the labours in which my services were involved. . . . It was therefore a matter of sincere regret with me that circumstances (which are said to be stronger then men) ultimately necessitated the discontinuance of my connection with work which had given me so much real pleasure." Then follows a page or so of reflections on the pleasure to be derived from original investigation; comparisons of the "scientist" and the "sentimentalist;" and so forth. "It was natural, then," he continues, "that, having experienced so much pleasure, I should be moved with equal regret in resigning the practical study of physiological chemistry; and in order to complete a well-remembered but brief connection with this subject, I determined to attempt a task which should prove of service to scientific men, namely, to collect and systematise, as far as could be, all the trustworthy work on record in relation to animal chemistry, so far as it concerns the human body." We submit that four years' practical work at a subject like animal chemistry, be the success of the worker never so unfluctuating, is hardly warrant enough to undertake that which taxes the matured judgment even of a master, viz., the making of a useful and comprehensive text-book. Nor do we perceive that Mr. Kingzett's desire to signalise his departure from the field of chemico-physiological research adds any urgency to the warrant. We hope to show in the sequel that this prefatory confession on the part of the author, of practical unpreparedness for the task he had set himself to do, is fully borne out by the internal evidence of the book.

Mr. Kingzett does not profess to have included any account of the practical methods of the science. This, while it much lightens the labour of writing the book, is, we think, doubly to be regretted; because the book is to be read by medical men, who are not supposed in every case to remember chemical methods, and by scientific chemists who cannot be expected to know, for example, the modes of practising fistulæ, or rapidly removing blood from brains intended for analysis.

Mr. Kingzett's haphazard preparation for his task is well displayed in his seeming ignorance—not of the latest, but even of the penultimate—advances of the chemistry of physiological processes. Thus, while treating of peptones, whether in this part (p. 63) or on p. 386, Kühne's well-known and suggestive researches on the action of the digestive juices on proteids are inexplicably omitted; and nowhere, indeed, is the formation of peptones and their relationship to the albuminous bodies attempted systematically or adequately to be discussed. In treating of pancreatic juice the beautiful and conclusive work of Heidenhain on the production of the active ferment—a subject surely of the first chemico-physiological interest—is not once referred to, and indeed, by implication, ignored. (Cf. p. 70, where the preparation of extracts of pancreas is briefly described without any caution being given as to the time the pancreas should be let stand before being used.)

The inaccuracy of the author may be illustrated by a reference to pp. 49 and 60. There the effects of alkalis and acids of various strengths in amylolysis and proteolysis are mis-stated, and the important inferences from the facts altogether ignored.

Let us now turn to the chapter on the blood in Part III. Here, if anywhere in the book, we should expect to find completeness and the traces of careful work. On the contrary, on turning up Coagulation (p. 144)—the much-investigated, if not best-understood, process of the blood—we find the phenomenon itself imperfectly stated, the retarding influence of alkaline salts described without any quantitative conditions being given, and the theory of A. Schmidt discussed so slovenly and unintelligently that the important *fibrin-ferment* is nowhere directly treated of, but only implied (p. 146), if, indeed, it is not confused with paraglobulin. (See p. 146, the first paragraph, and p. 144, the second paragraph: the various statements taken together will, undoubtedly, bear such an interpretation.)

The blood as a respiratory tissue fares no better (p.

165). What are we to think of a manual of animal chemistry in which the author treats of the gases of the blood in mere general terms without reference to quantities? or what of one in which the author, among the spectroscopical properties of hæmoglobin, forgets to mention the shortening of the spectrum and the situation of the absorption-bands, or even the chemical method of deoxidation? What are we to think of the judgment of an author of such a manual who refers only to Bert and Fernet among those who have studied the affinity of hæmoglobin for oxygen (p. 166)? And what of the erudition of one who considers the following statement (p. 167) a sufficient discussion of the liberation of CO_2 in the lungs?—"It is easy to understand how the free carbonic acid is liberated, but not so simple to explain the liberation of that part previously in combination with alkaline bases. Thudichum supposes that when the venous blood reaches the small breathing cells the hæmato-crystalline is partly oxidised into what he calls hematic acid, and this, passing into the serum at the same moment, decomposes the carbonates in the blood, setting free carbonic acid, which, with the watery vapour, escapes through the lung tissue into the respiratory passages."

The salts of the blood are dismissed with bare enumeration.

But it is in the section on Food and the oxidations of the body (in Part II.), that the author discovers the appalling inaccuracy of his physiology. In many statements he seems to assign great importance to oxidations occurring in the blood and even in the lungs. Thus on p. 152 he speaks of "alcohol which must be placed side by side with fat as a respiratory food or substance which admits of oxidation in the lungs." Again (p. 154), "From the fact that oxidation in the lungs is a process of combustion and the source of muscular power, the foods which undergo this process are termed heat-producers; but we shall see presently that it is by no means clear that blood oxidation is attended directly with the evolution of animal heat": (he is here alluding to certain views of a Dr. Hake to be immediately referred to). In other parts of the book, also, the same exaggerated importance seems to be attached to oxidations in the lungs and blood. Thus, at p. 321, he inclines to the view that "the cerebro-spinal system does not generate its own force, but derives it through the chemical changes of the lungs." See also at p. 463, where a similar statement is included in the chapter on "Character." And finally, on p. 198, speaking of the seat of production of urea, the author says that "more modern researches tend to show that vitality consists more in the changes occurring in the blood, and that these changes may result in the direct production of urea."

These statements are clearly made in the spirit of those who hold that the interior of the blood-capillaries is the arena of oxidations, if they do not indeed take us back to the view of Lavoisier, who considered the lungs to be the heating-furnaces of the body. The latter view, we need hardly say, was long ago given up: the former is not seriously advocated by any recent physiologist. The lungs and the blood, like most of the organised tissues, doubtless suffer oxidation in the performance of their functions; but the degree of it is unimportant as a source of heat compared with the universal oxidation of other active organs. Had the author adhered throughout to the view under the influence of which the above statements were set down, he would at least have escaped the charge of inconsistency. But this was hardly possible. In the course of his reading and extracting among modern papers for the purposes of this book, he could not but meet references, direct or implied, to the generally received doctrine of the origin of animal heat in the functional oxidations of tissue-cells; and we therefore find that, side by side with the false, the true doctrine is taught.

But, notwithstanding that Mr. Kingzett's physiology, even at a point which peculiarly affects the chemist, is unsound and wavering, he yet ventures to enlarge upon matters of mere speculative interest which have but a superficial connection with his subject. We shall quote the author's own words at the page where the subject is most fully dealt with, though by no means the only page where it is to be found. We are very sorry we cannot give the whole of it. The author is citing in his own words—and citing with approval—the views of Dr. Thos. G. Hake, M.D., F.C.S., which are contained in a paper entitled "On Vital Force: its Pulmonic Origin and the General Laws of its Metamorphoses," 1854 and 1867. "He (Dr. Hake) believes that the chemical changes as they occur in the blood system, and comprised in the act of oxidation, do not result in the evolution of heat, but force, which becomes electric by the agency of the blood corpuscles; and it is certain that this is perfectly consistent with what we know of cell-life. On this hypothesis, the blood-cells form chains and conductors for the electric current thus generated, and this is subsequently metamorphosed into heat at every point of the system. On reaching the cerebro-spinal centres it becomes vital force—another name for electric force—and this becomes eventually heat, namely, when it is transmitted to enable the consummation of vital acts, such as sensation, muscular motion, or secretion. Faraday and Du Bois Reymond, and hosts of other experimental inquirers, have insisted on the identity of electrical and vital force, and the experiments of Du Bois Reymond in particular, go to prove that nerve force is only electric force manifested through media not met with out of the living bodies." . . . "Our author even goes further, and with consummate skill, reasons that when this cerebro-spinal force is united in action within the same organic medium with other forces influencing us from without, viz., light, sound, heat, &c., new results are attained, and phenomena of sense and intelligence are observed." Why, he goes on to ask (whether the question is Mr. Kingzett's own, or only Dr. Hake's, endorsed by Mr. Kingzett, is not clear), why, in anæmia, does the brain lose somewhat of its intense vital force? "Because," he answers, "the source of vital force, viz., blood oxidation, is interfered with."

We have merely to add, before leaving this section, that, as a matter of course, the fine investigations of Prof. Hermann into the chemical changes in contracting muscle, upon which so much of our knowledge of cell-function in its chemical aspect is based, seems to have eluded Mr. Kingzett's eye altogether.

Part V. Mr. Kingzett heads "Chemical and Philosophical Subjects." We shall say nothing further respecting

the chemical part; for a treatise having the pretensions of the book we are reviewing, it is notably incomplete. English students and medical men who wish to inform themselves in the chemistry of the animal tissues will find far more to their purpose in Prof. Gamgee's annotated edition of Hermann, or Mr. Lea's Appendix to Foster, than they will find in Mr. Kingzett's Manual.

The last chapter but one of the book is devoted to a discussion of "Character." This, not being a chemical subject and not a physiological one, we presume Mr. Kingzett includes under the title "philosophical." Why Mr. Kingzett should select "character" out of the multitude of extraneous subjects; why "character" should be called specially a "philosophical" subject; and why it was deemed advisable to serve up scraps of philosophy at all in a "Manual of Animal Chemistry;" are difficulties which at once arise in our mind as we peruse the list of contents, and which are nowhere fully explained on closer inspection of the book. It is true that when we come to find that by "Character" Mr. Kingzett does not exactly mean character, but the whole mental and moral nature of man and its, at present, inexplicable connection with his physical nature, the difficulties recede if they do not diminish. They are certainly not entirely effaced. If the pure physiologist is content for the present to leave such subjects to the psychologist, the chemist must recognise, when he takes them up, that he does so quite gratuitously. But whether or not it is expedient to undertake discussions on psychology in chemical books, it is at least expedient, if they are undertaken, that they should be sensible and to the purpose; that they should not be encumbered by commonplaces or crude analogies; and that they should be got over as quickly as possible. Although it is a pity to disturb the order of Mr. Kingzett's reflections with the scissors, only space is granted us for a paragraph or so. They shall be neither worse nor better than the rest; and we strongly advise those readers who are in search of amusement to borrow the book and read the whole chapter.

He begins: "Character is almost universally regarded as something apart from the body of man himself; something for which man is individually responsible, something which, born with man, is developed and cultured into maturity by education and training, be that mature state one for evil or one for good." Mr. Kingzett does not appear to believe this, whatever it may mean; for he continues by way of antithesis, "Let first causes be what they may, and so also let us hide our face from the infinite future and regard man as an intelligent machine, complete, so far, in himself." This resolution having been taken, the difficulty of justly judging men's thoughts leads up to a magnificent simile: "And thus man never understands his fellow-man aright; he picks out a few crystalline threads of an individuality; he sees a few bright or black bands in the spectrum of his neighbour's life, and without touching the colloid mass which will not crystallise, and being blinded to those parts of the spectrum which are not revealed (*sic*), man judges his fellow."

The characteristic of man among living animals is then summed up in the following startling epigram: "In short, man is a cerebrating creature, as the cow is a ruminating creature;" and we immediately afterwards learn that he cannot help cerebrating. Nor, it appears, can he help being a genius—or the reverse—if his brain-cells are fitly formed and he has been judiciously trained,—"and it is quite true that brain-cells do differ in form and composition just in a similar sort of way (!) as lungs and hearts differ."

This naturally leads to the question of moral responsibility, and the difficulty of the materialist is thus stated: "Man, the result [*i.e.*, 'of a predetermining influence in the very fœtus'], steps on to the platform of life in some measure at least an automaton. He is born of others, and finds himself with a head upon his shoulders, but the quantity and quality of brain-matter in the head is not ordained of himself. He may be a genius; but, horror! he may prove a fool!"

We then reach what appears to be the *raison d'être* of the chapter, viz., a conclusion which however nowise follows from any premisses before stated: "Thus even mundane chemical science has a part to play in the *rôle* of what poor mortals call their souls; it has something to do with every poeism (*sic*) originating in the mind of the poet, with every transcendent hope of the philosopher, with the logic of a Mill, and the teeming intelligence of all."

Mr. Kingzett is then arrested by the thought that all the body, brain-cells included, are elaborated from food—a thought which leads him to exclaim, "Eat, drink, and be merry, for verily that which we eat and drink takes part in that with which we think!"

This is Mr. Kingzett's treatment of "character" as a philosophical subject! We can only say, as Dryden once said in a criticism of a play of Elkanah Settle's, "I am mistaken if nonsense is not here pretty thick sown." We challenge any one to find us five such pages of silly reflection and irrelevant twaddle in any other seriously-intended work.

At the end of the book there is an "Index of Authorities Quoted"—not, of course, the Index of the book. Turning up the K's, we find Mr. Kingzett's own name, and under it we discover that Mr. Kingzett is an "authority" on Character—the reference to the book being to p. 462, the very chapter we are discussing. As it nowhere appears that Mr. Kingzett has, in other places, treated of this subject, we have the happily rare spectacle of an author endeavouring to take time and the critics by the forelock by writing himself down an "authority" ere he knows his book will live. Sure self-complacency never touched a loftier pinnacle!

After this, a good anti-climax might have been regarded as hopeless; but Mr. Kingzett has achieved one. He closes his book with a list of "Suggested Matters for Research," in the hope and belief (as he tells us in his preface) that they may be a guide to the "scientific chemist." The "scientific chemist," if he has but a smattering of physiology, will know how to shrug the shoulder at such puerile, general, and useless suggestions as the following:—

"(1) The chemical composition and formula of ptyaline; its chemical relationship to albumin; a proper explanation of its ferment-power, and a better study of its general nature."

"(7) An explanation of the oft-recurring deposition of biliary matters near the pyloric end of the stomach."

"(18) The complete composition of lymph, chyle, and blood."

"(19) Particular studies of the blood-corpuscles."

"(40) Prolonged studies of the physics of the body directed particularly to work out the history of the force generated in blood oxidation."

OUR BOOK SHELF

The Patentee's Manual. By James Johnson and J. Henry Johnson. Fourth Edition. (London: Longmans and Co., 1879.)

THE law relating to letters-patent for inventions, as at present administered, has been the growth of one short sentence in a declaratory statute passed in the twenty-first year of the reign of James I. (A.D. 1623), by which the Crown was restrained from making extravagant or oppressive grants of monopolies. The history or details of patent cases may often form an interesting subject of inquiry for the scientific reader; for although men of the highest intellect may be content with the discovery of general laws, and may leave their useful application and development to the crowd of humbler followers whose only power consists in the exercise of mechanical ingenuity, yet it cannot be denied that the successive steps which have been made in the steam-engine, in the electric telegraph, in machinery for spinning, weaving, or sewing, for manufacturing paper, or for printing a newspaper, may each in turn afford matter of considerable interest to a philosopher whose imagination is wearied with an endeavour to trace the fantastic excursions of a molecule, or to carry his dynamical laws into new and unexplored regions.

A book which shows the manner in which the property in inventions is dealt with in our Courts, and which, in order to accomplish its object, must of necessity review the various cases in an historical and logical order, affords, in a small compass, an epitome of much valuable learning. It is remarkable that the first patent case of any importance involved the validity of Arkwright's invention of machinery for drawing out and spinning cotton (A.D. 1785), while the second occurred ten years later, and related to the invention of the separate condenser of a steam-engine by James Watt. Since that period a number of distinct steps in the useful application of physical or mechanical laws have successively passed the ordeal of judicial inquiry, and those who take up the volume before us will find a reference to such matters as Wheatstone's telegraph, the hot blast for smelting iron, the interlocking of railway points and signals, the operation of currents of air between the grinding surfaces of mill-stones, the combing of wool, the laying of submarine telegraph-wires, &c., and so on in a list which appears almost interminable.

But although the variety of subject-matter may be great, the principles which govern the cases are few and easily comprehended, and, in reading the statements of principles laid down by Chief-Justice Tindal and other judges who have moulded our patent law into a coherent form, the thought may arise that the purely scientific writer who is composing his manual for the use of students might with advantage borrow something of power of style and of clear logical exposition from the lawyer, who is popularly believed to be tied down and hampered by the jargon of technical phraseology.

The book now under notice has already passed through three editions, and the authors have enlarged it by the interpolation of recent cases, as well as by the addition of new chapters. It is not within the scope of this journal to examine such a treatise from a strictly legal point of view, but we should describe it as exhibiting abundant evidence of being the work of writers who are practically engaged in professional pursuits. One important appendix consists of a digest of the patent laws in force in foreign countries, and in the body of the work there is a chapter on the "oppositions to the grant of patents," which suggests many melancholy thoughts to the sanguine inventor, and leads one to hope that some improvement of the enactment of 1852 will be conceded at an early period. In conclusion we have only to say that the book has fairly earned the circulation which has carried it to a fourth edition.

T. M. G.

A Manual of the Carbon Process of Photography, &c. By Dr. Paul E. Liesegang. Translated from the German by R. B. Marston. With Illustrations. (London: Sampson Low, Marston, Searle, and Rivington.)

WHEN, forty years ago, Mungo Ponton discovered that a sheet of paper, moistened with a solution of potassium dichromate, became darker when exposed to the rays of the sun, he made the first of a series of experiments which have led to the discovery of a method of rendering photographic pictures as permanent as engravings made in printing ink, though the completion of the work to a point at which it could fairly be said to be capable of competing with the well-known silver chloride print was not made till nearly thirty years afterwards, when Swan, by an admirable series of inventions, made it a practical means of producing prints.

In the history of the long struggle with nature which has produced so great a result every Englishman has reason to be proud, for it may be fairly said that the world owes the process from first to last to English workers. The process is now worked on an immense scale in this country by the Autotype Company and others, while another branch of the same stem has developed into the well-known Woodbury-type system of press-printing. Notwithstanding, however, the success of the process in its original home, we are somewhat deficient in connected accounts of it, most of the English publications on the matter being, like the autotype manual, confined to working details of the methods in use. We therefore welcome Dr. Liesegang's work as attempting something more than this, and presenting what is really a most interesting account of the whole subject, interesting, indeed, to any one who has a taste for well-written scientific technology, and apart from its value as a manual for actual working details. In one respect, indeed, the carbon process has all through been singularly fortunate. It seems, from the first, to have fallen into competent scientific hands, and to have escaped the dreary round of mess and muddle experimenting which is so characteristic of the history of the collodion negative processes, and which reminds one of nothing so strongly as of the story ascribing the invention of a certain process for the purification of sewage to its inventor going into a laboratory and taking down bottles at random, to the number of some half dozen, adding their contents to a sample of sewage, and patenting the mixture. From this misfortune the carbon process has been free, and Dr. Liesegang has been able to make its history instructive and interesting; he has given clear and precise accounts of the processes in use, and we note that he has kept well up with the latest improvements, while the illustrations are well and clearly cut. The popularity of the work in Germany has caused no less than six editions to be demanded.

It would be unfair to close this notice without a word of praise to the translator, who, in a modest note, states that his share of the work was done in leisure hours. We can only wish that he will continue, as he has begun, to introduce sterling foreign technical works to the public in as vigorous and correct English as that in which he has dressed Dr. Liesegang's little book.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

The Gulf-Weed (*Sargassum bacciferum*) a Means of Migration for Fishes and Marine Invertebrates

OWING to the October number of NATURE having been mislaid, I have not had an opportunity until lately of seeing Mrs. Merrifield's remarks upon Gulf-weed which appear in vol. xviii. p. 708, where the Bermudas are alluded to as a locality where this species grows *in situ*.

Having during my several visits to those islands of late years paid some attention to the Sargassum and its inhabitants, perhaps the few facts I am in possession of may prove interesting to botanists, and those who study the geographical distribution of marine animals.

The Bermudas, being situate within that somewhat circular area of the North Atlantic, formed by the currents of the Gulf Stream, the North African, and equatorial currents, within which exists that vast accumulation of weed known from the time of Columbus to the present day as the "Sargasso Sea," afford excellent opportunities for studying the plant in its floating condition, and also adherent in its natural state to the reef. During the winter months the prevailing gales, which are generally from south-east to south-west, bring to the islands large fields, as well as isolated patches, of the Gulf-weed, which prove a great boon to Bermudan farmers, who, but for this ocean waif, would often be minus manure sufficient to raise their root-crops with. To an observer a field of weed coming in from sea presents a somewhat variegated surface as regards colour, the major portion of it being of a dark brown, interspersed with spots and patches of light yellow. On closer inspection, these masses of floating weed are found to be inhabited by various species of pelagic and littoral crustaceans, particularly a small light brown crab, having a blotch of white on the carapace. Here and there the eye rests on a little pearly-white object, the well-known shell of that almost unknown cephalopod, *Spirula prototypus*, of Peron. The pretty purple shell of *Ianthina communis* is also to be seen, as are the singular forms of those truly oceanic acalephs, *Valella communis* and *Physalia pelagica*, which occasionally occur in large numbers, as they did during a heavy southerly gale on April 16, 1861, when countless myriads were literally wrecked upon the shores, together with the shells and rafts of Ianthinæ. About the margins of these floating fields, which are of some depth, may be seen various species of fishes, most of which have, no doubt, accompanied the fields, and lived in them, as game would do in a preserve where food and shelter are found. There is one species of fish which, above all others, seems to belong to the Sargassum, viz., the Marbled Angler (*Antannarius marmoratus*), which, from its peculiar arm-like pectorals, is specially fitted to rest upon the weed. Here it makes its wonderful nest amidst the mass, suspended by means of those silk-like fibres, which prove amply strong enough to support the large bunches of eggs, which hang like grape clusters within their orbicular case. These nests are occasionally to be found, but cannot be considered common; and only a few have been obtained from the weed on the Bermudan shore.

There is hardly a doubt that it is from this fish-preserve in mid-Atlantic that those tropical and semi-tropical forms which occur incidentally at the Bermudas, Azores, Canaries, Madeira, and also on the east coast of America, come, for I have frequently obtained from these masses of gulf-weed, species which are not recognised as Bermudan, and would probably never have visited the island waters unless under the friendly shelter of the weed. Moreover, I have observed even in heavy storms that the sea never breaks throughout these floating fields, but although heaving and swelling to the usual height, remains unruffled just as if oil floated on the surface. This absence of disturbance would of itself commend the field of weed to the fishes; but when we consider other suitable adjuncts, such as supply of food, and shelter from enemies, we cannot fail to realise the excellent means of migration which this common possession affords, not only to fishes, but to all kinds of those lower invertebrate forms, many of which have most certainly been brought to the shores of the Bermudas by this means. The isolated patches of weed, which follow the course of the Gulf Stream, and become broken into lesser fragments, are also accompanied by those tropical and semi-tropical fishes which are found almost every summer on the coast of Nova Scotia, and even as far north as Newfoundland; and it is evident that without some such agency we could never account for the abundance of certain southern pelagic fishes which annually occur in our high latitude.

In regard to the original habitat of *S. bacciferum*, as also the origin of that vast mass of floating weed which exists in mid-Atlantic, and is wholly composed of this species, I fear we must await further oceanic exploration. Although I am well aware that it grows in certain places on the Bermuda shores, those shores, even if they were wholly clothed with it, could not supply a tithe of the material which forms the vast accumulation of the weed existing in the Sargasso Sea. As to the allusion in Mrs. Merrifield's paper (quoting Agardh), made concerning the *S. bacciferum* being an inhabitant of the banks of Newfoundland, and other parts of the coast of north-east America, I can safely say that it is wholly unknown on this coast, save occasional sprays, which are brought north by the Gulf Stream, as are the fishes I have before alluded to.

Halifax, Nova Scotia, January 25 J. MATTHEW JONES

The Highest Tide on Record

IN Lyell's "Principles of Geology," tenth edition, 1867, vol. i. p. 494, occurs a statement, given on the authority of Admiral Sir F. Beaufort, to the effect that the tides at Chepstow on the Wye sometimes rise to 69 and even to 72 feet. The statement is familiar to all who have read Lyell's work. If it be correct then this tide of 72 feet at Chepstow is apparently the greatest in the world, that in the Bay of Fundy being given as 70 feet in the extreme. I can find no authority for a tide so great as 72 feet at Chepstow other than that above cited. The old "Bristol Channel Pilot" books of 1821 and 1839 say nothing of the matter, as I am informed by Capt. Tizard, R.N., and the latest published "Pilot" gives 56 feet as the extreme rise of tide at Chepstow. There is thus no official knowledge of so high a tide as 72 feet, and I can find no published account of Admiral Sir F. Beaufort's observations; Sir C. Lyell refers to none such.

I should be extremely obliged to any reader of NATURE who can refer me to any certain record of exceptionally high tides at Chepstow and confirmation of Sir C. Lyell's statement. There seems to be some uncertainty as to whether the highest tides on record occur in the British Islands or not.

The Glacial Period and Geographical Distribution

PROF. ASA GRAY, in his very interesting lecture on the distribution of the forest trees of the northern temperate region (NATURE, vol. xix. p. 327), after pointing out the remarkable differences that exist between the forests of the eastern and western sides both of North America and the Old World, suggests that the great poverty of the European as compared with the Japan-Manchurian region in this respect was caused by the Mediterranean cutting off the retreat of the flora which then occupied Europe, as it retired, at the approach of the glacial epoch, before the ice from the north. This explanation derives considerable support from some other facts in geographical distribution. The most characteristic Alpine and Arctic butterflies of the Palæarctic region belong to the three genera, *Parnassius*, *Chionobas*, and *Erebia*. Of *Parnassius*, Dr. Staudinger, in his latest catalogue (1871) enumerates fourteen Palæarctic species, of which three occur in North and Central Europe, ranging as far south as the Balkans, but always in or near high lands, about a dozen occur in temperate Asia, ranging as far east as the Amur, and probably as many in North America, where they also are truly Alpine butterflies. Of *Chionobas* one species (*C. aëllo*, confined to the Alps) occurs in Central Europe, whilst six or seven others range from Lapland over Russia and Siberia, Mongolia, &c., to the Amur, and there are numerous species in Arctic and Alpine North America. Of *Erebia* there are forty-five Palæarctic species enumerated by Staudinger, and of these no less than twenty-five occur in the central Alpine chains of Europe. The genus likewise ranges all over temperate Asia, going as far south as the Himalayas and Moupin, and in North

America is represented by a dozen or more species. Now, though an *Erebia* (*E. Tyndarus*, var.) occurs as far south in Europe as the Sierra Nevada, *not a single species of any* of these three genera occurs in North Africa, although the Atlas Mountains would seem eminently well suited for such Alpine insects. In this case, then, it seems clear that the same cause—the barrier of the Mediterranean—which in the case of the miocene flora of Europe prevented any further retreat south, has operated to prevent any similar southerly spread amongst the victorious invaders from the north which pressed on the retiring host.

With regard to the general similarity in facies and richness between the East American and East Asiatic tree-flora, certain facts pointing in the same direction will at once occur to the zoologist. Thus the *Menopomas* of the Ohio and Alleghany have their only near relations in the gigantic *Sieboldias* of north-east Asia, one species of these occurring in Japan, the other being one of Père David's discoveries in Moupin. Similarly with the genus *Polyodon* amongst ganoids. Only two species of this genus are at present known, *P. folium*, inhabiting the Mississippi, *P. gladius* the Yang-tse-kiang. The recent discovery of at least two species of *Scaphi rhynchus* in Turkestan makes it probable that ere long species of that Americo-Asian genus will be found in the Chinese rivers as well. The parallelism in the case of the salamanders is particularly interesting, when one remembers the celebrated *Andrias Scheuchzeri* of the Œningen beds, and it tends to favour the view that at that time practical identity in the forms of animals and plants reigned throughout the northern temperate zone. W. A. FORBES

Cambridge, February 14

P.S.—The reported discovery (NATURE, vol. xix. p. 351) of a true *alligator* in the Yang-tse-kiang, will, if confirmed, add a still more remarkable case to those mentioned above.

Leibnitz and the Royal Society

PROF. TAIT and myself ought not to be at issue on this question. I suppose we both want to get at the facts; and, for my part, I have no more desire to whitewash a foul reputation than he can have to blacken a fair one. Where we differ appears to be, as to how far Leibnitz's reputation can stand the test of facts. The question, however, is not whether Leibnitz acted disingenuously in respect to Gregory's series, or any other subordinate matter, but whether he was indebted to something of Newton's, surreptitiously imparted to him, for his differential calculus. If the grounds upon which that charge was made are swept away, there is an end of it. But if, on the other hand, that is not found feasible, and evidence to character becomes a factor in the final decision, then it is right to examine into those subordinate matters. Till then, I, for one, decline to touch them. At the same time let me say that I never undertook to be bail for Leibnitz's impeccability. All I said or say is, that on the published facts I believe that Leibnitz was led to the calculus by his own honest speculations, and *had not the means* of stealing from Newton, had he been that way disposed. But there are so many relative papers still unpublished, but publishable, that it is impossible to arrive at a true decision till at least some of them have been submitted to an authorised tribunal.

Prof. Tait recommends me to repeat the fruitless attempt of Dr. Slowman. I decline to follow the example of that ominously surnamed *savant*; for it is contrary to precedent that the pursuer should ask the defender to show his hand; and I am quite sure that "the proper authorities" abroad have too much sense to take the initiative. So I appeal to the Council of the Royal Society of 1879 (not that of 1712, as Prof. Tait gives it), and I do so for these two reasons:—

1. The so-called *Commercium* of 1712, which was merely a statement, arriving at no decision on the principal question, contained several allegations (apparently inconsistent with known facts) which give colour to the charge against Leibnitz; it is then an obvious duty on the part of the Royal Society, who were on the occasion represented by the Committee, to give the proof, or make the reparation.

2. The first-published charge against Leibnitz, which was made by Wallis in 1695, was based on allegations said to have been derived from papers and letters in the possession of the Royal Society; it is but fair, then, that those papers and letters should be published.

I therefore once more respectfully urge upon the Royal Society to reopen the main question, and publish such of the relative papers, &c., in their possession as directly bear upon the original charge. C. M. INGLEBY

Athenæum Club, February 8

Ear Affection

THE experience of "P." as given in NATURE, vol. xix. p. 315, is physiologically interesting, and by no means usual. Before attempting an explanation it may be as well to assume that only one of "P.'s" ears was affected by the disorder, as by this hypothesis we get the greatest possible divergence from the healthy state. It would have been easy to ascertain which was the faulty organ at the time by requesting a musical friend to listen while "P." vocalised the note of the tuning-fork as conveyed to him by each ear separately. The discordant ear would then have been revealed.

The fault of hearing must have been due either to some mechanical misadjustment of the auditory apparatus, by which a wrong sensation was conveyed to the brain, or else to some deep-seated brain or nerve lesion, which led to a faulty conception of the original sound. Let us consider briefly the first of these cases.

From the exceedingly scanty description of his disorder given by "P." I gather that the discord was mostly conspicuous when the note was high pitched (such as when whistled). Now it sometimes happens from paralysis of the chorda tympani nerve, or even from occlusion of the Eustachian tube, that the tension of the ear-drum is preternaturally increased. Such affections, as aurists well know, frequently intensify to a distressing degree the hearing of high pitched notes, whilst they correspondingly diminish the sound of the lower tones of the chromatic scale. This result is probably obtained by the fact that the tense membrane responds more readily to the rapid vibrations of the higher tones than it does to those of a slower rate. We must also remember that the power of lessening the tension of the membrane is in such cases very seriously impaired, and, as a consequence, the power of adjustment also. I do not suppose that in "P.'s" case there was any actual paralysis of the tympanic muscles, but it is just possible that there may have been a certain degree of misadjustment of the drum of the affected ear due to a feeble and imperfect contraction of one or the other of the muscles referred to. If the disorder was, as I surmised, accompanied with great tenseness of the membrane, the laxator tympani would be the faulty muscle. We might, I believe, under such circumstances, expect the ear-drum to vibrate discordantly in response to a note, for Helmholtz's experiments with stretched strings would suggest that this is feasible within certain limits. As a matter of fact this discordance is rare, and therein rests the interest of "P.'s" case.

I can scarcely believe that in his case any of the deeper structures of the ear were seriously implicated, otherwise he would hardly have made such a rapid and complete recovery as he did.

Brighton, February 10 W. AINSLIE HOLLIS

YOUR correspondent "P." (NATURE, vol. xix. p. 315) desires an explanation of the phenomenon of alteration in the pitch of sounds, which he has experienced in his own person whilst suffering from temporary deafness. Your second correspondent on this subject, Dr. Wallich (p. 340), was under my observation at the time of his experiencing the same peculiar and comparatively rare aberration, and I was able myself to verify his statements.

I propose with your permission to give an explanation which appears satisfactory to myself, and hope it may be so to your correspondent "P."

Persons suffering in this way find that sounds heard by the affected ear appear to be sharper or flatter than their true pitch as heard by the other ear, and hence a sound may even appear double.

The internal ear, or labyrinth, must be the part affected, and in all probability it is the cochlea which is at fault. Now most authorities are agreed that the pitch of a sound is appreciated by the cochlea in the following manner. Each tone, or division of a tone, has its corresponding portion on the spiral lamina of the cochlea, which under ordinary circumstances can only be affected by that tone. So that the sound-wave produced by a certain tone passes along the keyboard (as it were) of the spiral lamina until it reaches its own key, which it strikes or so affects as to cause an impression to be sent from that portion of the lamina to the brain. Hence the appreciation of variation in the pitch of sounds.

This theory being accepted, for an explanation of the aberration in question we have only to suppose some slight physical alteration in the contents of the cochlea, which would cause the sound wave to strike or affect the wrong portion of the lamina spiralis, and thus a false impression would be carried to the brain. URBAN PRITCHARD

Now attention is drawn to the above allow me to give another experience.

On two separate occasions while playing the English concertina, and more particularly when single notes or simple chords were struck, I noticed that each was followed by a loud and distinct note an octave lower which appeared to be that of its fundamental tone. The musical tones of the voice of any person addressing me, also, had their deeper reverberations in a similar manner, these being numerous and of rapid succession; the confusion arising was very like that which is heard in a hall unsuitably constructed for sound.

The nuisance, for such it amounted to, I was troubled with for a couple of days each visitation, the abnormal state of hearing being peculiar to the left ear only. JOHN HARMER

Wick, near Arundel

Intellect in Brutes

THE following case will perhaps interest those who believe that the reasoning faculty in man and animals differs in degree only, and is essentially the same in kind. Some years ago a plumber told me that he had, on several occasions, been called in to examine into the cause of leakage of water-pipes under the flooring of houses, and had found that the rats had gnawed a hole in the leaden pipe to obtain water, and that great numbers of them had made it a common drinking-place, as evidenced by the quantity of dung lying about. The plumber brought me a piece of leaden pipe, about $\frac{3}{4}$ inch in diameter and $\frac{1}{8}$ inch in thickness, penetrated in two places, taken by himself from a house on Haverstock Hill. There are the marks of the incisors on the lead, as clear as an engraving; and a few hairs and two or three of the rats' vibrissæ have been pinched into the metal in the act of gnawing it. This crucial proof of brute intelligence—a rat will not drink foul water—interested me so much, that I ventured to send an account of it to Dr. Chas. Darwin, asking his opinion on the means by which the rats ascertained the presence of water in the pipe. To this he replied: "I cannot doubt about animals reasoning in a practical fashion. The case of rats is very curious. Do not they hear the water trickling?" It may be conceded that this explanation is the most probable, and if it be the true one we have an example of an animal using his senses to obtain the data for a process of reasoning, leading to conclusions about which he is so certain that he will go to the trouble of cutting through a considerable thickness of lead. Obviously man could do *no more* under the same conditions. ARTHUR NICOLS

OUR ASTRONOMICAL COLUMN

THE COMPANION OF ALGOL.—There are grounds for suspecting that the light of the small star about 80″ distant from Algol in the S.P. quadrant is also variable. Schröter in his letter to Bode, wherein he first drew attention to this object, mentions that he detected it with a 7-feet reflector on October 12, 1787, and although small it was distinctly seen. Soon afterwards he estimated its distance from Algol at 1′ 30″. On April 9, 1788, the star was not to be found, and he therefore concluded that it must be variable. In 1792, when he was in possession of a 13-feet reflector, which he describes as the most powerful instrument then available in Germany, he re-examined the vicinity of Algol, and on March 9 saw the companion much brighter than before, and compares its distinctness in the larger telescope with its faintness in the smaller one with which he had discovered it. But on April 5, in a state of atmosphere at least as favourable as on March 9, with the same instrument and magnifying power, not the slightest trace of the companion could be perceived; on increasing the power to 370, with the utmost straining of the eye, the faintest glimmering was now and then suspected in its position. Schröter then, in this second communication to Bode, expresses himself more confidently as to the variability of the small star.

In the early part of the year 1874 the writer of these lines made several ineffectual attempts to observe the companion, using various powers on a 7-inch refractor; though the skies were favourable enough, nothing could be glimpsed in its place. It was not therefore without surprise that upon re-examining the vicinity under similar conditions on September 9 of the same year, the companion was caught at once, and seen with great distinctness. It was measured with Mr. J. G. Barclay's 10-inch refractor at Leyton, by Mr. Talmage, on October 2 following, when the angle was found to be 194°·4 and the distance 79″·02; the magnitude was estimated 11·12. An observation by Smyth in 1835 is recorded, but his distance is much too small; it is not stated whether he found the companion himself or whether his knowledge of its existence was due to Schröter's communications to Bode. It does not occur amongst the objects in the "Bedford Cycle," which were re-measured by Secchi.

While upon the subject of variable stars we may just mention that ι Andromedæ, to which attention is directed in the last number of the *Monthly Notices* of the Royal Astronomical Society as "a new variable star," is no novelty: we referred to the star as almost certainly entitled to insertion in the catalogues of such objects, four years since (NATURE, vol. xi. p. 308).

"A MISSING STAR."—From a letter addressed by Prof. C. H. F. Peters, Director of the Observatory, Clinton, New York, to the Superintendent of the Naval Observatory, Washington, which Admiral Rodgers has communicated to the *Astronomische Nachrichten* (No. 2240), it appears that he has strangely misinterpreted a note with the above heading, which was lately printed in this column. We referred to an object observed at Washington, with *Hygeia* in 1850, and afterwards sought for at that observatory and elsewhere on the assumption that it might possibly have been a trans-Neptunian planet, and in view of the failure of a careful search on this hypothesis, we remarked: "the only likely explanation appears to be that there was a variable star in this position, and that the observations in right ascension were affected with greater error than might be expected, considering that on two of the days of observation several comparisons were made." Prof. Peters, however, explains the difficulty by referring several transits to the first instead of to the second wire of the movable plate of the micrometer employed, in which case the star is identified with Lalande 36613, and Prof. Hall has found, on examining the original observing-books, that Mr. Ferguson had altered several correct observations to correspond with erroneous ones, and Admiral Rodgers accepts the explanation as satisfactory. But Prof. Peters is alarmed about the matter now that NATURE "stirs it up again," and writes to the Superintendent of the Washington Observatory "in order that nobody thereby might be induced to spend months and years upon a renewed search," and to "stop any further perpetuation of the credence, that a trans-Neptunian planet is revealed by the Washington Observations." It will be seen that our suggestion was that a variable star might exist in the observed position, and was in no way connected with a renewed search for a trans-Neptunian planet. Prof. Peters must entertain rather odd notions as to the probable knowledge of his astronomical *confrères* respecting the contents of the ecliptical region of the sky, if he believes that any one would be induced, by remarks that we might offer, to undertake in these days a search for a distant planet close to the ecliptic amongst stars of the *ninth* magnitude!

COMET 1871 V.—Dr. B. A. Gould, with his usual energy, has secured an excellent series of post-perihelion places of the comet discovered by Dr. Tempel on November 3, 1871, which in a fortnight's time sank below

the European horizon. The discussion of these observations in conjunction with those made in the northern hemisphere, will lead to a much more precise knowledge of the orbit than we have at present.

Olbers' Comet of 1815.—In a recent note upon this comet it should have been stated that, acting upon the wish expressed by Olbers at the time, Triesnecker printed his observed differences of right ascension and declination between the comet and comparison-stars in *Zeitschrift für Astronomie*, vol. ii. The Vienna observations, therefore, admit of a new reduction, in addition to those previously named.

DIURNAL OSCILLATIONS OF THE BAROMETER

IN the "Meteorological Notes" which appeared in Nature, vol. xviii. p. 198, some interesting results are referred to, which show marked differences in the diurnal variations of the barometer at places quite near to each other, as Greenwich, Kew, Oxford. It is remarked especially that the forenoon maximum in the months of May to July occurs near 9 A.M. at Greenwich, and near 8 A.M. at Kew; while at Falmouth and Valentia it is delayed to 11 A.M., or noon, and occurs in June as late as 2 P.M. at Helder.

Having made several investigations relatively to these questions (which I have not been able to publish as yet in detail), I think it may not be without advantage to give at present conclusions relating to the results above noticed.

It is obvious that it is of the highest importance with relation to the research as to the cause or causes of the remarkable semi-diurnal oscillations of the barometer, that we should have only real variations of atmospheric pressure to deal with, and not instrumental irregularities; and that, if there is any part of the mean diurnal variations which is due to local causes, we should be able to separate that part from any other which may be due to general or cosmic causes.

When it is remembered that the range of the mean diurnal variation with us is from two to three hundredths of an inch of mercury, and that the epochs of maximum or minimum may be shifted an hour by a difference of one or two thousandths of an inch, it will be seen how essential it is that the instruments, the observations, and the corrections shall be the best, in order to be sure that we have real variations of atmospheric pressure before us.

In order to obtain the best possible results, my investigations have been limited to observations made in first-class observatories with standard instruments. From observations made during several years at Makerstoun, Dublin, Greenwich, and Brussels, I have sought by the harmonic analysis the functions of sines which represent them most accurately. I give here the equations for the means of the three months in question—May, June, and July. The variation, v, is in ten-thousandths of an inch of mercury; the origin for each of the four stations M, D, G, and B, is mean midnight ($\theta = 0$):—

$$\begin{aligned}
\text{M},\ v &= 56 \sin(\theta + 355^\circ) + 68 \sin(2\theta + 143^\circ) + 21 \sin(3\theta + 171^\circ)\\
\text{D},\ v &= 51 \sin(\theta + 358^\circ) + 72 \sin(2\theta + 144^\circ) + 25 \sin(3\theta + 153^\circ)\\
\text{G},\ v &= 63 \sin(\theta + 346^\circ) + 88 \sin(2\theta + 143^\circ) + 25 \sin(3\theta + 154^\circ)\\
\text{B},\ v &= 43 \sin(\theta + 354^\circ) + 92 \sin(2\theta + 140^\circ) + 24 \sin(3\theta + 170^\circ)
\end{aligned}$$

The terms on the right of each equation represent the oscillations, whose superposition completes the whole diurnal variation. We find—

From the 1st term that the epochs of the maximum and minimum were the same within a few minutes at M, D, and B (as shown by the arguments 355°, 358°, and 354°), differing at Greenwich from the others by about 40m.

From the 2nd term, that of the semi-diurnal oscillation, that the epochs were the same at all the stations within a few minutes.

From the 3rd term, that they agreed at D and G and at M and B, those for the former being about 23m. different from those for the latter.

When we consider the coefficients of the different terms, which represent half the ranges of the oscillations, slight differences are found for the 1st and 3rd terms; for the 2nd the *range diminishes regularly as the latitude increases* at the rate of 0·00101 inch for each degree of latitude.

The exact agreement in the epochs of maxima and minima and the regularity of the variation of range with latitude in the semi-diurnal oscillation show that this oscillation obeys a general law. Dr. Lamont has supposed that the 1st term, or single oscillation, is due to variation of temperature; this, I believe, is not the case. When we compare the terms for different *seasons* of the year, we find that for the *same place* the epochs of maximum and minimum may vary twelve hours in the single oscillation, while the epochs deduced from the same term for the temperature variations do not differ one hour. Not only so, I have found on the South Indian Ghats that the epochs deduced from the 1st term of the barometric equations vary seven hours in ascending 6,000 feet; while those shown by the 2nd term are absolutely constant.

For all these reasons I conclude that the semi-diurnal oscillation of the atmospheric pressure is due to a cosmic cause, independent of local influences, while the single diurnal oscillation shows that part of the solar action which is modified by atmospheric conditions yet to be determined. The results for the four stations just given are a few links in a long chain of facts which tend to prove that the semi-diurnal oscillation of the barometer is due to an action of the sun, which is repeated equally, twice in each day, like the solar oceanic tide.

It will be seen, I think, from the results obtained from the Brussels, Greenwich, Dublin, and Makerstoun observations that the differences noticed at the beginning of this article cannot be allowed to enter as data into the domain of meteorology without much greater study of all the circumstances on which they depend. The facts of atmospheric variations are very difficult of explanation, but if we begin to admit results which may be purely instrumental among these facts explanation will become impossible.

It is a fact that the true temperature of the mercurial columns has not always been obtained, and when we have to discuss observations with self-registering instruments, many sources of error, including those of temperature on the apparatus itself, have to be cared for.[1] At stations near the sea, such as Helder, Valentia, and Falmouth, we have also to remember that in the varying height of the partial base of the atmosphere, through the *solar* oceanic tide, there is a real cause of diurnal barometric oscillation whose amount and epochs should be ascertained and deducted before exact comparisons can be made with observations inland. At the same time I would remark that of the stations here considered Dublin is near the sea, while the others are more or less distant from it.

John Allan Broun

MAROCCO AND THE ATLAS[2]

THE expedition of which an account is given in this most interesting volume was undertaken by Sir Joseph Hooker and Mr. Ball in the spring of 1871, and lasted a little over two months. Many causes com-

[1] The observations here studied at the four observatories are all made by the eye.

[2] "Journal of a Tour in Marocco and the Great Atlas." By Joseph Dalton Hooker, K.C.S.I., C.B., Pres. R.S., Director of the Royal Gardens, Kew; and John Ball, F.R.S., M.R.I.A. With an Appendix, including a sketch of the Geology of Marocco, by George Maw, F.L.S. (London: Macmillan and Co., 1878.)

bined to hinder the publication of this journal until now, but the delay will, we feel sure, not in the least detract from either the novelty or value of its contents.

The coast-line of the territory of Marocco extends from the frontier line of Algeria on the Mediterranean, along through the Straits of Gibraltar to the Atlantic Ocean, nearly opposite to the Canary Islands. Inland it would seem to have no absolutely well-defined boundary-line except towards Algeria, but it is supposed to stretch far into the Great Desert on the southern side of the Great Atlas range. Of this great region, possibly as large in extent as Spain, and the chief ports of which are within a few days' steaming of Southampton, almost nothing, if we except the mere coast-line, is known; and a journey across the dark continent itself seems easier of accomplishment than one to the town of Tarudant, in the southern valley of the Great Atlas.

The distance from Gibraltar to Tangiers is scarcely thirty-five miles. The five peaks of the Beni Hassan are seen from the Rock, yet we have no records of their having been investigated, and when the authors earnestly desired Sir John Drummond Hay, the British Minister Plenipotentiary in Marocco, to assist them in exploring their recesses, he was reluctantly obliged to pronounce against the feasibility of any such excursion, and even when they started for a short excursion to Cape Spartel it was considered prudent to give them an escort of two soldiers.

Argan Trees.

With this excursion the botanical interest of this journal begins. Plants of many sorts were seen and collected. Where a little slender stream ran through some damp meadows they were charmed by the delicate tint of a pale blue daisy that enamelled the green turf. It was merely a variety of the little annual daisy (*Bellis annua*) so common in many parts of Southern Europe; but the blue tint does not seem to have been noticed elsewhere. The botanical district to which this northern corner of Marocco belongs has been called that of the cistus and heath. One very interesting plant to be often seen living in the Botanical Gardens of Kew and Dublin is thus described:—

"The most singular of these is the *Drosophyllum lusitanicum*, a plant of the sun-dew tribe, whose branched stem bears several large yellow flowers. The numerous slender strap-shaped root-leaves, nearly a foot in length, that are gradually contracted to the thickness of whipcord, are beset with pellucid ruby-tipped glands, and present a peculiarity that appears to be unique in the vegetable kingdom. Any one who has remarked the growth of ferns must have seen that in the young state the leaves are rolled or curled inwards, so that in the process of unfolding the face or upper side of the leaf, which was at first concealed, is gradually opened and turned to the light. A similar process occurs in many other plants; but in *Drosophyllum* alone, so far as we know, the young leaf is rolled or curled the reverse way, so that the upper side of the leaf is that turned outwards. It appears to grow in many parts of Southern Portugal; reappears on the north side of the Straits of Gibraltar near Tarifa and Algeciras, and on the southern side about Cape Spartel and on the hills above Tetuan, where it commands a view of the opening of the Mediterranean, but extends no farther eastward."

Tetuan was visited from Tangiers. The season (April 10) was scarcely far enough advanced for the flowering of many of the sea-side plants, "but there was more than enough to rejoice the heart of a botanist, especially one escaping from the ghastly spring season of the north, where, when the days grow longer, they become only the more dreary, and where the bitter east winds parch and blast the young leaves and blossoms that are tempted to unfold themselves to their own destroying by the mildness of the winter weather." At Tetuan, Beni Hosmar was ascended. It was about 3,000 feet high, and had not been ascended by any European since Barker Webb's time. The season was still too little advanced, and the botanist who will follow the travellers' footsteps about the beginning of June is promised a much richer harvest. Ceuta, about thirty miles from Tetuan, was next visited, and in order to catch the steamer to Mogador, our authors had to cross over to Gibraltar, from whence they again departed on April 20, in the *Vérité*, landing for a brief moment at Casa Blanca. They were in the port of Mogador on the 26th.

Arrangements were soon made, through the goodness of the late Consul Carstensen, for the excursion to the Great Atlas. Mules were bought, the question of costume was decided, the interpreter of the Consulate, Abraham by name, was lent for the trip. The necessary escort consisted of four soldiers under the command of a captain. The necessary dinner at the Governor's was eaten, and about 7 A.M. on the morning of April 29 the cavalcade took its departure from Mogador for Marocco. Instead of following the direct road, a detour nearly at right angles was made, to enable the botanists to gain a fuller acquaintance with the great Argan Forest. Their course was first through a sandy soil, but as it rose and receded a little from the coast, the tertiary calcareous rock that underlies the sand cropped out here and there, and the first Argan trees appeared.

"As we advanced, the trees grew larger and nearer together, and as we approached our intended halt, at a place called Douar Arifi, they formed a continuous forest.

"The Argan tree is in many respects the most remarkable plant of South Marocco; and it attracts the more attention as it is the only tree that commonly attains a large size, and forms a conspicuous feature of the landscape in the low country near the coast. In structure and properties it is nearly allied to the tropical genus *Sideroxylon* (Iron-wood); but there is enough of general resemblance, both in its mode of growth and its economic uses, to the familiar olive tree of the Mediterranean

region to make it the local representative of that plant. Its home is the sub-littoral zone of South-western Marocco, where it is common between the rivers Tensift and Sous. A few scattered trees only are said to be found north of the Tensift; but it seems to be not infrequent in the hilly district between the Sous and the river of Oued Noun, making the total length of its area about 200 miles. Extending from near the coast for a distance of thirty or forty miles inland, it is absolutely unknown elsewhere in the world. The trunk always divides at a height of eight or ten feet from the ground, and sends out numerous spreading, nearly horizontal branches. The growth is apparently very slow, and the trees that attain a girth of twelve to fifteen feet are probably of great antiquity. The minor branches and young shoots are beset with stiff thick spines, and the leaves are like those of the olive in shape, but of a fuller green, somewhat paler on the under side. Unlike the olive, the wood is of extreme hardness, and seemingly indestructible by insects, as we saw no example of a hollow trunk. The fruit, much like a large olive in appearance, but varying much in size and shape, is greedily devoured by goats, sheep, camels, and cows, but refused by horses and mules; its hard kernel furnishes the oil which replaces that of the olive in the cookery of South Marocco, and is so unpleasant to the unaccustomed palate of Europeans. The annexed cut, showing an average Argan, about twenty-five feet in height, and covering a space of sixty or seventy feet in diameter, with another, where goats are seen feeding on the fruit, exhibits a scene which at first much amused us, as we had not been accustomed to consider the goat as an arboreal quadruped. Owing to the spreading habit of the branches, which in the older trees approach very near to the ground, no young seedlings are seen where the trees are near together, and but little vegetation, excepting small annuals; but in open places, and on the outer skirts of the forest, there grows in abundance a peculiar species of Thyme (*T. Broussonnetii*), with broadly ovate leaves and bracts that are coloured red or purple, and the characteristic strong scent of that tribe. It is interesting to the botanist as an endemic species, occupying almost exactly the same geographical area as the Argan. As we afterwards found, it is replaced in the interior of the country by an allied, but quite distinct, species. Its penetrating odour seems to be noxious to moths, as the dried twigs and leaves are much used in Mogador, and found effectual for the preservation of woollen stuffs."

Stopping at Shedma, Aïn Oumast, Sheshaoua, Misra ben Kara, Marocco was at last in view. From whatever side it be approached, this city presents an imposing appearance. The western side presented an outline about a mile and a half in length. Massive walls some thirty feet in height, with square towers at intervals of about 170 yards, completely inclose it, and on two sides at least it is girdled by a wide belt of gardens in which the date palm, the olive, and fig, are conspicuous objects. We must refer the reader to the volume for an account of the sojourn in Marocco. Some difficulties with the Governor were got over by the quiet determination of Sir Joseph Hooker, whose knowledge of the Oriental character acquired in Asia here stood him in good service.

The outline of the Great Atlas range was quite visible from the terraced roof of the house in Marocco occupied by the travellers, though owing to the prevalence of clouds they failed to secure a satisfactory sketch of these. Through the kindness of Sir J. D. Hay, they are, however, enabled to insert a copy of a drawing made in 1829 by Mr. William Prinsep, the correctness of which they endorse. On May 8 Marocco was left for the mountains. The cavalcade was a large one, consisting of thirty-seven souls and thirty-three horses and mules. The baggage formed a good load for nine mules. The route lay south-east, but the upward slope became hardly perceptible, when before sunset they were compelled to stop for the night at the house of the Kaïd of Mesfioua, at an elevation of about 2,400 feet over the sea. The next morning they were off pretty early, and soon began to ascend, often riding along hollow ways between high banks or lofty hedges formed of tangled shrubs and climbing plants, in which were mingled some familiar forms with several altogether new.

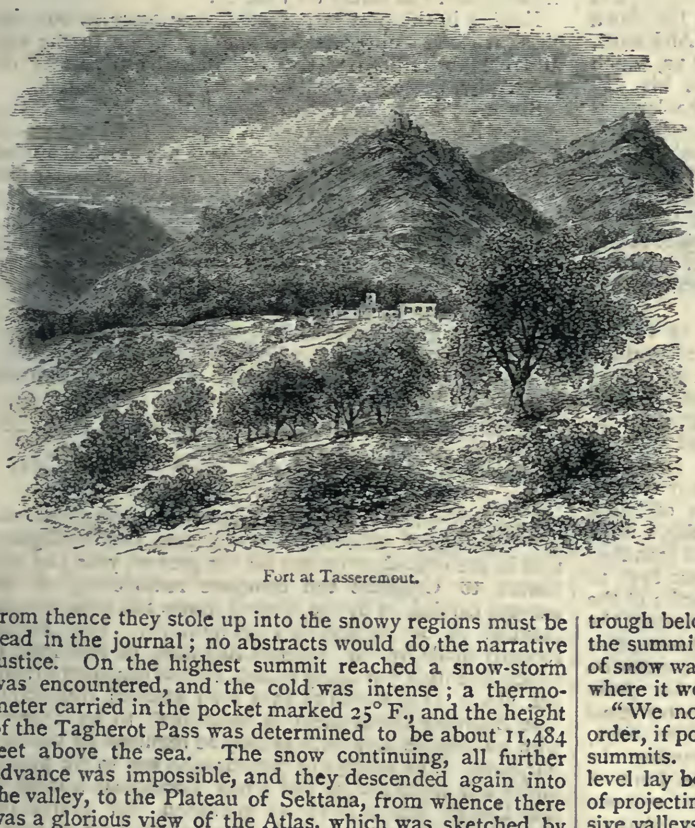
"The date-palm had disappeared soon after we entered the hills; here, and elsewhere on our route, it seems to be confined to the lower region, rarely attaining the level of 3,000 feet above the sea. Its place was here supplied by the palmetto (*Chamærops humilis*), which seldom forms a trunk, perhaps because it is not allowed to attain a sufficient age. As we advanced, the vegetation constantly offered a more varied and attractive aspect; and one of our first prizes was a new species of thyme (*Thymus maroccanus*, Ball), somewhat like the species of the Argan zone, but with oblong leaves and uncoloured bracts. Of comparatively familiar forms there were *Cistus monspeliensis* and *C. polymorphus*, the first species of that genus that we had seen in South Marocco, the pretty little *Cleonia lusitanica*, with many other Labiatæ. Of plants new to our eyes by far the most interesting was the curious *Polygala balansæ*. To those who know only the milkworts of Europe and North America it must seem strange to hear of a large shrubby Polygala, with branches that end in a sharp point, few small leaves, so quickly deciduous that it generally appears quite leafless, and large flowers of a showy purple-red colour. In truth, although there is great variety of form in this large genus, the species which is common throughout the lower valleys of the Great Atlas is very distinct from all its congeners. In Arabia and South Africa there are some species forming dwarf bushes with spinescent branches, but in other respects very different. When full grown this is six or eight feet in height; and the round, green, almost leafless stems give it, when the flowers are absent, much the appearance of *Spartium junceum*, the large broom of Southern Europe.

"After riding some way up a rather steep stony track, we reached a grove of very fine olive trees, and our escort came to a halt. We had reached Tasseremout. For some time we had seen a large pile of solid masonry which crowned the hill immediately above the olive grove. This seemed to deserve a visit; but, on the other hand, the attractions of the surrounding vegetation were irresistible to botanists. The matter was settled by Hooker proceeding to visit the castle with the Kaïd, while Ball botanised, and Maw secured living specimens of some of the more interesting plants."

The castle of Tasseremout is one out of a large number of similar buildings standing on the northern outworks of the Great Atlas chain that will afford interesting matter for inquiry to future travellers when the country becomes more accessible, and the lessened jealousy of the natives will make a thorough examination of them less impossible than it would be at present. The natives vaguely attribute their construction to Christians or Romans, the same word conveying either meaning; but the Jews often explain this to mean Portuguese. The general character of these buildings, as far as our information goes, is tolerably uniform. The walls are of great thickness and built of rough hewn stone: the arches are always rounded, and the lower chambers vaulted; and they are evidently places of defence. There is little reason to believe that the Portuguese, who held at one time or other most of the Atlantic coast of Marocco, ever established a firm footing inland, and still less that they had such a hold on South Marocco as would be implied by the erection of a chain of forts along the foot of the Atlas. On the other hand, the history of Mauritania during the long period of the decline of Rome, and preceding the Saracen conquest, is an almost complete blank, save for a few apocryphal stories.

It is certain that the lower country was once completely subject to Roman power and Roman institutions, and it remains to be ascertained how far an organised government survived the weakening of the central authority. That the independent tribes of the Atlas may have been inconvenient neighbours to the half-Romanised inhabitants of the plain is more than probable, and that the forts should have been erected to hold the former in check seems the most likely conjecture as to their origin. Excavation, whenever that may be practicable, will scarcely fail to tell something of the original occupants of these buildings, and to diminish our ignorance of a dark period of past history.

At sunrise on April 10 (a misprint for May 10) the thermometer stood at 60°, and the travellers were in the best of spirits for undertaking the work that seemed ready cut out for them. They would explore the fine valley that led directly from their camp station to the heart of the great mountain chain, up until they reached the snow; but here comes the exciting portion of the narrative, and the record of how their progress was checked, how they were forced to return, what troubles they had with their escort, how they camped in Ait Mesan Valley, and how from thence they stole up into the snowy regions must be read in the journal; no abstracts would do the narrative justice. On the highest summit reached a snow-storm was encountered, and the cold was intense; a thermometer carried in the pocket marked 25° F., and the height of the Tagherot Pass was determined to be about 11,484 feet above the sea. The snow continuing, all further advance was impossible, and they descended again into the valley, to the Plateau of Sektana, from whence there was a glorious view of the Atlas, which was sketched by Mr. Ball. Amsmiz was reached about May 19; the position of the town reminded them of some of the villages in Piedmont that stand at the openings of some of the interior valleys of the Alps, or still more of similar places on the Apennines of Central and Southern Italy; and from it they reached the poor village of Imintelli, where they sojourned for two days. From Imintelli a desperate and fortunately successful attempt was made to climb to the summit of Djebel Tezah.



Fort at Tasseremout.

"Hooker reached the summit about 2 P.M., and was rejoined by Ball nearly half an hour later. Excepting some light fleecy cumuli floating over the low country to the north, at a lower level than the eye, the sky was cloudless; but in some directions a thin haze obscured the details of the vast panorama. Our first glance was inevitably directed towards the unknown region to the south, and there, at a distance of fifty or sixty miles, rose the range of Anti-Atlas, showing a wavy outline, with rounded summits, and no apparent deep depression, rising, as we estimated, to a height of from 9,000 to 10,000 feet above the sea. The highest portion within our range of view, and the only part with a somewhat rugged outline, bore a few degrees west of due south, and corresponded in position with the Djebel Aoulouse of the French map. A somewhat darker shade traceable at some places on the flanks of this dimly seen range, possibly indicated the existence of forests, or at least of shrubs covering the slopes.

"When the first impulse of curiosity was partially satisfied, we began to take more careful note of our position, and to study in detail a view which had been so long denied to us. The first fact that struck us, was that the peak on which we stood lies a considerable way north of the watershed. The axis of the main chain, which here subsides into undulating masses from 2,000 to 3,000 feet lower than Djebel Tezah, lay between us and the central portion of the Sous valley, and, even if the prevailing haze over the lower districts had not veiled the details, would probably have cut off the course of the stream and the rich tracts that are said to fringe its banks. The higher strata of the atmosphere, above the level of about 7,000 feet, were, however, delightfully clear towards the east and west, and every feature of whatever portion of the main chain lay within our range was easily traced even at distances of thirty or forty miles. An extraordinary change had occurred during the three days since we had viewed the chain from Sektana, covered in deep snow down to the level of about 7,000 feet, and showing only a few crests of precipitous rock here and there protruding. The white mantle had now completely disappeared, and only long streaks of snow filling the depressions of the surface now seamed the flanks of the higher mountains, leaving the summit ridges everywhere bare. During the ascent of the northern face of the mountain, we had kept close to one of these long and comparatively narrow snow-slopes that extended through a vertical zone of over 2,000 feet, with a breadth of some 300 to 400 feet, and we now saw a still longer and wider strip of the same character, filling a shallow trough below us, on the east face of the peak. Near to the summit, and on the ridges leading to it, not a trace of snow was to be seen, even in the crevices of the rocks, where it would find partial shelter from the sun.

"We now proceeded to survey the field of view, in order, if possible, to fix the positions of any conspicuous summits. Looking due west, nothing approaching our level lay between us and the dim horizon. A succession of projecting spurs of the Atlas, dividing as many successive valleys, subsided into the plain; the most prominent, and that extending farthest from the main chain, being the mountain above Seksaoua. Turning the eye a little to the left, about west by south, we saw crowded together many of the higher summits of the western portion of the main range, which was here seen foreshortened, so that it was impossible to judge of their true relative position. The highest of these, seamed with snow, we judged to be about twenty-five miles distant, and higher than Djebel Tezah by 600 or 800 feet. In nearly the same direction, but only about ten miles distant, was a rugged projecting peak, rising some 300 feet above our level, and very many more of somewhat lower elevation were discernible in the space between us and the more distant points. Between

S.W., and S.S.E., the range of Anti-Atlas, rising behind the broad Sous valley, bounded the horizon.

"At our feet, and cutting off from view the course of the river Sous, the mountain mass that here forms the axis of the main chain presented the appearance of a troubled sea of a light ferruginous colour, declining gradually in elevation from W. to E. At a distance of about eight miles E.S.E. of Djebel Tezah it sinks to an estimated height of little over 7,000 feet, at the head of the main branch of the Oued Nfys, and offers the only apparently easy pass over the main chain which we had yet seen.[1] The rocky sunburnt flanks of the mountains were dotted with trees of dark foliage, doubtless some form of the evergreen oak, up to a height of about 8,000 feet above the sea, for the most part solitary, sometimes in clumps, but nowhere forming a continuous forest. The numerous feeders of the Oued Nfys had cut deep ravines in the flanks of the mountains, and were lost to sight, except where gleams of silver light shot upwards from the deeper valleys amid the walnut trees that fringed their banks. Numerous hamlets were seen, some perched upon projecting ridges, some lying in hollows and girdled with a belt of emerald-green crops.

"It was impossible not to speculate on the condition of these primitive mountaineers, who have since the dawn of history preserved their independence. Leo Africanus, speaking of the very district now overlooked by us, which he calls Guzula, says that the people were in his day molested by the predatory Arabs and by 'the lord of Marocco;' but they successfully resisted all encroachments, and no attempt is now made to assert the Sultan's authority among them, or to enforce tribute. Something they have doubtless gained in material, and still more in moral, welfare by stubborn resistance to alien rule; but the prosperity that is sometimes attained by tribes subject to the semi-feudal rule of chiefs, and among whom intestine feuds are rooted in immemorial tradition, is usually short-lived.

"Our hope of getting further knowledge as to the eastern extremity of the Sous valley, and the orographic relations between the Atlas and Anti-Atlas ranges was not to be satisfied. Djebel Tezah, as we found, stands some way north of the axis of the chain, while the great mass that rose over against us between E.N.E. and E.S.E., extending to the head of the Aït Mesan valley, sends out massive buttresses to the south, and by these our view of Anti-Atlas was cut off to the S.E. On one of these western projecting buttresses we could distinguish a large village belonging to the district of Tifinout, and standing at an elevation of nearly 7,000 feet. Turning our eyes to the north of true east, many of the higher summits of the chain were seen rising above the intervening ranges, the most distant probably belonging to the Glaoui group, east of Tasseremout. Once more we came to the conclusion that throughout the portion of the Great Atlas chain visible from the city of Marocco, between the easternmost feeders of the Oued Tensift and those of the Oued Nfys, there are no prominent peaks notably surpassing the average level. Many of them must surpass the limit of 13,000 feet above the sea, but it is not likely that any one attains the level of 13,500 feet. The last object that attracted our attention in the panorama, in a direction about east by north, was an isolated mass, forming a bold promontory on the northern side of the chain, of which a rough outline is here given.

"When the engrossing interest of the distant view had so far subsided as to let us pay attention to nearer objects, we were struck by the unexpected appearance of considerable remains of dwellings on a platform of level ground, only a few feet below the actual summit of the mountain. About a dozen rude stone dwellings, all in a ruinous condition, with chambers sunk a couple of feet below the level of the ground, and the roofs fallen in, had at some former period been here erected; but we saw no traces of recent occupation. It seemed most probable that they were intended as shelter for herdsmen, who had driven their flocks in summer to this lofty station.

"As we lingered on the topmost point of the mountain, the intense silence of the scene was broken by the distant scream of a large grey eagle that soared over our heads, and then sailed away southward over the Sous valley, making the deep stillness still more sensible than before."

No wonder that after the excitement of such a day, which only ended when their quarters were reached at half-past eight at night, the travellers let their collections rest in the collecting boxes and portfolios for the night, and after supper fell themselves to sleep.

Wars among the native tribes at last drove our authors to the necessity of returning to Mogador, passing through the wonderfully singular defile of Aïn Tarsil, which is like a trench some thirty to fifty feet wide and the same deep, running for a length of nearly three miles. Four days were spent on the occasion of the second visit to Mogador, and Sir Joseph Hooker reached London with his collections in safety on June 21.

Having in this notice exceeded the space at our disposal, we can only quite incidentally allude to the very valuable appendices to this volume, which treat of the geography, geology, and flora of the districts visited.

Since we some years ago closed the pages of "Palgrave's Personal Narrative of a Year's Journey through Central and Eastern Arabia," we have not perused a more delightful or instructive book of travels than this account of a tour in Marocco. From the well-known acquirements and great experience of the authors we expected much, and we have not been disappointed. The journal is, without doubt, especially pleasant reading to a botanist, but the geographer will find in it much to interest him, the politician will find in the description of the state of things now existing in such a country material for some serious thought, while the literary taste of every reader will be gratified by the excellent manner in which the narrative is written.

[1] This is apparently the pass spoken of by Leo Africanus as leading from near Imizmizi (Amsmiz?) to the region of Guzula (the northern branch of the Sous valley). He says it is called Burris, that word meaning downy, because snow frequently falls there.—See "Ramusio," vol. i. p. 17, B.

REORGANISATION OF THE AMERICAN SURVEYS

ALL well-wishers of the progress of geographical and geological research will welcome the intelligence that in the official estimates for the present year just presented to Congress the complete remodelling of the surveys carried on by the United States has been recommended to be immediately undertaken. The Report recently made by the National Academy of Sciences, to which attention was lately called in these pages (NATURE, vol. xix. p. 213), seems to have been adopted *simpliciter*. The Engineer Department is henceforth to be charged with no surveys save such as may be required for military purposes. The surveys of mensuration are to be placed under one organisation, and a new Geological Survey of the United States is to be instituted. Of course the changes are at present only recommended for adoption by the Committee on Appropriations, and there may be a struggle over some of the proposals. We hear indeed that the Engineers are leaving no point in their defence unguarded and are preparing for what is called a "heavy fight." For their own sakes as well as for the cause of scientific progress we cannot wish them success.

They object to the constitution of the Academy's Committee on the ground that only one of the members of it knows anything practically of surveying. And this objection will no doubt be urged with force and persistence in the debates in Congress. But surely they can hardly expect to throw dust in the eyes of the legislature by such a flimsy argument. The Committee, as we formerly pointed

out, was a thoroughly competent one. They might as well insist that nobody is competent to pass a judgment on poetry unless he has written an epic, or to criticise fine art if he has not painted a picture, or modelled a statue. The Bureau of Engineers has done such admirable work and deserves such thorough respect, that its best friends can only hope that it will not embitter a fruitless struggle against the inevitable. We have no fear that its scientific *prestige* will in the least be diminished by the projected revolution. The nature of the change will be best understood from the following extracts from the Bill of the Committee on Appropriations, which has been read twice and "committed to a committee of the whole House on the state of the Union and ordered to be printed":—

"For the salary of the Superintendent of the Coast and Interior Survey, 6,000 dollars: *Provided,* That the present coast and geodetic survey, with supervisory and appellate powers over the same authorised by law, is hereby transferred from the Treasury Department to the Department of the Interior, and shall hereafter be known as the Coast and Interior Survey, and shall have charge of all surveys relating to questions of position and mensuration of the coast and interior, except the special survey necessary for geological purposes, the survey of the northern and north-western lakes now under the direction of the War Department, and local surveys required for the improvement of rivers and harbours and surveys necessary for military purposes immediately connected with the operations of the army, in accordance with the plan reported to Congress by the National Academy of Sciences, under the Act of June 20, 1878, entitled 'An Act making Appropriations for Sundry Civil Expenses of the Government for the Fiscal Year ending June 30, 1879, and for other purposes:' *And provided further,* That the offices of surveyors-general are hereby abolished, to take effect on June 30, 1879; and the compensation of said surveyors-general, and all employees under them, shall cease on that day; and the duties pertaining to the offices of surveyors-general shall thereafter be performed by the Superintendent of the Coast and Interior Survey; and the parcelling surveys of the public lands shall hereafter be made by employees of the Coast and Interior Survey: *And provided further,* That the rectangular method with township and sectional units shall be retained wherever it can be appropriately and economically applied, but all surveying by contract shall be prohibited; and the Superintendent of the Coast and Interior Survey is hereby authorised to adopt such additional surveying methods as he may deem most economic and accurate; but the surveys of mineral claims shall be made by deputy surveyors, as now provided by law. And such of the archives and records now in the offices of the surveyors-general as may not be required for the office of the Superintendent of the Coast and Interior Survey shall be turned over to the governors of the several States and Territories, upon the same terms and conditions and in the same manner that the archives have heretofore been delivered to the State authorities in States where the public surveys have been completed and the offices of the surveyors-general closed: *And provided further,* That the Secretary of the Interior shall direct the archives and records of the surveyor-general's office of any State or Territory to be kept in the place where they are now located, if thereby the interests of the people of said State or Territory will be best subserved, such archives and records to be placed under the charge of an employee of the Coast and Interior Survey: *And provided further,* That hereafter surveys of public lands shall, at the discretion of the Secretary of the Interior, be made under the deposit system, on petition of not less than five persons for the survey of a township; the sum of money to be deposited for the survey of the township shall equal the cost of the survey at the present rates allowed for the several classifications of the land to be surveyed, including such sum as shall be estimated for office-work: *Provided,* That the excess of any deposit over and above the aforesaid cost shall be returned to the depositor; and all moneys so deposited and actually required for said survey and office-work, for the amount of land for the survey of which the petition is filed, shall be applicable, either in the hands of the depositor or his assignee, to pay for lands to which the said depositor or others may be entitled under the law. It shall be the duty of the Commissioner of the Land Office to make all needful rules and regulations necessary for carrying into effect the detail of this law, so far as relates to the new conditions established by it in reference to the public lands.

"For the salary of the Director of the Geological Survey, which office is hereby created, who shall be appointed by the President by and with the advice and consent of the Senate, 6,000 dollars: *Provided,* That this officer shall have the direction of the geological survey, and the classification of the public lands and examination of the geological structure, mineral resources, and products of the national domain, in accordance with the plan reported to Congress by the National Academy of Sciences under the act of June 20, 1878, entitled 'An Act making Appropriations for Sundry Civil Expenses of the Government for the Fiscal Year ending June 30, 1879, and for other purposes;' and that the director and members of the geological survey shall have no personal or private interests in the lands or mineral wealth of the region under survey, and shall execute no surveys or examinations for private parties or corporations; and the Geological and Geographical Survey of the Territories, and the Geographical and Geological Survey of the Rocky Mountain Region, under the Department of the Interior, and the Geographical Surveys west of the 100th meridian, under the War Department, are hereby discontinued, to take effect on June 30, 1879; and all collections of rocks, minerals, soils, fossils, and objects of natural history, archæology, and ethnology, made by the Coast and Interior Survey, the Geological Survey, or by any other parties for the Government of the United States, when no longer needed for investigations in progress, shall be deposited in the National Museum.

"That all laws, parts of laws, and all departmental regulations relating or having reference to the coast and geodetic survey now in force and effect are hereby continued in force and effect, and made applicable to the Coast and Interior Survey until changed by competent authority.

"For the expense of a commission on the codification of existing laws relating to the survey and disposition of the public domain, and for other purposes, 20,000 dollars: *Provided,* That the commission shall consist of the Commissioner of the General Land Office, the Superintendent of the Coast and Interior Survey, the Director of the United States Geological Survey, and three civilians, to be appointed by the President, who shall receive a per diem compensation of 10 dollars for each day while actually engaged, and their travelling expenses; and neither the Commissioner of the General Land Office, the Superintendent of the Coast and Interior Survey, nor the Director of the United States Geological Survey, shall receive other compensation for their services upon said commission than their salaries, respectively, except their travelling expenses, while engaged on said duties; and it shall be the duty of this commission to report to Congress within one year from the time of its organisation: first, a codification of the present laws relating to the survey and disposition of the public domain; second, a system and standard of classification of public lands as arable, irrigable, timber, pasturage, swamp, coal, mineral lands, and such other classes as may be deemed proper, having due regard to humidity of climate, supply of water for irrigation, and other physical characteristics;

third, a system of land-parcelling surveys adapted to the economic uses of the several classes of lands; and, fourth, such recommendations as they may deem wise in relation to the best method of disposing of the public lands of the western portion of the United States to actual settlers.

"The publications of the Coast and Interior Survey shall consist of the annual report of operations, such geographic and topographic maps, and geodetic and coast-charts, and such discussions and treatises connected therewith, as the superintendent shall deem of value. The publications of the Geological Survey shall consist of the annual report of operations, geological and economic maps illustrating the resources and classification of the lands, and reports upon general and economic geology and palæontology. The annual report of operations of the Coast and Interior Survey and of the Geological Survey shall accompany the annual report of the Secretary of the Interior. All special memoirs and reports of both surveys shall be issued in uniform quarto series. The style and scale of the cartographic publications shall be determined by the head of each organisation, so as to express the scientific results in the most effective manner. Three thousand copies of each shall be published for scientific exchanges by the heads of the surveys and for sale at the price of publication; and all literary and cartographic materials received by the heads of the surveys in exchange shall be the property of the United States, and form a part of the libraries of the two organisations; and the money resulting from the sale of such publications shall be paid into the Treasury of the United States."

HEINRICH GEISSLER

A YEAR since we were called upon to chronicle the death of Ruhmkorff, whose name is so closely identified with the history of electricity. In recording the death of Dr. Heinrich Geissler at Bonn, January 24, we regret the loss to the world of science of an equally important and esteemed worker. He was born in the village of Igelshieb, in Central Germany, in the year 1814. At an early age he mastered the art of glass-blowing—an industry which has long flourished in his native duchy of Sachsen-Meiningen—and for a number of years he led the life of a German *Handwerksbursch*, rambling from one place to another, accepting employment wherever it was offered. The German University towns offered to him the chief attraction, the preparation of the articles requisite for scientific research having for him a peculiar fascination; and his wandering life finally ended in a permanent settlement at Bonn. Here he developed rapidly. In the treatment of glass before the blowpipe he attained a degree of perfection hitherto unknown, and in his day unsurpassed. Despite the disadvantages of his early life, and the demands of his occupation, he succeeded in making rapid acquisitions in various departments of the natural sciences; and favoured by association with numerous leading celebrities, in physics and chemistry, he soon attained a remarkably comprehensive and intimate familiarity with scientific facts and principles. The union of this knowledge with his constructive ability and manual accomplishments was productive of the happiest results, and the past thirty years have witnessed a constant succession of novel and ingenious devices for the furtherance of scientific discovery, issuing from his *atelier*. Not only was he able to accomplish the practical realisation of the designs submitted to him, but in a multitude of cases, when simply the end in view was proposed to him, Geissler planned and produced apparatus of the most delicate construction, and exact precision, involving a mastery of physical laws to be expected only in one who had devoted his life to the solution of scientific problems. The impulse thus given by him to the march of original investigation is not easy to measure, for his name is rarely associated with the numerous discoveries where his fruitful ideas have contributed in a greater or less degree to the successful result. One of his earliest direct investigations was in companionship with the distinguished physicist, Plücker, in 1852. By means of a delicate apparatus, in which the expansion of the glass was exactly compensated by the introduction of mercury, they made a series of accurate observations on the expansion of water, and established the maximum of density at 3·8°. With an equal degree of accuracy the coefficient of expansion for 1° of ice between $-24°$ and $-7°$ was established at 0·0001585, and the coefficient of expansion for water when freezing at 0°, was ascertained to be 0·09195. In 1869, Geissler, in company with Vogelsang, demonstrated in an ingenious manner the presence of liquid carbonic acid in the cavities of topaz and quartz. The minerals were decomposed by means of a galvanic current, the resultant gases were collected in a vacuum, and the presence of CO_2 was shown by the electric arc. They succeeded, likewise, in producing a precipitation in lime-water, and established beyond doubt the character of the liquid present. Shortly after Geissler succeeded in changing ordinary phosphorus into the amorphous state by the action of the electric current.

The apparatus with which Geissler's name is most popularly associated consists in the famous *tubes* arranged for the exhibition and study of the phenomena accompanying the electric discharge in various gases and vapours. Their ingenious disposition has contributed much to the progress of research on the nature of the electric light and the condition of matter in the gaseous state. Scarcely less important are his inventions of the vaporimeter, the mercury air-pump, as well as the balances, normal thermometer, and normal areometer, and other instruments of precision devised by him, which have rendered such incalculable service to those engaged in exact research. A few years since the University of Bonn rendered a fitting tribute to the varied merits of Geissler by bestowing on him the honorary title of Doctor of Philosophy.

The career of Geissler was in many respects similar to that of Ruhmkorff. Both advanced from the lowest ranks of life to positions of honour in the scientific world, both gave, in a quiet and almost unrecognised manner, an important impulse to the cause of physical investigation, and both have left their names as "household words" in the nomenclature of the science to which they were so faithfully devoted.

T. H. N.

GEOGRAPHICAL NOTES

LIEUT. WEYPRECHT informs us, with reference to his proposed scientific expedition to Novaya Zemlya that the statements which have appeared are very inaccurate, nothing having as yet been decided. He and Count Wilczek certainly intend to go there and make one year's thorough scientific observation in some place on the northern coast; special attention will be given to cosmical physics. They would prefer, however, if in other places of the Arctic and Antarctic regions, others would make observations simultaneous with them. Before the war broke out they had the best hopes of seeing their proposals nearly everywhere accepted, but the disturbed state of Europe during the last two years has prevented them from taking further steps. In April the International Meteorological Congress, which was to have met in 1877, will meet in Rome. One of the questions to be decided there will be, in what manner the Congress can contribute to the realisation of the proposals of Count Wilczek and Lieut. Weyprecht. On the decision come to at that meeting will theirs mainly depend. The programme which it is intended to carry out will be found described in NATURE, vol. xvii. p. 29.

THE commemoration of the centenary of Cook's death by the Paris Geographical Society on Friday seems to have been thoroughly successful. Several addresses were given, showing the services done by Cook to geography, to humanity, to navigation, and to science. M. Huber gave an account of Cook's career, showing how he dispelled the tenacious notion of an Antarctic continent, gave England New Zealand and Australia, discovered a multitude of islands, simplified nautical astronomy, studied oceanic currents, the variations of the compass, and the "Aurora Australis," laid down principles of hygiene, still of value, and opened new horizons to civilisation and religion. He paid a tribute to Cook's care of his crews, his mildness and forbearance towards the natives, his resort to reprisals only when the interests of the expedition or the lives of his men were imperilled, his intrepidity and inventiveness. In connection with Cook's death, M. Huber briefly adverted to the native account of the tragedy, as published four years ago by M. de Varigny, fourteen years a member of the Sandwich Islands Government. It is in the shape of a poem on Captain Cook, attributed to Kupa, an eye-witness of what happened. It describes how two forests were seen gently floating on the waters; how Kupa and others were ordered to swim up to them; how they found Goords, who breathed out fire and smoke from their nostrils and mouths, had dazzling white skins and sparkling eyes, wore skins of various colours, with holes in the sides, into which they plunged their hands, and which appeared full of treasures. A god with his thunderbolt kills Kupa's father, whereupon the other swimmers take to flight. The priest declares that the floating island is the war vessel of the god Lono, who, after murdering his wife through jealousy, left Hawaii long ago to explore the seas, and had now returned, according to his promise, after six generations. He bids the natives take them bananas, cocoa-nuts, and oranges, which are accepted. At night Lono and his fellow-gods shoot hissing arrows of fire at the stars, making some of them fall into the sea. Flames of strange colours descending from the trees of the floating islands and extraordinary sounds alarmed the natives. Next morning Lono lands; is treated as a god, with sacrifices and prostrations; but whether from anger, or from having forgotten the language, he makes no answer. Several of his inferior gods seize on sacred fish destined for the altar. Others begin pulling up the palisades surrounding the sacred inclosure, the Morai, where the elders meet. King Kalaimano remonstrates, but they laugh and persist. Lono comes up, crosses the sacred boundary, and is about to enter the Morai. Kalaimano intercepts his progress, but Lono rudely pushes him away. Kalaimano takes Lono up in his arms, and, on his struggling to free himself, presses him lightly. Lono cries out with pain. "He cries, so he is not a god," exclaims Kalaimano, and kills him. The other gods, who were pulling up the stakes, fly, but the natives fall on them, and, strange to say, their blood flows like that of mortals. Kalaimano, however, while launching arrows from the shore is killed by the invisible fire. Thus your fathers, concludes Kupa, saw the death in one day of their god and their chief. In this song the two visits of the vessels are fused into one. This confirms the story we referred to last week, and the impression that it was not treachery but vexation and disappointment that led to Cook's death. Much surprise, the *Times* correspondent states, was expressed in conversation at the inaction of the London Geographical Society. In Paris not only was a special festival organised with collections, which remained on view till Monday, but the Society has inserted in its *Bulletin* Mr. James Jackson's catalogue of the 300 works published in various languages relating to Cook. Dr. Hamy referred to Cook's observation of the transit of Venus at Tahiti, the rivalry and attacks of Dalrymple, and the fate of Cook's collections in being buried in an Austrian museum. He described Cook as ranking with Columbus and Magellan.

WE understand that the forthcoming number of the *Monthly Record of Geography*, published by the Royal Geographical Society, will contain a full bibliography and cartography of Zulu Land.

THE Russian Geographical Society proposes to give its great gold medal to Prof. Nordenskjöld.—The Berlin Geographical Society has given its gold medal to M. Prjvalsky.

WE hear that Capt. Henry Sengstacke, who had intended to accompany Dr. Otto Finsch in his projected scientific expedition among the islands of the Pacific, is shortly about to proceed to Behrings Straits for the relief of Prof. Nordenskjöld. Capt. Sengstacke took a leading part in recent German Arctic expeditions, and had but lately returned from the west coast of America. At his special request the Council of the Royal Geographical Society have, we understand, undertaken to furnish him with copies of the sailing directions for, and the latest and best charts of, the part of the world which he is now about to visit. The latest information, however, with regard to the relief of Nordenskjöld's party seems to be contained in the following telegram received by the Russian Government from the Governor-General of East Siberia:—"Irkutsk, January 28.—Sibiriakoff telegraphs to me from Zurich that a steamer belonging to Bennett will, immediately after the opening of the navigation, proceed from San Francisco to Behrings Straits to assist Nordenskjöld. It is therefore not necessary to send a steamer from Nicolajefsk."

AT the last meeting of the Berlin Academy of Sciences an account was given of the programme of Dr. Finsch's journey, the cost of which will be defrayed by the Humboldt Fund, and which is estimated at about 13,000 marks (650*l.*). Dr. Finsch will direct his principal attention to Polynesia. He will proceed to Honolulu *viâ* New York and San Francisco; thence he will visit the Marshall and King'smill group, the Caroline, Mary Anne, and Bonin Islands, and he intends to return *viâ* Japan, China, and the Philippine Islands.

MOVING OF HEAVY ORDNANCE

MODELS of the poop and topgallant forecastle decks of H.M.S. *Iris*, and midship main deck of H.M.S. *Dwarf*, are now exhibited by Mr. George Fawcus at the floating dock, North Shields, to explain how naval ordnance can be traversed and trained round elliptical or circular sterns and parabolic bows of vessels, from side to side amidships, or from a point blank or direct broadside, to a fore and aft range of barbette or over all fire "all round" without any changing of pivots; and how muzzle-loading guns can be turned round to load in board, to avoid the inconvenience of loading in front, and thus obtain all the presumed advantages of breech-loading ordnance.

A simple and compact mechanical motion has been developed from the action of the trammel or elliptograph, and is communicated rapidly along the diameters or minor and major axis of an ellipse or oval, as a shorter road than slowly round the circumference, with a small elliptical circuit instead of a circular segment of a larger circle. Two moving pivots replace a single central one. These pivots mutually assist each other to produce a reciprocal compound lever movement, one good graceful turn being succeeded by another, and are kept each in its own track of two intersecting straight lined grooves, which may be adjusted, by various angles of intersection and varied distances of the centres apart from each other, to obtain any imaginable curvilinear movement, so that guns of all kinds can be worked in less space with greater ease of movement, and therefore with less labour and waste of time, than has ever yet been previously effected.

NOTES

MR. PREECE and Mr. Stroh, who have been working for the past twelve months upon the acoustic properties of the phonograph, have completed their labours as far as the vowel sounds are concerned, and their paper on the synthetic examination of these sounds will be read before the Royal Society probably on the 27th inst. Several new instruments of great novelty and marvellous ingenuity will be exhibited, including a new phonautograph, an automatic phonograph, a compound curve-tracer, a new syren, and a new musical instrument.

WE record with deep regret the death, at Luxor, in Egypt, on the 1st inst., of Dr. C. E. Appleton, the founder and editor of *The Academy*. Dr. Appleton was under forty years of age, and had been in declining health for the past two years. His name will be familiar to many of our readers in connection with the Endowment of Research, on which subject he frequently wrote, and a volume of essays on which he edited a year or two ago. Dr. Appleton was himself mainly a student in metaphysics, but he clearly perceived the value of physical science, and the immense advantages likely to accrue to its progress, to our universities, and to the country, by the appropriation of part of the great wealth of the universities, and of the funds of the state, to the encouragement of original research. He laboured earnestly to advance these views, believing that it was the country's duty and interest to encourage the discovery of new truths. He will be greatly missed by his many friends.

WE have to record the death of Mr. Bennet Woodcroft, F.R.S., which happened on the 7th inst. at his residence in Brompton. Mr. Woodcroft will be best remembered in connection with the Patent Office, which he may be said to have originated, and the working of which he so ably and zealously superintended from the time of its establishment down to within the last two years. He was born at Bennet Grange, near Sheffield, in December, 1803, and was consequently in his seventy-seventh year when he died. Early in life he studied science under Dalton, of Manchester, and in course of time joined his father in his business, which was that of a Manchester manufacturer. After a while Mr. Woodcroft came to London, and was appointed Professor of Machinery at University College, London, in 1847; he held that appointment until 1851, when he resigned it. Next year witnessed the passing of the Patent Law Amendment Act, and the then Lord Chancellor, Lord Cranworth, appointed Mr. Woodcroft as superintendent of the specifications, for which post his great experience in patent matters especially qualified him. He retired from office in March, 1876, and during his administration of affairs he carried out the provisions of the Act with efficiency and liberality. The establishment of the library in connection with the Patent Office was mainly due to Mr. Woodcroft, as was also the formation of the Patent Office Museum at South Kensington, to which he was a very liberal contributor, and which was made a free institution solely through his exertions. Among other mechanical improvements effected by Mr. Woodcroft was that of giving to the screw-propeller what is known as an increasing pitch. He was the means of rescuing from oblivion the first marine steam-engine ever made. Mr. Woodcroft was the author of several scientific treatises, and wrote a series of biographical sketches of inventors. He was elected a Fellow of the Royal Society about twenty years since. An excellent notice of Woodcroft appears in the *Engineer* of February 14.

WE regret to announce the death at Berlin on January 15 of Prof. Philipp Spiller, one of the most eminent of German philosophers. Prof. Spiller was born on September 26, 1800, at Einsiedel, near Reichenberg, in Bohemia, and has enriched scientific literature by many valuable publications. His recent work, "Die Urkraft des Weltalls nach ihrem Wesen und Wirken auf allen Naturgebieten" (Berlin: Stuhr, 1876), is a work of the greatest importance and worthy of the attention of all interested in philosophy.

RUSSIA has lost one more of her mathematicians, Prof. Popoff, of Kazan. His works on the integration of differential equations, on hydrodynamics, on the waves which arise from the motion of a body, on definite integrals, on the calculus of variations, &c., have given to the late professor an eminent place among mathematicians.

MR. COWPER'S new "Writing Telegraph" will be brought before the Society of Telegraph Engineers at their next meeting, on the 26th inst., at the Institution of Civil Engineers.

THE Anthropological Institute has just received a legacy of 1,000*l*., bequeathed by the late Mr. Sydney Ellis of Nottingham.

M. CHEVREUL, who although about ninety years of age, enjoying good robust health, has resigned the administration of the Jardin des Plantes. M. Jules Ferry, the new Minister of Public Instruction, has written him a letter eulogistic of his career, and appointing him Honorary Administrator. M. Jules Ferry has appointed to the post, for a term of five years, M. Fremy, the eminent Professor of Chemistry, Director of the Laboratory at the Gardens, the practical School of Chemistry in Paris.

THE people of Penzance have been attempting to celebrate in a mysterious, hole-and-corner way, the centenary of the birth of their great townsman, Sir Humphry Davy, two months after the actual date. What their notion of the "adjacent" world is we do not know, but we doubt if they have any adequate appreciation of the greatness of Davy, whose only merit in their eyes seems to be that he was born in Penzance. Why, if they wanted worthily to honour one of England's greatest scientific worthies, did they not take the Royal and Chemical Societies into their confidence? or how is it that the Royal Society, being aware of the occurrence of this important centenary (they seem to have contributed to the exhibition), have made no efforts to take part in the celebration officially? We leave it to a foreign nation to honour the memory of one of our greatest explorers, and to a petty provincial town to commemorate the birth of one of our greatest chemists. There are surely several screws loose in our scientific organisation.

THE Russian Physical and Chemical Society is now discussing the means of a thorough study of the surface of the moon, especially by means of spectrum analysis.

PROF. FAMINTZIN, of St. Petersburg, has been elected member of the Russian Academy of Sciences in the place of the late Prof. Geleznoff.

A MEETING of the General Committee of the Hanbury Memorial Fund was held in the rooms of the Pharmaceutical Society yesterday. The Sub-Committee reported that the nett proceeds of the one-guinea subscriptions collected from all parts of the world amount, after payment of the cost of the die for the medal, &c., to about 350*l*. The Sub-Committee have to recommend:—1. That the proceeds be invested in consols; the interest to be expended in defraying the cost of a gold medal to be awarded biennially (or otherwise) "for high excellence in the prosecution or promotion of original research in the natural history and chemistry of drugs." 2. That trustees be appointed, who, from time to time, shall request the following gentlemen to award the medal:—The presidents for the time being of the Linnean Society, the Chemical Society, the Pharmaceutical Society, and the British Pharmaceutical Conference, and one pharmaceutical chemist, who shall be nominated by the two presidents last-named.

A Royal Commission, consisting of Mr. Warington W. Smyth, F.R.S., Sir George Elliot, M.P., Mr. F. A. Abel, C.B., Mr. Thomas Burt, M.P., Mr. Robert Bellamy Clifton, F.R.S., Prof. Tyndall, F.R.S., Mr. Lindsay Wood, and Mr. William Thomas Lewis, has been appointed for the purpose of inquiring and reporting whether, with respect to the influence of fluctuations of atmospheric pressure upon the issue of fire-damp from coal, to the adoption and efficient application of trustworthy indicators of the presence of fire-damp, and generally to systematic observation of the air in mines, to improved methods of ventilation and illumination, to the employment of explosive agents in the getting of minerals, and to other particulars relating to mines and mining operations, the resources of science furnish any practicable expedients that are not now in use and are calculated to prevent the occurrence of accidents or limit their disastrous consequences.

Mr. R. McLachlan, F.R.S., writes us that he is informed from two independent sources that Italy has lost its head from dread of the visitation of the *Phylloxera*. The restrictions on the importation of plants of any kind whatever, *and from any quarter*, are most rigid. A consignment of the newly-discovered gigantic Aroid, from Sumatra, received in Genoa, was subjected to formalities and delays in permission to be delivered, of a nature that seriously compromised the welfare of the tubers. In some places gentlemen must dispense with the ordinary floral decorations in their button-holes. On the French frontier no one is allowed to gather a bouquet of wild flowers on foreign soil and take them across the border, for fear that the much-dreaded pest should exist in it. All scientific reasoning seems to be at an end in the minds of the Italian Government officials. But let us not forget that in 1877 we ourselves were almost in the same condition, owing to the panic spread among us with regard to the Colorado beetle. A knowledge of the rudiments of phytological entomology appears to be so universally deficient that it only requires some agitator to raise a panic in order to bring about the most absurd restrictive enactions. No one can blame the Italians for endeavouring by all means in their power to prevent the introduction of the *Phylloxera* into their vineyards; but they might show a little common-sense discrimination. A restriction on the importation of foreign vines would be sensible enough, and they might go further, and prohibit the discharge of earth-ballast taken in by vessels at ports in districts known to be infected. To stop the introduction of *all* vegetables and flowers is quite unnecessary.

On January 4, at 11 P.M., and on the following day at 9 A.M. a strong earthquake was felt at Maikop (Russia); there were five shocks, at intervals of about fifteen minutes.

The installation of objects sent in for the Anthropological Exhibition at Moscow will begin in the end of March. The interesting collections from Samarcand have already arrived, as well as very interesting objects sent by the East Siberian branch of the Russian Geographical Society. Those of stone implements and of quaternary mammals especially draw the attention of the organising committee, as well as several numismatic collections.

We notice a communication made by M. Kontkevitch, at the last meeting of the St. Petersburg Mineralogical Society, on the recently explored iron mines in the provinces of Kherson, Ekaterinoslav, and Taurida. At the confluence of the Saksagon and Ingulda rivers there are no less than forty layers of iron from 35 to 200 feet thick and several miles wide, containing 58 to 70 per cent. of iron, and representing a store of two and a half milliard cwts. of iron.

The Aosta section of the Italian Alpine Club proposes to celebrate this year the centenary of Saussure's travels in the Alps, which opened up quite a new world for science and for travellers. In 1779 he stayed for the first time in the Valley of Annecy, and the Club proposes to put a commemorative marble plate on the house he inhabited in the village of Dolonne, near Courmayeur. An inscription will probably be placed also on the Grammont Mountain, whence Saussure made his famous observations on Mont Blanc, the first ascent of which he made in 1787.

The Indian Government *Gazette*, we learn from the *Times of India*, contains papers on the proposed Presidency Botanic Gardens, including a Government minute and the report of the Committee. The Committee's consideration was invited to the question whether Puna or Bombay should be chosen as the place for the principal botanic garden of the Presidency. They decided in favour of Ganesh Khind. They recommend, however, that a small branch garden, consisting of four or five acres, be established in Bombay, and that the Grant College compound be selected for the purpose. The Government highly approved of all the recommendations, which will be carried out whenever financial means may permit. The main scientific garden, which will embrace about forty acres, is to be laid out in the irregular picturesque style, with special reference to landscape effect, and the planting of the ground will be done gradually and without any undue haste. It may be mentioned here that the chief resources of the garden are to be devoted to the bringing together of the indigenous plants of Western India, and until this is satisfactorily accomplished no pains will be taken, except in special cases, to introduce foreign plants. An extraordinary expenditure of Rs. 22,037 will have to be incurred for the purpose of constructing roads and footpaths, excavating a ground, erecting houses and sheds, providing iron piping, &c., for water supply, fitting up rooms for the herbarium, library, and class-room, and for the purchase of botanical books and diagrams. The estimated annual expenditure is, in round numbers, Rs. 12,000.

At the last meeting of the French Geographical Society a letter was read from the Abbé Desgodins, dated Yerkalo, August 27, 1878, in which he states that, contrary to the common assertion which represents the sheep as the beast of burden most used in Thibet, this function belongs in preference to the yak (*Bos grussiens*); the mule, ass, and horse are also made use of. The sheep, he says, is only employed as a beast of burden at one period, viz., when the parties of Thibetans quit the high plateaux to descend into the valleys at the approach of winter. The Buddhist pilgrims are sometimes to be met with sheep and goats carrying their baggage, but, as the Abbé Desgodins remarks, there is a wide difference between that and representing the sheep as the beast of burden of Thibet.

The first fascicule of the sixth volume of the "Repertorium für Meteorologie," published by the Russian Central Physical Observatory, contains a memoir, by Prof. Wild, on the temperature of the soil at St. Petersburg and Nukus (Amu-darya); geographical, magnetic, and hypsometric observations, by M. Fritsche, made during his journeys from St. Petersburg to Peking in 1866 and 1877; photochemical measurements of the intensity of daylight in St. Petersburg, by M. Stelling; determinations of the coefficients of anemometers, and magnetic observations on the Amu-darya, by the late M. Dorandt; and researches, by M. Frölich, into the temperature of space.

The German *St. Petersburger Zeitung* states that the cost of the bronze monument to be erected at Dorpat, in memory of Carl Ernst von Baer, is estimated at 15,000 roubles (about 2,300*l*.), and solicits subscriptions towards this sum.

The use of a paper dome for an astronomical observatory is a novelty in modern architecture, although, according to Prof. Greene, of Troy, U.S., under whose supervision this has been constructed, it promises to answer a satisfactory purpose. The

dome is a hemisphere with an outside diameter of twenty-nine feet. The framework is of pine properly seasoned, and the covering is of paper, such as is used by Messrs. E. Waters and Sons for the construction of paper boats. The entire weight of the dome and appurtenances, as completed, is about 4,000 pounds. It can be easily revolved by a moderate pressure without the aid of machinery.

THE director of the Postal Telegraph Service of the French Republic has been made a member of the Cabinet and placed on the same footing as the Postmaster-General of the British Government. The present holder of that office is M. Cochery.

THE Royal Institute of Sciences at Venice offers three prizes of 3,000 lire each (about 115*l.*) for three monographs containing (1) an account of the advantages which the application of physics to medical science has brought about; (2) a summary of the most recent investigations made in the field of theoretical hydrodynamics, as well as a statement of the true and essential progress made by this branch of scientific mechanics; (3) a treatise on the commercial and industrial conditions of the city of Venice. Further particulars may be learnt by applying directly to the "Istituto Reale Veneto" at Venice.

THE petrified remains of a Dinotherium belonging to the miocene period have just been discovered at Schöneg, near Salmhausen (Swabia), at a depth of 13 metres in a sand-hill.

WE recently referred to the all-embracing scientific agency of Friedländer and Son of Berlin, and this week we have received the first three parts of a new fortnightly publication from that house, likely to be of the greatest service to students in all departments of science. It is entitled *Naturæ Novitates*, and is a fortnightly bibliographical list of current literature of all nations, methodically arranged, in the various departments of science. The publication deserves encouragement; it may be had through Messrs. Williams and Norgate.

THE first part has reached us of an important German undertaking, an Encyclopædia of the Natural Sciences, constructed somewhat after the method of the old "Encyclopædia Metropolitana." It is to consist of methodical treatises in the various departments of science, followed by an index, which will give it all the advantages of an alphabetical cyclopædia. Each department has a separate editor, and some of the best men in Germany are engaged upon it. The first part is an instalment of a "Handbuch der Botanik," edited by Prof. A. Schenk, and contains a treatise on "Fertilisation of Flowers," by our friend Dr. H. Müller, and another on "Insectivorous Plants," by Dr. O. Drude. Trewendt of Breslau is the publisher.

THE Rev. W. A. Leighton has nearly completed the printing of the *third* edition of his "Lichen-Flora of Great Britain, Ireland, and the Channel Islands," which, it is expected, will be ready for issue early in March. This new edition is rendered necessary by the recent important discoveries in the west of Ireland, the north of Scotland, and the author's own researches in North and South Wales, whereby the number of our lichens, in the former editions amounting to 1,156, has been raised to 1,706, thus rendering our lichen-flora quite equal in number, rarity, and novelty, to that of any country in Europe.

AMONG recent deaths is that of M. Chauffod, Professor of Zoology at the Paris School of Medicine. M. Chaufford during his whole career opposed M. Claude Bernard's determinism, and advocated the existence of a vital principle and final causes in a number of books largely circulated.

FOR some time past the well-founded fear of trichina has led to a microscopic examination of much of the meat, especially pork, sold in Berlin. Recently the occurrence of this pest there has been more frequent, and Dr. Luedtge (who claims the invention of the microphone) has consented to give a course of instruction in this branch of microscopy, which began February 17. The course, with practical exercises, will occupy five hours, and is open to ladies and gentlemen at the price of 5*s*. The instruction is to be given in the old Mint, at the Microscopic Aquarium, of which Dr. Luedtge is the director.

DR. AUB, one of the oldest Rabbis in Berlin, recently received from the University of Munich a new doctor's diploma, commemorative of his having received that degree there fifty years ago. It was conferred by Dr. Steinthal in the name of the philosophical faculty.

IT is stated in the *Diario de Manila* that a mine of amianthus, or earth flax, has been discovered in the Island of Luzon. Several specimens of the mineral have been taken to Manila, and have been pronounced by competent judges to be of excellent quality.

IN December last a convention between Spain and China was signed in Spanish, French, and Chinese at Peking relating to the treaty which regulates the emigration of Chinese to the Island of Cuba.

A CORRESPONDENT to the *Times of India*, who lately rode through the Kohat Pass, gives a somewhat curious description of an Afridee village, or, rather, an Afridee family home. The first thing seen is a mud wall oddly slit and pierced, and over its summit rise a number of mud and generally round-shaped projections, on the tops of which may be seen a few children and women. These projections are the roofs of the little rooms or mud inclosures in which the family live during the day; but what immediately strikes the attention on approaching is the loopholed mud tower overshadowing the mud inclosure. The house proper is reached by passing through a very narrow entrance between the family fort and the mud inclosure. Inside are winding lanes between high mud walls, loop-holed at every turn. The writer found the inhabitants of the village he visited exceedingly hospitable. "The men around him," he says, "had a curiously frank, inquiring, and manly look. Nothing in their demeanour as they stood examining me and watching me eat, could have embarrassed the most sensitive stranger; but as I attentively watched some of their countenances, I could not help observing how often their expression changed, and how often there flitted across their faces a look that made one insensibly shudder." It is worth noting that the women of the Afridees, although Mohammedans, do not cover their faces.

WE understand that Mr. J. R. Gregory, the well-known mineral dealer, has several specimens of that extremely rare mineral, *Percylite*, of which the only known specimen, till quite recently, was the example in the British Museum; he also has, we hear, specimens of another rare mineral, named *Schwartzenbergite*, both from the same locality—a new one for these minerals—in Bolivia.

THE additions to the Zoological Society's Gardens during the past week include a Ring-tailed Lemur (*Lemur catta*) from Madagascar, presented by Mr. Thos. G. Mann; a Cape Hyrax (*Hyrax capensis*) from South Africa, presented by Mr. A. H. Jamrach; two Black-headed Gulls (*Larus ridibundus*), a Common Gull (*Larus canus*), European, presented by Mr. Harry W. Preston; a Wood Owl (*Syrnium aluco*), European, presented by Mrs. George Blagden; a Garnett's Galago (*Galago garnetti*) from South-East Africa, two Yellow-billed Sheathbills (*Chionis alba*) from Antarctic America, purchased; a Yellow-footed Rock Kangaroo (*Petrogale xanthopus*), born in the Gardens.

SIR JOHN LUBBOCK ON ANTS

SIR JOHN LUBBOCK read two papers on ants at the Linnean Society on February 6. The first gave an account of their anatomy; but from the extreme complexity of these interesting little creatures, it would be impossible to make this communication intelligible without the figures. The second paper was a continuation of his observations on the habits of ants. He mentioned that he had at first isolated his nests by means of water. This was effectual enough, but, especially in summer, the water required to be continually renewed. Kerner, however, had suggested that the hairs of plants served to prevent ants from obtaining access to the honey, and it accordingly occurred to him that strips of fur arranged with the points of the hairs downwards might answer his purpose. He had tried this, and finding it successful, he thought a similar arrangement might perhaps be found useful in hot countries.

It is generally stated that the queen ants alone lay eggs, but Sir John has found that in most of his nests some few of the workers are capable of doing so. It appears, however, that these eggs always produce males. In the case of bees we know that the queen is fed on a special kind of food. In ants it is not feasible to make observations similar to those by which in bees this has been established. It is, however, rendered more than probable by the fact that while males and workers have been bred by hundreds in his nests, no queen has yet been produced.

It is well known that ants keep other species of insects in their nests, which they use just as we do cows, &c.

The *Mat. p. l'Hist. prim. de l'Homme* for 1869 contains a short but interesting account by M. Lespes of some experiments made by him on the relations existing between ants and their domestic animals, from which it might be inferred that even within the limits of a single species some communities are more advanced than others. He found that specimens of the blind beetle, *Claviger duvalii*, which always occurs with ants, when transferred from a nest of *Lasius niger* to another which kept none of these domestic beetles, were invariably attacked and eaten. From this he infers that the intelligence necessary to keep *Clavigers* is not coextensive with the species, but belongs only to certain communities and races, which, so to say, are more advanced in civilisation than the rest of the species.

Sir John Lubbock, however, removed specimens of the curious blind *Platyarthrus* from one nest to another, but they were always amicably received. He even transferred specimens from a nest of *Lasius flavus* to one of *Formica fusca*, with the same result.

As regards the longevity of ants he has now two queens of *F. fusca*, which seem quite in good health and which have lived with him since 1874; they are therefore probably five years old. He has also workers of *Lasius niger*, *Formica sanguinea*, *F. fusca*, and *F. cinerea*, which he has had under observation since 1875.

In his previous papers he had given various instances which seem to show that ants do not exhibit such unvarying kindness to their friends as has been usually supposed. He wished to guard himself, however, against being supposed to question the general good qualities of his favourites. In fact, ants of the same nest never quarrel among themselves; he had never seen any evidence of ill-temper in any of his nests. All is harmony. He had already in previous papers given various instances of tender kindness. Again, in one of his nests of *Formica fusca*, was a poor ant which had come into the world without antennæ. Never having previously met with such a case, he watched her with great interest, but she never appeared to leave the nest. At length one day he found her wandering about in an aimless sort of manner, and apparently not knowing her way at all. After a while she fell in with some specimens of *Lasius flavus*, who directly attacked her. He then set himself to separate them; but she was evidently much wounded, and lay helplessly on the ground. After some time another *Formica fusca* from her nest came by. She examined the poor sufferer carefully, then picked her up tenderly, and carried her away into the nest. It would have been difficult, Sir John thinks, for any one who witnessed this scene to have denied to this ant the possession of humane feelings.

It is clear from the experiments recorded in the present and in Sir John's former papers, that the ants recognise all their fellows in the same nest, but it is very difficult to understand how this can be effected. The nests vary very much in size, but in some species 100,000 individuals may probably be by no means an unusual number, and in some instances even this is largely exceeded. Now it seems almost incredible that in such cases every ant knows every other one by sight; neither does it seem possible that all the ants in each nest should be characterised from those of other nests by any peculiarity. It has been suggested in the case of bees that each nest might have some sign or password. The whole subject is full of difficulty. It occurred to Sir John, however, that experiments with pupæ might throw some light on the subject. Although the ants of every separate nest, say of *Formica fusca*, are deadly enemies, still if larvæ or pupæ from one nest are transferred to another, they are kindly received and tended with, apparently, as much care as if they really belonged to the nest. In ant warfare, though sex is no protection, the young are spared—at least when they belong to the same species.

Moreover, though the habits and dispositions of ants are greatly changed if they are taken away from their nest and kept in solitary confinement, or only with a few friends, still under such circumstances they will often carefully tend any young which may be confided to them. Now if the recognition were effected by means of some signal, or password, then, as it can hardly be supposed that the larvæ or pupæ would be sufficiently intelligent to appreciate, still less to remember it, the pupæ which were intrusted to ants from another nest would have the password, if any, of that nest, and not of the one from which they had been taken. Hence, if the recognition were effected by some password, or sign with the antennæ, they would be amicably received in the nest from which their nurses had been taken, but not in their own.

He therefore took a number of pupæ out of some of his nests of *Formica fusca* and *Lasius niger*, and put them in small glasses, some with ants from their own nest, some with ants of another nest of the same species. The results were that thirty-two ants belonging to *Formica fusca* and *Lasius niger*, removed from their nest as pupæ, attended by friends and restored to their own nest, were all amicably received. What is still more remarkable, of twenty-two ants belonging to *Formica fusca*, removed as pupæ, attended by strangers and returned to their own nest, twenty were amicably received. As regards one Sir John was doubtful; the last was crippled in coming out of the pupæ case, and to this, perhaps, her unfriendly reception may have been due. Of the same number of *Lasius niger* developed in the same manner from pupæ tended by strangers belonging to the same species, and then returned into their own nest, seventeen were amicably received, three were attacked, and of about two Sir John felt doubtful.

On the other hand, fifteen specimens belonging to the same species, removed as pupæ, tended by strangers belonging to the same species and then put into the strangers' nest, were all attacked.

The results may be tabulated as follows:—

	Pupæ brought up by friends and replaced in their own nest.	Pupæ brought up by strangers. Put back in own nest.	Pupæ brought up by strangers. Put in strangers' nest.
Attacked	0	7[1]	15
Received amicably	33	37	0

Sir John intends to make further experiments in this direction, but the above results seem very interesting. They appear to indicate that ants of the same nest do not recognise one another by any password. On the other hand, if ants are removed from the nest in the pupæ state, tended by strangers, and then restored, some at least of their relatives are certainly puzzled, and in many cases doubt their claim to consanguinity. Strangers, under the same circumstances, would be immediately attacked; these ants, on the contrary, were in every case—sometimes, however, after examination—amicably received by the majority of the colony, and it was often several hours before they came across one who did not recognise them.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

THE Medical Faculty of the University of Zurich gave, last week, the degree of M.D. to Miss Draya Sjocie, from Shabats, in Servia, and the Countess Vilma Hugonai, from Teteny, Hungary.

THE success of the high classes for ladies at Odessa has exceeded all expectations. On the opening day, January 21, instead of the expected sixty or seventy students, 215 ladies were inscribed. The University has offered its rooms for the classes.

[1] Of about three of these Sir John did not feel sure.

We learn from the Annual Report of the Moscow University that the number of students at the University was, during 1878, 1,643, with 108 professors; 318 of them were in the Jurisprudence Faculty, 131 in the Philological, 240 in the Physico-Mathematical, and 954 studied Medicine. No less than 62 medical students have taken part in the last war; the majority of students are very poor, and 417 of them received pecuniary help which has reached, during the year, the sum of 11,500*l*.

SCIENTIFIC SERIALS

American Journal of Science and Arts, January, 1879.—Prof. Loomis's important paper in this number on storms on the Atlantic, &c., has been noticed elsewhere. Prof. Marsh (in an appendix) describes a new order of extinct reptiles (*Sauranodonta*) from the Jurassic formation of the Rocky Mountains; they closely resemble Ichthyosaurus (of which no remains have hitherto been found in America), but are without teeth. The same author continues his "Principal Characters of American Jurassic Dinosaurs."—Prof. Greene, of Troy, New York, describes a paper dome constructed from his plans for an astronomical observatory. The paper covering is in sixteen equal sections, the framework of each section consisting of three ribs of pine meeting at the apex. There are also a circular sill at the base and two parallel semicircular arch girders spanning the dome (all of pine). The entire structure weighs about 4,000 lbs. The dome is supported on six 8-inch balls rolling between grooved iron tracks by direct pressure.—Mr. Edison describes his tasimeter as applied to measuring the heat of the stars and of the sun's corona.—Mr. Fontaine writes on the mesozoic strata of Virginia, and Mr. Holden on the brightness and stellar magnitude of the third Saturnian satellite.—A list of fifty species of east coast fishes (many of them new to the fauna) is supplied by Messrs. Goode and Blan.—In the "Miscellaneous Intelligence" will be found the report of the committee appointed to consider the scientific surveys of the United States territories.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, January 23.—"On the Microrheometer." By J. B. Hannay, F.R.S.E., F.C.S., lately Assistant Lecturer on Chemistry in the Owens College, Manchester. Communicated by H. E. Roscoe, LL.D., F.R.S., Professor of Chemistry in Owens College, Manchester.

In this paper the author reviews the work done by chemists and physicists in determining the relation between the chemical composition of a liquid and its rate of flow through a capillary tube. Poiseiulle [1] ascertained, in a very accurate manner, all the physical laws relating to the rate of flow, as regulated by temperature, pressure, and dimensions of the tube; but on examining saline solutions he could make nothing of the numbers presented, because he used percentage solutions instead of solutions proportional to the equivalent of the body dissolved. Graham,[2] noticing that Poiseiulle had discovered a hydrate of alcohol by running various mixtures of alcohol and water through the tube, examined mixtures of the various acids with water, and found that the hydration proceeded by distinct steps of multiple proportions. Several others, notably Guerout,[3] have since worked on the same subject, but as they have only worked on organic liquids, and have done all the rates at the same temperature, the results throw no light on the phenomena. Thus water runs about five times as quickly at 100° as at 0°; and in a series of alcohols, such as Guerout experimented upon, the differences between their boiling points were very great, so that, their vapour tensions or molecular mobilities being quite incomparable while at the same temperature, the experiments do not admit of any real interpretation. The author reserves the organic part of the investigation, which requires the determination of vapour tensions, till a future paper, and in the present deals with saline solutions.

The phenomenon of the flow of liquids through capillary tubes has been called in this country transpiration, while in other countries no distinct name has been adopted; and as the English word is already in use in French for another purpose, and properly applies to gases (the laws relating to which are quite different), the author proposes to use for liquids the term "Microrheosis," from μικρός and ῥέω, the instrument being called the microrheometer. The form of apparatus which the author finally adopted is figured in the paper, and is so arranged that when the liquid is introduced, as many experiments as may be desired may be tried, and the pressure and temperature, as well as the atmosphere in which the experiment is conducted, may be varied, while the thermometer indicating the temperature is at the mean point of the system. The author gives a curve for water from 0° to 100°, the differences of rate being smaller as the temperature rises.

[1] *Ann. de Chim. et de Physique*, [3], t. vii. 50.
[2] *Phil Trans.*, 1861, p. 373.
[3] *Comptes Rendus*, lxxix. p. 1201; lxxxi, p. 1025.

Various salts are then examined, being dissolved to form "normal" solutions; but as the solubility of some salts is too low for such solutions, the effect of the amount of salts dissolved is determined. This is found to be directly proportional to the amount of salt in solution. Values for many salts in solution are then given, each number being the mean of ten experiments, and the probable error of the mean is calculated in each case. The conclusions arrived at are these. The rate of flow does not depend on any of the "mechanical" features of the salt, such as crystalline form, specific volume, solubility, &c.; but upon the mass of the elements forming the substance and the amount of energy expended in its formation. Each element has a value of its own, which is continued in all its compounds. Thus all the salts of potassium and sodium formed by the same acids have a constant difference. In like manner each metalloid and acid radicle has a value which is continued in all its combinations. Then the greater the combining value of an element the quicker is its microrheosis; thus potassium has a higher rate than sodium, barium than strontium, strontium than calcium, and so on. The microrheosis also varies with the amount of energy in the compound; thus nitrates stand highest, as they contain most energy; then chlorides; and, lastly, sulphates, which are exhausted compounds.

The instrument, bringing to light as it does the fundamental relations of combining weight and energy in chemical action, will be of the utmost importance in chemical physics, as by its use not only will the amount of energy evolved in reactions be determined, but the mass combined; or, in other words, the chemical equivalent of the elements involved will be found.

February 6.—"On certain Dimensional Properties of Matter in the Gaseous State." By Osborne Reynolds, F.R.S., Professor of Engineering at Owens College.

Mathematical Society, February 13.—C. W. Merrifield, F.R.S., president, in the chair.—Sir J. Cockle, F.R.S., was admitted into the Society.—Mr. R. Hargreaves and Prof. W. E. Story were proposed for election.—Dr. Hirst, F.R.S., communicated a paper by M. Halphen on the number of conics which satisfy five independent conditions.—Sir J. Cockle spoke upon a construction for making magic squares. Messrs. Cayley, Harley, Henrici, Roberts, Hart, and other gentlemen took part in a discussion on the subject. Prof. Henrici, F.R.S., gave some properties of frames.—Prof. H. J. S. Smith, F.R.S., read two papers on a modular equation and on the formula for four Abelian functions.—Mr. J. J. Walker communicated a quaternion proof of Minding's theorem.

Linnean Society, February 6.—Prof. Allman, F.R.S., president, in the chair.—Mr. J. R. Jackson exhibited specimens from the tombs of ancient Thebes. Among these were fruits of the Doum Palm (*Hyphæne thebaica*) and of *H. aigun*, formerly, but wrongly, described as an *Areca*. Small berries also obtained were identified as those of *Juniperus phœnicea* as against those of *J. excelsa*.—Mr. J. G. Baker showed dried bulbs of *Buphane toxicarea*, which furnish a principal ingredient of the poison the Bushmen of South Africa tip their arrows with. Structurally, the numerous tunics of the bulb are a peculiarity. The range of this plant has been found to be as far north as Lake Tanganyika. In Sir C. W. Strickland's hothouse a plant flowered last year, and this for the first time in England.—Mr. W. T. Thiselton Dyer shortly described specimens of, and pointed out the special characters and probable advantages of, a new fodder grass, *Euchlæna luxurians*, and he also exhibited and made remarks on curious instruments used for weaving fibre of *Curculigo latifolia* by the natives of Borneo.—Mr. T. Christy drew attention to a sample of tea grown in Natal, and to a bottle of the milky secretion of the African Rubber Tree (*Landolphia*), the same having been freshly drawn from the living plant and immediately thereafter forwarded to this country; slight coagulation of the juice had nevertheless occurred.—The Rev. G. Henslow passed round for examination a specimen of female

mistletoe bearing male shoots. The botanists present expressed opinion of its being an androgynous condition rather than a male parasitic on a female plant, as had been supposed.—Mr. R. Irwin Lynch exhibited and made remarks on parts of the Bull's Thorn Acacia (*A. sphærocephala*), the Imbauba Tree (*Cecropia peltata*), and on a couple of Orchids (viz., *Espidendron bicornutum*, and *Schomburghii tibicinus*), as exemplifying their economy in affording protection to, and food for, ants. Mr. F. Darwin has already described the two former (*L. S. J. Bot.*, xv. p. 398), but that orchids should furnish a nidus for ants is apparently a new fact.—A short paper on the position of the genus *Sequenzia* among the Gasteropoda was read by Dr. J. Gwyn Jeffreys. His opinion differs from that lately promulgated by the Rev. R. B. Watson, believing that it belongs to the Solarium group rather than to the Trochus family, where placed by the latter naturalist. —There followed two papers on the anatomy and on the habits of ants, the gist of which we give elsewhere.

Physical Society, February 8.—Annual meeting.—The President (Prof. W. G. Adams) read the Report of the Council, which showed that the papers had been more numerous during the past than in any previous year, and that their value and interest had been well sustained.—A copy of the collected papers of the late Sir Charles Wheatstone was laid on the table, and the work will shortly be issued to the members of the Society.—The President then gave a brief review of the physical work of the past year, dwelling more especially on the papers read at the meetings.—Votes of thanks were then passed to the president, to the Lords of the Committee of Council on Education, to the demonstrator, treasurer, secretaries, and auditors, and the following were elected as Council and Officers for the ensuing year:—President—Prof. W. G. Adams. Vice-Presidents—Prof. G. C. Foster, Prof. R. B. Clifton, Lord Rayleigh, Dr. Spottiswoode, Sir Wm. Thomson. Secretaries—Prof. A. W. Reinold, Mr. W. Chandler Roberts. Treasurer—Dr. E. Atkinson. Demonstrator—Prof. F. Guthrie. Other Members ot Council—Capt. W. de W. Abney, Dr. Warren de la Rue, Major E. R. Festing, Prof. Fuller, Dr. Huggins, Prof. A. B. W. Kennedy, Prof. McLeod, The Earl of Rosse, Mr. G. Johnstone Stoney, Dr. Wormell. Honorary Members—Prof. G. R. Kirchhoff, Dr. J. Plateau.—The meeting was then resolved into an ordinary one, and Dr. O. J. Lodge read a short paper on a method of calculating the course of temperature in a rod along which heat is being conducted.—Mr. Shoolbred gave an account of electric lighting illustrated by diagrams of the most recent magneto- and dynamo-electric machines and examples of the lamps in vogue. The only surviving magneto-machine is that of De Meritens, which is incomparably superior to the older ones of Nollet and Holmes. The dynamo-electric machines described were the continuous-current machines of Siemens, Gramme, Wallace-Farmer, and the alternating current machines of Wilde, Gramme, and Lontin. Wilde's machine is the first of these, or parent machine, and Lontin's so resembles it that the latter cannot be used in England. In these machines the current from a continuous machine is passed through a second machine, which yields the alternating currents. In Lontin's machine also a number of distinct currents are generated in separate circuits, each of which is capable of feeding several lights. There is now one in use on the Western Railway of France which gives three distinct currents, each of which supplies four different lamps, making a total of twelve lights. The American Brush machine was also mentioned. The Dubosq lamp, which was the first regulator, is well adapted for laboratory purposes, but for practical purposes the Serrin is preferable. Rapieff's lamp is used in the *Times* office. The De Mersanne, which was highly spoken of at the Paris Exhibition, moves the carbons by bevelled gearing. The Wallace-Farmer lamp, though durable, is unsteady, perhaps because only inferior gas carbon has yet been used. Jablochkoff's candle was found to be defective from the solid insulator, such as plaster, used between the carbons. This made it very expensive also. Experiments in Paris had shown that whereas Jablochkoff's system cost 10*d*. per hour per light, the other systems only cost one half of that. In Wilde's candle the solid insulator was dispensed with, air taking its place, the arc always tending to keep at the tip of the candle by electro-dynamic repulsion. In the De Meritens' candle three strips of carbon were used, the intermediate one being a stepping-stone to the arc, which passes between the two outer ones. Werdermann's and Regnier's so-called incandescent lamps were also shown. Mr. Shoolbred, after alluding to the fact that the upper positive carbon takes a crater form, and hence becomes a reflector, shedding the light downwards, stated that experiments had proved the line of maximum intensity of light to pass downward at an angle of 60° to the axis of the vertical carbons. By giving the positive carbon a horizontal displacement behind the lower negative one, Mr. Douglass, of the Trinity House, had been able to raise this line till it became horizontal, an advantage in lighthouses. He also pointed out that whereas in Paris the Jablochkoff waxed for a period, short compared to that in which it waned, in London it waxed for longer than it waned, which was, of course, an improvement, and Mr. Shoolbred suggested that it might be due to the fact that the engine worked at speed nearer to that of the machine, and that the machine was founded more solidly in London than in Paris. Mr. Werdermann said that it was a mistake to call his lamp an incandescent one, the fact being that all carbon lamps gave light from the incandescence of the positive carbon, and that a small arc was formed in his lamp between the two electrodes, which could be varied by the pressure between them. He maintained that it was as easy to produce 500 lights as 10 from the electric current by subdivision, as he hoped soon to show; and stated that the size of the carbons greatly controlled the intensity of the light. Prof. Ayrton held that the obstacle to the subdivision of the electric light was not an electrical one, but was due to the fact that the amount of light produced by the current is not in direct proportion to the amount of the heat produced. In contradiction to Prof. Ayrton, Mr. Werdermann stated that in the electric arc the opposing electromotive force was proportional to the original electro-motive force. Prof. Silvanus P. Thomson pointed out that residual magnetism in the cores of the bobbins of dynamo-electric machines lowered their efficiency, and hence short cores, as in the Wallace-Farmer machine, were an improvement.

EDINBURGH

Royal Society, January 20.—Prof. Kelland, president, in the chair.—Prof. Crum Brown gave the third part of a paper by him and J. Adrian Blaikie, B.Sc., on the action of heat on salts of tri-methyl-sulphine. They find that—I. the aqueous solution of tri-methyl-sulphine does not yield crystals when evaporated over sulphuric acid in vacuo, but only a thick syrup was obtained. On heating this at 100° it decomposes—water acetate of methyl and sulphide of methyl being given off.

$$CH_3{-}COO{-}S(CH_3)_3 = CH_3{-}COO{-}CH_3 + (CH_3)_2S.$$

II. The aqueous solution of benzoate of tri-methyl-sulphine cystallises in small thin plates which it is difficult to separate from the thick mother-liquor. On heating, the imperfectly dried salt yields at 110° water, sulphide of methyl and benzoate of methyl; the later boiling at 198°.

$$C_6H_5{-}COO{-}S(CH_3)_3 = C_6H_5{-}COO{-}CH_3 + S(CH_3)_2.$$

III. The dithionate of tri-methyl-sulphine is obtained by neutralising free aqueous dithionic acid with the hydrate. It crystallises readily in small clear cubes with one molecule of water of crystallisation. It is not hygryscopic. On heating at 220° sulphurous acid begins to come off, and afterwards along with it sulphide ot methyl, leaving methyl-sulphate of tri-methyl-sulphine.

$$\{(CH_3)_3S\}_2S_2O_6{-}H_2O = \{(CH_3)_3S\}CH_3SO_4 + SO_2 + S(CH_3)_2 + H_2O.$$

—Prof. Tait then gave the result of some experiments he had been making to determine the electro-motive force of the Gramme magneto-electric machine at different speeds. The experiments were not completed but they seemed to show that the electromotive force varied approximately in the duplicate ratio of the rate of turning. He explained that the Gramme machine with an electromotive power of about 37 Bunsen cells could give as powerful an electric light as a battery of 60 Bunsen cells, for the resistance in the Gramme is very much less than that in the battery of Bunsen.—Prof. Tait gave a note on the law of cooling of bars. He mentioned that in his continuation of the experiments of the late Principal Forbes on the condition of heat in bars, he had been able to reproduce all Forbes's results with one exception. This was that the rate of cooling of the bar when exposed after being heated to a high temperature, was found by Forbes to be rather slower at first than afterwards. Or if we express the temperature of the bar in terms of its excess of temperature above the air, he found that at first it grows till it reaches a maximum and then falls off. Prof. Tait found this phenomenon always at the beginning of his experiments, but by heating the bar to temperatures higher than was required for his experiments, this peculiarity vanished before

the temperatures were reached upon which the results were based. On trying to explain this phenomenon by Fourier's conduction of heat, he found that the difference between the true and the false law of cooling should not last more than a fraction of a second, whereas it lasted more than 10 minutes. He accordingly concluded that it must be due to the fact that the thermometers did not acquire at once the temperature of the bar, but that some minutes must elapse before the whole of the thermometer has the proper temperature. He tested this by heating a bar and placing a thermometer in it as soon as it was allowed to cool. The phenomenon appeared. After a few minutes, when the thermometer was indicating the true rate of cooling of the bar, a second thermometer was placed in the bar close to the first. The second showed the same phenomena, though the first was now following the usual law of cooling. In 5 or 6 minutes the first and second thermometers gave identical results, but a third thermometer gave the old phenomenon when newly inserted alongside the others. Other experiments confirming these were also made. —Mr. J. Y. Buchanan read a note on the distribution of temperature under the ice in Linlithgow Loch. He had made these experiments while testing a new deep-sea thermometer by Negretti and Zambra. His results showed that with the depths for abscissæ and the corresponding temperatures for ordinates, the curve so plotted was one of contrary flexure—the contrary flexure being at the temperature of 37·6° F., which he expected further experiments would show was the temperature of maximum density for the water of the loch. One remarkable fact was that the temperature rose as the bottom was reached, being about 40·1° there. This he thought was due to the oxidation of matter at the foot, and this idea was confirmed by the fearful stench of the water.—Dr. Alexander Macfarlane continued his paper on the principles of the logical algebra. He showed that $x^2 = x$ is of the nature of a condition imposed on x and that a more general form is $x^2 = \pm x$. He applied the principles of the logical algebra to deduce the general conclusion from data of certain common forms, and gave theorems on the number and nature of such general conclusions.

Paris

Academy of Sciences, February 10.—M. Daubrée in the chair.—The following papers were read:—Last reply to M. Pasteur, by M. Trecul.—Fourth reply to M. Berthelot, by M. Pasteur.—On the existence of an apparatus prehensive or complementary of adherence, in parasitic plants, by M. Chatin. This apparatus is most commonly furnished by the parasite, sometimes by the sustaining plant, or both. More often the form is that of a bell, of which the sucker corresponds to the tongue. Sometimes the tissue of the supporting plant rises round and embraces the sucker; and sometimes both plants furnish uniting growths round the point of attachment of the sucker. The author shows how the prehensive arrangement is more or less strong according to circumstances, and he gives histological details.—M. de Lesseps read a letter from M. Roudaire, giving news of boring operations in the region of the isthmus of Gabes, which are so far encouraging. One fact stated is that fresh water was found at 4 metres depth at the highest point; this would be important in the case of cutting through the tongue of land.—Observations on the project of forming an interior sea in Eastern Sahara, by MM. Martins and Desor. Having visited the region in 1863 they disapprove of the project, on the score of mirage possibly falsifying observations, the water of the new sea and any change of climate ruining the date palm cultivation, on which the natives so largely depend, &c.—Researches on the formation of latex and laticiferous vessels, during germinative evolution, in the embryo of *Tragopogon porrifolius*, by M. Faivre.—On the determination of imaginary roots of algebraic equations, by M. Farkas.—Remarks on differential linear equations and those of the third order, by M. Combescure.—On a simple way of presenting the theory of potential, and on the differentiation of integrals in cases where the function under the sign $\int$ becomes infinite, by M. Boussinesq. —Hydroelectricity and hydromagnetism; experimental results, by M. Bjerknes. These relate to actions of two pulsating or two oscillating bodies with each other, or a pulsating with an oscillating body. In one set of experiments air columns in two bell jars immersed in water, were varied through tubes, by means of pumps, causing pulsations.—On green and phosphorescent light from molecular shock, by Mr. Crookes.—On the dissociation of hydrate of chloral (new method) by MM. Engel and Moitessier. The dissociation is effected at about 61° in an atmosphere of chloroform. (A mixture of hydrate of chloral and chloroform is submitted to distillation.)—Researches on the yeast of beer, by MM. Schützenberger and Destrim. They compare the modifications of yeast in presence and absence of sugar. Simple digestion of yeast at 30° for twenty-four hours made it lose 1·77 per cent. of solid matter. With yeast and sugar there was an increase of solid matter; about 11·3 per cent. of yeast, or 5·7 per cent. of sugar.—On the homologues of oxyheptic acid, by M. Demarçay.—Analysis of a honey of Ethiopia, by M. Villiers. This honey, called *tazma*, is gathered (without wax) in subterranean cavities by an insect resembling a large mosquito. It differs from other honeys by absence of cane-sugar.—On the banana, by M. Corenwinder. He points out variations in its composition. In the fruit, sound and ripe, the total proportion of sugar may rise to 22·06 per cent.—On a process of enriching phosphates of carbonated gangue, by M. L'Hote. He effects decarbonatation of the phosphate, by heating it to near a cherry red, and making steam act on it. The quick lime is separated by means of weak hydrochloric acid.—On various epizooties of diphtheria of court-yard fowls at Marseilles, and on possible relations of this disease with human diphtheria, by M. Nicati. Inoculation of a rabbit succeeded; and the appearance of the disease in the fowls seemed to occur along with an increase of human diphtheria.—On the sensibility of the eye to action of coloured light more or less diluted with white light, and on photometry of colours, by M. Charpentin. The chromatic sensibility remained constant provided the white light added did not exceed a certain pretty high maximum (in the case of red, ten or twelve times the intensity of the red). A very simple element of comparison (of white and colourless lights) is had in determining for each light used, the minimum quantity capable of causing the original sensation of colourless light.—Researches on the physiological properties and the mode of elimination of methyl-sulphate of soda, by M. Rabuteau.—On sub-periostic ossification and especially on the mechanism of formation of Haversian systems in the periostic bones, by M. Laulanié.—Researches on the liver of cephalopod molluscs, by M. Jousset de Bellesme. The liver in these animals is not analogous in function to the liver of vertebrates. It is a digestive gland, merely transforming albuminoid matters, and without action on fatty or amylaceous matters.—Observations on a shower of sap, by M. Mussel. This was observed in autumn from the leaves of *Abies excelsa*.—The death of M. Gervais was announced.

Göttingen

Royal Academy of Sciences, December 7, 1878.—On the ponderomotor elementary law of electrodynamics, by Herr Riecke.—The mean depth of the ocean and the proportions of land and sea, by Dr. Krümmel.

January 4.—The meteorite collection of Göttingen University on January 2, 1879, by Herr Klein.—Electrolytic friction compared with capillary friction, by Herr Kohlrausch.

THE GROWTH OF THE STEAM-ENGINE

A History of the Growth of the Steam-Engine. By Robert H. Thurston, A.M., C.E., Professor of Mechanical Engineering, Stevens' Institute of Technology, &c. (London: C. Kegan Paul and Co., 1878.)

WE have before us a very striking instance of the value of a popular knowledge of mechanical philosophy.

The book is essentially divided into two parts. The first six chapters contain a history of the steam-engine as a machine; while Chapters vii. and viii. are devoted to the philosophy of the steam-engine, its history, and application.

As regards the first part we have but little to say. In two points this part of the book is distinctly commendable; the author gives ample reference to the numerous sources from which he has derived his information, and he has cast aside all national partiality. The literature of the history of the steam-engine is now so considerable that it can have been no small task to condense an abstract into something less than the limits of a small volume and at the same time make it interesting; and the success which has been attained must be largely attributed to the excellent illustrations. Much of the matter has doubtless come ready to the author's hand, requiring but little modification. In places the style of the author very closely resembles that of Mr. Smiles. The plan adopted is that of awarding unlimited praise to the various inventors instead of distinguishing between their various claims. Throughout this part of the book little or no attempt is made to explain the physical questions involved or to record the steps by which a knowledge of the physical properties of steam has been acquired.

Had, however, the first six chapters constituted the book, it must have been allowed to pass as a fairly full and very interesting account of the development and application of the mechanism of the steam-engine; much in the same style as the work of Dr. Lardner but in many respects much better and containing considerably more matter.

The history of the philosophy of the steam-engine contained in Chapter vii. might also be allowed to pass, although the assurance with which commendations are distributed to such men as Carnot, Joule, Mayer, Rankine, Regnault, and Thomson could only have been justified by evidence of the possession on the part of the author of a very unusual appreciation of the highest theory of his subject—an appreciation for which the earlier part of the work had in no way prepared us, and which is certainly not shown by the merit of the author's comments in this chapter. These comments, however, are of the most cursory kind, and although for the most part unintelligible, they did not prepare us for the disclosure of the last chapter, in which we have the author's own exposition of the philosophy of the steam engine and its application.

A suspicion that the author's physics are not what they should be began to dawn upon us when we came to the paragraph in which he describes the essentials of a good furnace, which suspicion was strengthened at the following sentence—"A pound of carbon has been found to be capable of liberating by its perfect combustion resulting in the formation of *carbonic oxide* 14,500 British thermal units—" but we still reserved our judgment, as carbonic oxide might be a misprint for carbonic acid. However, on turning over the page we find the following erroneous deduction:—

"The laws of thermo-dynamics teach, as has been stated, that the proportion of the heat-energy contained in the steam or other working fluid which may be transformed into mechanical energy is a fraction, $\frac{H_1 - H_2}{H_1}$, of the total, in which H_1 and H_2 are the quantities of heat contained in the steam at the beginning and at the end of its operation, measuring from the absolute zero of heat motion. In perfect gases,

$$\frac{H_1 - H_2}{H_1} = \frac{\tau_1 - \tau_2}{\tau_1} = \frac{T_1 - T_2}{T_1 + 461{\cdot}2^\circ \text{ Fahr.}};$$

but in imperfect gases, and especially in vapours which, like steam, condense, or otherwise change their physical state, this equality does not exist, and $\frac{H_1 - H_2}{H_1} > \frac{\tau_1 - \tau_2}{\tau_1}$; and the fluid is more efficient than the perfect gas as a working substance in a heat-engine. In any case it is seen that the efficiency is greatest when the whole of the heat is received at the maximum and rejected at the minimum attainable temperatures."

This paragraph shows how completely the author has misapprehended the second law of thermo-dynamics. And this is not nearly all; the theory of the steam-engine is not so simple but that a slip of this sort might have been pardoned, but when we come to the author's application of the theory to the deduction of the economy of the "possible engine of the future," we have page after page of perfect nonsense, which not only shows that the author does not understand what he is writing about, but also shows that his erroneous views of, and imperfect acquaintance with, the theory of the steam-engine have led him into absurd errors from which the earlier inventors on whose work he has so boldly pronounced had emancipated themselves. How far this is the case will appear from the following quotations:—

"Heat-engines may be divided, for present purposes, into three principal classes, according to their disposition of rejected heat:

"I. Those which restore all heat rejected from the working cylinder to the reservoir from which it was derived.

"II. Those which restore a part of the unutilised heat of the working fluid, discharging the remainder from the system and allowing it to be wasted.

"III. Those which waste all heat rejected from the working cylinder.

"No existing type of steam-engine belongs to the first of the classes specified. Some forms of air and gas-engines are theoretically assignable to that class, as, by means of some form of 'regenerator,' they store up rejected heat and restore it to the succeeding charge of working fluid as it enters the cylinder. . . .

"There are two forms of engines of Class I., in which—were it possible to fully avail ourselves of them—all this waste of energy may be avoided:

"Type A. The working fluid, if expanded from the temperature and pressure of the boiler or reservoir quite down to the absolute zero, would have all its heat-energy transformed into mechanical work, and there would be no waste. The efficiency would be perfect.

"Type B. All heat rejected from the cylinder unutilised may be gathered up and restored to the boiler, there to serve as a basis upon which to pile a new stock of transformable heat-energy, instead of being, as now, rejected from the system entirely and lost. This done, there could be no loss, as all heat leaving the machine would be transmitted to exterior bodies as mechanical energy. Nothing being lost as heat, the efficiency of the engine would be unity and its economy a maximum.

"Forms of steam-engines may be conceived in which these methods (of saving heat now wasted) may be applied. Practically, however, it is evident, the first form of these two ideal engines can never be made successfully, since it would require to be made of such immense size that all the power derivable from it would be insufficient to move it."

An instance of the Type B is given. It is proposed to expand the steam in the cylinder until it is half liquefied, then separate the water from the steam and return them separately to the boiler, whereupon it is concluded.

"Under the conditions now assumed, it is evident that only that portion of the heat entering the engine which is surrendered by the condensation of steam doing work can be utilised. It is also evident that, in this form of engine, no heat can be lost; and, consequently, that the engine of Type B, which is operated as just indicated, will have yielded the exact equivalent of the net amount of heat expended upon it. *All heat rejected from the working cylinder, unutilised, being returned to the boiler*, there to form 'a basis on which to pile up a new stock of utilisable energy,' the engine is a 'perfect engine' in a broader sense than that adopted by Carnot. It is further evident that perfect efficiency is given for all ranges of temperature, and that what working fluid shall be adopted, and what temperatures shall be chosen, will be determined simply by practical conditions to be ascertained by experiment. . . .

"When this possible 'engine of the future' is likely to be introduced, if at all, can be scarcely even conjectured. It seems evident that its success is to be secured, if its introduction is ever attempted, by the adoption of high steam-pressures, of great piston-speeds, by care and skill in design, by the use of exceptionally excellent materials of construction, by great perfection of workmanship, and by intelligence in its management. There seems no tangible obstacle to its introduction." [1]

KINAHAN'S GEOLOGY OF IRELAND

Manual of the Geology of Ireland. By G. St. Kinahan, M.R.I.A., &c. (London: C. Kegan Paul and Co., 1878.)

THE appearance of another volume on Irish Geology, so soon after that of Prof. Hull, seems to show that the geologists of the Emerald Isle can be as active with their pens as with their hammers. Mr. Kinahan, indeed, has just claims to be heard when he treats of the rocks of his native country, for we suppose there is hardly any other living Irishman who has worked so long and so continuously among them. His volume, of course, coming before us as it does, cannot but challenge comparison with that of his director, Mr. Hull; and in truth it would almost appear as if this had been, consciously or not, in his mind. The two books, however, are on two very different plans. The general reader who wishes a pleasantly-written sketch of Irish geology, and of its relation to the scenery of the island, will find what he needs in Prof. Hull's chapters. Mr. Kinahan's work is more suited for professed geologists who propose to visit Ireland, and want to have some idea of the best districts to visit for their special purpose.

The volume is divided into five sections. In the first the author describes the sedimentary formations of Ireland, going over the country district by district, and pointing out in a useful, if somewhat prolix manner, the peculiarities of each. In the second he enters upon more speculative matter in an account of metamorphic and eruptive action as displayed among the Irish rocks. The third is devoted to the superficial accumulations, including the drift, the proofs of glaciation, changes of level, peat-bogs and prehistoric remains, and extinct mammalia. In the fourth section a brief description of the physical features is given from the writer's own point of view. The remaining division treats of the economically useful minerals of the country.

One cannot read Mr. Kinahan's pages without recognising his sturdy force of character. He takes up a position and holds it, one might almost think sometimes against his better judgment. It is satisfactory, however, to find him willing to yield sometimes, as, for instance, in his relinquishment of the absurd *yte* termination of rocks, though he takes care to inform us that while he yields to the entreaties of publishers and friends, he remains of the same opinion still. What a labour it must have been originally to change all his i-s into y-s! There are some other matters of orthography or even of grammar, which, when he feels himself to be in a compliant temper, he may take into his consideration. Why does he so constantly speak of "Cambrians" and "Silurians?" These are adjectives, and not nouns, and though in the field-slang of the Geological Survey, or of geologists generally they may be tolerated, they ought not to appear in any grave published work.

In the first section of the book it will probably occur to most readers that there is a want of breadth in the treatment of the subject. The local details are valuable as guides to the places and for the scattered facts they contain. But they lack that connecting thread which would have strung them all together and have carried the reader intelligently along, instead of leaving him, as he can hardly help feeling, struggling after the seven-leagued strides of Mr. Kinahan as he hops from district to district. Brief summaries for the separate regions, and a general connected summary of the whole for the system or formation, would have given the reader the key to the details. And as regards these details we fear they are often too vague to be of as much service to the field-geologist as he would wish them to be. The kind of detail he needs is supplied by the valuable "Explanations of the Geological Survey of Ireland." Mr. Kinahan often, indeed, refers to these "Explanations," but he would have given his volume a more practically useful character had he inserted in the account of each district a reference to the particular explanation in which a fuller description may be found. Such references, for the purposes of the student and the geologist who wants to study the matter on the ground, cannot be too precise and frequent. As it is, Mr. Kinahan's chapters on the rocks and struc-

[1] "The idea first suggested itself to the mind of the writer in 1858–59, when at Brown University, and while designing a peculiar form of 'drop cut-off engine,' which was intended to work with exceptional economy. The plans then conceived have gradually assumed a different shape, but still embody the essential principles here outlined. Mr. C. E. Emery, in 1868, proposed a similar plan."

ture of Ireland are full of suggestive matter, and will be consulted by all who wish to learn what has been done in Irish geology.

The section which will provoke most criticism is, no doubt, the second—on Metamorphic and Eruptive Rocks. The author himself hints something to this effect in his preface. There are objections to the terminology he has invented, the words themselves being unfortunately selected. For Daubrée's term "regional metamorphism" he substitutes *metapepsis*, and, speaks of *metapeptic* rocks. A dyspeptic geologist—and we suppose such beings exist in some number—will shudder at the very sound of these words. Then the old term "contact metamorphism," long ago so elaborately illustrated by Delesse, is replaced by *paroptesis*, and its rocks are called *paroptetic*. Another term, *methylosis*, is applied to a local kind of metamorphism, "due to the introduction and action of chemical substances from without;" and the rocks affected by it are named *methylotic*—a word which many a learner will at once surmise to be connected in some way with the methylated spirit he used to spill and smell of in the days of his practical chemistry.

But accepting these terms, there will be graver objections to some of Mr. Kinahan's metamorphic notions. It is specially unfortunate that he does not give any adequate grounds in this volume for enabling the reader who has not perused his other writings to judge on what detailed evidence his conclusions have been based. For example, he treats quartz-rock as one of the intrusive granitic rocks, and distinguishes it from quartzite or quartz-schist. But we have been unable to discover any passage which explains how he could distinguish these rocks, and what are their relative mineralogical and petrographical characters. Nay, while in one place he includes quartz-rock among the highly siliceous intrusive granitic rocks, he elsewhere speaks of it as having been again and again deposited by springs connected with volcanic action. Surely he does not wish us to believe that even a tyro in petrography would confound siliceous sinter with any form of granitic rock? Again, without giving any data, he speaks of "protrusions of limestone and dolomite." How does he imagine they were protruded? Were they thrust out as solid masses, or like the quartz-rock of his springs? He mentions them in connection with "a sheet of quartz-rock," and speaks elsewhere of having himself observed intrusive quartz-rock in many places. It is evident, however, that it would lead to the most hopeless confusion if the term quartz-rock, which has for generations included hardened siliceous sandstones, sometimes even with traces of organisms, were applied also to any member of the granitic family. Mr. Kinahan should invent another name for his intrusive quartz-rock. He has no timidity in names, and might hit upon one quite as euphonious as those already referred to.

Probably the most valuable part of the book is that which treats of the prehistoric remains. Mr. Kinahan is an authority on *crannoges*; and the digest therefore which he has given of known facts in this subject, besides its interest to the general reader, will be welcomed by geologists to whom the scattered papers in the Transactions of the Irish Societies are not familiar.

The illustrations are singularly poor, and seem all the more so by contrast with the sketches of the lamented Du Noyer, which have made the geology and scenery of Ireland familiar to many eyes all over the world. Could not Mr. Kinahan have availed himself of some of the drawings, published or unpublished, of his friend? Any additional publicity he could have given them would have been another tribute to the memory of a true artist.

While the author recognises the debt of gratitude owed by Irish geologists to Griffith and Jukes, there are some names which he passes over in strange silence. Why, for instance, could he find no room for the honoured name of Harkness? Surely, when he was writing about the metamorphic rocks of Donegal, he might have made grateful allusion to the geologist who, more than any one else, has thrown light upon these rocks. He quotes two or three times an opinion of Prof. Hull only to reject it, and these are all the direct references he deigns to make to the labours of one who has already done and is still doing so much for the cause of Irish geology; there being not the least allusion anywhere to the previously published volume by that writer. This may have arisen from mere inadvertence, and in that hope we take leave of Mr. Kinahan and his book, wishing for both that appreciation from geological readers which they deserve.

OUR BOOK SHELF

Studies in Comparative Anatomy. No. I. *The Skull of the Crocodile.* By L. C. Miall. No. II. *Anatomy of the Indian Elephant.* By L. C. Miall and F. Greenwood. (London: Macmillan and Co., 1878.)

PROF. MIALL has given in the first of these "Studies" a careful and systematic description of the Skull of the Crocodile, his object being to furnish to students a more complete account of the skull in this family of reptiles than is found in the usual treatises on the Comparative Anatomy of the Vertebrata. He commences by giving a general view of the crocodilian skull, and then sketches its mode of development, pointing out at the same time the relation of the cranial nerves to the post-oral clefts and arches. The individual bones of the skull are then described in detail. An elaborate account is given of the tympanic cavity and of its communications with the several Eustachian passages, which, together with the external auditory meatus, represent the cleft between the mandibular and hyoidean arches. Mr. Miall gives in an appendix a translation, with annotations, of Rathke's account of the development of the skull of the crocodile. The essay will be of great service to those desirous of acquiring a knowledge of the crocodile's skull.

In the second of these "Studies" Prof. Miall writes, in conjunction with Mr. Greenwood, an account of the anatomy of the muscular, vascular, digestive, and genito-urinary systems of the Indian elephant, together with some observations on the organs of special sense. This essay appeared originally in the *Journal of Anatomy and Physiology* for 1878, and in reprinting it the authors have reproduced the plates and woodcuts employed in illustrating their description as it appeared in that *Journal.* Throughout the essay frequent reference is made to the previous literature of the subject, and the authors point out any discrepancies between their observations and the descriptions of the other anatomists who have examined this species of elephant. The part of this essay which contains the greatest number of new facts is the description of the muscular system, which is very carefully done, and forms an important contribution to the myology of this huge animal.

Seconda Contribuzione morfologia e sistematica dei Selachi. Del Prof. Pietro Pavesi. (Genoa, 1878.)

IN 1874 Prof. Pavesi, of Pavia, described in the *Annali del Museo Civico* of Genoa a shark which had been captured at Lerici, in the Gulf of Spezzia, in 1871. It belonged to the genus *Selache*, but, from a peculiarity in the conformation of the rostrum, Pavesi considered it to be a distinct species from the great basking shark, *Selache maxima*, and named it *Selache rostrata*. The specific difference of this specimen has, however, been called in question by Canestrini, Steenstrup, and other ichthyologists, who were inclined to regard it as a monstrous form of the *Selache maxima*. In June, 1877, a male shark, also belonging to the genus *Selache*, was caught in the harbour of Vado, near Savona, and, being examined by Prof. Pavesi, forms the subject of this second communication to the *Annali del Museo Civico*, vol. xii. Its length was between ten and eleven feet. It had been eviscerated before coming into his possession, so that the memoir does not give an account of the abdominal viscera, but the external characters, the skeleton, the pectinated appendages, the brain and cranial nerves, and the vascular system, are described. The shark from Vado is almost identical, says the author, with that previously caught at Lerici. He then carefully reconsiders the systematic position of these specimens. He is strongly of opinion that the view that the specimen originally described was a monstrous form of *Selache maxima* is quite untenable. But his examination of this second specimen has convinced him that these sharks can no longer be regarded as a distinct species, and that they are young examples of the great basking shark, *Selache maxima*. The memoir is illustrated by a lithographic plate and by twenty-seven woodcuts.

Das Leben. Naturwissenschaftliche Entwickelung des organischen Seelen- und Geisteslebens. Von Philipp Spiller. (Berlin: Stuhr'sche Buchhandlung, 1878.)

THIS work may be said to be but an enlarged reproduction of a division of an earlier and more important work: "Die Urkraft des Weltalls nach ihrem Wesen und Wirken auf allen Naturgebieten," by the same author. Prof. Spiller, whose death it was our painful duty to announce last week, is the originator and founder of a philosophical theory on the first cause of all things. According to his view the world-ether is the architect of the universe as well as the fundamental cause of gravitation. In his works, particularly in the one just mentioned, the learned professor treats this world-ether theory in a most masterly manner, and whatever view we may take as to the correctness of his views—a question which we certainly do not wish to decide—it is only justice to point out that his explanations and definitions are all written in such a spirit of firm conviction of the truth of his theory, that an attentive reader cannot refuse his admiration and respect.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

Leibnitz's Mathematics

I UNDERSTOOD Dr. Ingleby to say that he was prepared to make good his assertions, and to respond to Mr. Nelson's "call" as soon as I retracted, or justified, my former statement.

In 1871 Dr. Ingleby said it was exactly twenty years since the last vestige of presumption against the fair fame of Leibnitz was "obliterated."

Dr. Ingleby is evidently unacquainted with the work of Dr. Sloman (Leipzig, 1858; in English, Macmillan, 1860), else he would not have spoken of the "last vestige of presumption."

Kant's opinion of Leibnitz, which is *far more favourable* than that of Dr. Sloman, compares him to chemists "who gave themselves out to be possessed of secrets, when they had really nothing but a persuasion and a conviction of their capacity for acquiring such." This verdict, from a *true* metaphysician, ought to have much weight with Dr. Ingleby.

P. G. TAIT

Guthrie's "Physics"

SOME weeks ago (p. 311) you published in NATURE a review by Prof. Maxwell of a little book of mine on Practical Physics. It is not my intention to complain in any way of the review, partly because it would be a profitless trespass on your space, but mainly because, while the tone is unfavourable, the instances adduced by the reviewer go a long way to confute his own statements in all cases where there is any connection between the two.

Some well-meaning friend has composed and sent me a copy of the inclosed. There appear to be various opinions as to the authorship. It has even been suggested that Prof. Maxwell, with that sense of humour for which he is so esteemed, and with a pardonable love of mystification, is himself the author.

February 24 FREDK. GUTHRIE

REMONSTRANCE TO A RESPECTED DADDIE ANENT HIS LOSS OF TEMPER

Suggested by Prof. CLERK MAXWELL'S *review of* GUTHRIE'S "PHYSICS".

WORRY, through duties Academic,
It might ha'e been
That made ye write your last polemic
Sae unco keen:

Or intellectual indigestion
O' mental meat,
Striving in vain to solve some question
Fro' "Maxwell's Heat."

Mayhap that mighty brain, in gliding
Fro' space tae space,
Met wi' anither, an' collidin',
Not face tae face.

But rather crookedly, in fallin'
Wi' gentle list,
Gat what there is nae help fro' callin'
An ugly twist.

If 'twas your "demon" led ye blindly,
Ye should na thank him,
But gripe him by the lug and kindly
But soundly spank him.

Sae, stern but patronising daddie!
Don't ta'e 't amiss,
If a puir castigated laddie
Observes just this:—

Ye 've gat a braw new Lab'ratory
Wi' a' the gears,
Fro' which, the warld is unco sorry,
'Maist naught appears.

A weel-bred dog, yoursel' must feel,
Should seldom bark.
Just put your fore paws tae the wheel,
An' do some Wark.

$d\sqrt{\frac{m}{n}}$.

Unscientific Art

IN *Punch's* series of cartoons, "the man at the wheel" turns up now and again. The most recent example is that of date February 22: John Bull and Punch are strenuously holding a steering-wheel between them, in a tempestuous scene. I have a second example before me in the series of cartoons of Beaconsfield recently issued, No. 61: Disraeli has one hand on a steering-wheel, while the other holds a pistol directed to the powder magazine below; and he threatens to blow up the ship if Gladstone and Bright (climbing over the bulwarks behind) step on board. Other cases will be remembered. Now (neglecting here the political meaning of the pictures) these steering-wheels are wonderful productions, and how they serve for steering is a mystery. The wonder, remarked on by St. James, of "a very small

helm" turning great ships, is here outdone. The wheel stands, in all simplicity, between two uprights, or a slitted upright, fixed on the deck (or a raised platform); there is nothing behind or before the outer surfaces of the uprights. But an essential part of ordinary steering-wheels is the drum or axle extending generally a little way behind (and covered, it may be), on which are wound ropes or chains passing round pulleys to the tiller. A more modern form well known is a screw shaft with levers, &c. The omission in question in these cartoons leaves the scientific mind decidedly "at sea," and with little confidence in the steersman. I suspect the artistic type of mind is rather apt to neglect such details.

It is remarkable, indeed, how many matters belonging to simple observation escape notice by artists. I may perhaps be allowed to note a few points which have occurred to me in glancing over *Punch* from November to the present time, and the three books of cartoons of the *Punch* series.

The electric machine sometimes makes its appearance in *Punch*. In No. 53 of the Beaconsfield cartoons, that gentleman (as a professor) is arranging a circuit between an aristocrat and a working man for a shock. The electric machine behind is evidently meant for one of the Ramsden type, but the brass-work with points to collect the electricity is wanting, and the glass plate seems to have great concealing power. Again, the clever and fantastic sketch at the beginning of the Almanack shows an electrical machine of quite indescribable type, unless it be a Holtz, but it defies all mechanical conception. Perhaps it is not allowable to apply scientific rules to the brilliant insanity of such drawings, but I think there should be more basis of real existence than this one presents.

From many pictures we might be led to infer that left-handedness is much more common than it really is. Thus, a *pince-nez* is held in the *left* hand by Mr. Bright (in No. 19 of the Bright cartoons), by a church dignitary speaking to his daughters (*Punch*, December 21, p. 282), and by an old gentleman who receives a letter on the road on a snowy day (*Punch*, February 1, p. 39). In the Almanack (p. 5) a workman holds a cup in his left hand and a saucer in his right. Reins are frequently held in the right hand (which, I understand, is wrong)—one example is the cartoon of *Punch*, December 14, "Post Equitem." If something might be said for these cases, it is difficult to see how an artist can be justified in putting a quill pen behind the *left* ear, as in the case of Gladstone, when meeting Bismarck (last of Gladstone series), unless, indeed, the right ear were already occupied with one (which is not here the case). A similar remark seems applicable to a caricature of Ruskin by Sambourne (*Punch*, December 7, p. 254).

In an ingenious sketch (*Punch*, February 1, p. 37), in which a complex pocket-knife or sort of *multum in parvo* is made to take the aspect of a formidable animal, the spiral of the corkscrew turns the wrong way.

In one of the Bright cartoons (No. 33), that gentleman appears in court costume before a mirror which slants away from him upwards, but the image, I think, hardly corresponds to this.

One word more, and of a somewat different order of criticism. Heat of certain intensities and in certain circumstances may, of course, be very unpleasant. But, as we have had good reason to know lately, heat may be very welcome and agreeable. Therefore I venture to indict the cartoon of *Punch*, February 15, "Hot water, sir!" as flagrantly at fault. Beaconsfield is bringing in the morning's hot water to John Bull in bed. In the session of 1879 John Bull may very likely find himself "in hot water;" but in the connection to which the picture refers, hot water is a pleasant mitigation to the inevitable discomfort of washing. So John Bull's horrified look could not possibly refer to that. If he were being awoke, as I have been, in a hydropathic establishment, about 6 A.M., by a fiend in human shape, who showed a cynical determination to pack him in a cold wet sheet, the man's implements *might* arouse some horror. In the Beaconsfield cartoon, No. 90, "The Turkish Bath," the metaphor is, of course, all right: "You made it so confoundedly *hot* for me!"

Some of the foregoing are little points, but they prove this much, that there is room for improvement among artists of this class as regards correctness of observation and strict fidelity to fact. A. B. M.

Intellect in Brutes

In Mr. Nicols' instance of intellect in brutes (Nature, vol. xix. p. 365) he tells us that a plumber "had on several occasions been called in to examine into the cause of leakage of water-pipes under the flooring of houses," and then records *a single instance* of rats having knawed through a pipe. It is important to know whether the plumber knew of another case: for the idea at once suggests itself that the pipe had cracked through frost, and the rats then discovering the leakage gnawed it to get more water.

It has always seemed to me that brute reasoning is always *practical* but never *abstract*. They do wonderful things suggested by the objective fact before them; but, I think, never go beyond it. Thus, a dog left in a room alone rang the bell to fetch the servant. Had not the dog been taught to ring the bell (which on inquiry proved to have been the case) it would have been abstract reasoning, but it was only practical. The Arctic fox—too wary to be shot like the first who took a bait tied to a string, which was attached to the trigger of a gun—would dive under the snow and so pull the bait down below the line of fire. This is purely practical reasoning; but had the fox pulled the string first out of the line of fire *in order* to discharge the gun, and *then* to get the bait, *that* would have been abstract reasoning which he could not attain to.

This practical reasoning is just what young people do, before they can reflect. A boy the other day found the straps of his skates frozen. The fact only suggested *cutting* them. Not one of his schoolfellows reflected upon the abstract fact that the ice would melt if he sat upon his foot a few minutes. Hence brutes and boys are just alike, in that nothing occurs to either beyond what the *immediate* fact before them may suggest. The one kind I call purely *practical* reasoning, which both have; the other, *abstract*, which brutes *never* acquire; but the boy *will* as his intelligence develops. George Henslow

---

In Central Park one very hot day my attention was drawn to the conduct of an elephant which had been placed in an inclosure in the open air.

On the ground was a large heap of newly-mown grass, which the sagacious animal was taking up by the trunkfull, and laying carefully upon his sun-heated back. He continued the operation until his back was *completely thatched*, when he remained quiet, apparently enjoying the result of his ingenuity.

It seems to me that *instinct* should have prompted the elephant to eat the grass, and that it was *reason* which caused him to use it for the purpose of diminishing the effect of the sun's rays.

New York, February 8 James J. Furniss

Bees' Stings

Will you allow me, as possessor of a couple of score of hives, to say a word respecting the discussion in your columns as to the effect on *Apis mellifica* of the loss of its sting and appendages.

As far as my observations go, the bee is not seriously injured by the loss, for though imprisoned and watched for some hours, as soon as released it flies back to its hive, and apparently resumes its work as before. However, any one sufficiently painstaking can settle the question finally by marking some such bees, and watching for their departure, and return laden with honey or pollen.

May I ask if any of your readers have yet determined the identity of bee poison and formic acid. The former is said, on exposure to the air, to solidify to a white crystalline mass, but formic acid requires, I believe, a temperature of 0° C. to effect this modification. J. P. Jackson

Bull's Mill Apiary, Hertford, February 18

P. LE NEVE FOSTER

A very numerous body of friends will have heard with regret of the sudden death of Mr. Le Neve Foster, the secretary of the Society of Arts. Though not himself an original worker in science, there were few men better known in scientific circles, or so universally liked where he was known, as Mr. Foster. His connection with the Society of Arts threw him amongst men working in nearly all lines of research, and there are probably few recent instances of the practical application of any new scientific discovery to industrial purposes in which he did not take some interest. Coming up to London with a fellowship from Trinity Hall, he was called to the bar in 1836, and practised for some fifteen or sixteen years

as a conveyancer. The natural bent of his mind, and some association of his relatives with the Society of Arts, led him to join it, and he soon became a member of its council. The Society was then in anything but a flourishing state. The necessity for such work as it had usefully done at the beginning of the century had passed away, and those who then controlled its destinies were hardly capable of striking out for it a fresh line of action. It was, however, just beginning to revive a little, when the proposal to hold the first great exhibition was taken up by Mr. (now Sir) Henry Cole, Mr. (afterwards Sir) Wentworth Dilke, and some others of the more enterprising spirits who were then gaining the upper hand in the Society. With this reforming party Mr. Foster was associated, and it tells much of the character of the man, of his freedom from self-seeking tendencies, that while other members of the little body worked their way upwards to honours and high positions, he was content to remain without reward, either pecuniary or titular, as a worker for the whole of his life. When Mr. Grove gave up the secretaryship of the Society of Arts in 1853, Mr. Foster, resigning the post he then held on its Council, was appointed to the office, an office which he held till the day of his death, last Thursday. Since then his career has been associated with that of the Society. This grew in numbers and influence, and so the Secretary's office increased in importance. During the twenty-five years in which he guided it, it did a great deal of good work, and, it may be owned, some which was not of much value. The trivialities soon passed away and were forgotten, the good work endures. In undertakings such as that of a public society most of the work and but little of the credit falls to the executive officer, and probably, if the truth were known, many of the crude ideas first launched into the world at the Society of Arts owed their ultimate success to their having been hammered into a practical form by the secretary. Ever ready with advice, the fruit of long experience, never bored even by the most importunate of inventors, ready to find something good, something to praise in the most impracticable of schemes, he won the friendship, even the affection, of all who knew him.

At many scientific gatherings his genial presence will be missed. His was a well-known figure at the British Association meetings. For thirteen years he acted as secretary to Section G (Mechanical Science), and from 1863 to 1866 he served on the Council of the Association. Taking an intelligent interest in several branches of science, it was to photography that he principally devoted himself. He was one of the earliest amateur photographers, and continued to work energetically at his favourite pursuit down to the time of his death. One of his last bits of out-door work, before his camera was laid aside for the winter, was to take a view of the Obelisk on the Embankment, a day or two before it was swung from a horizontal into a vertical position. He wrote a good deal on photographic subjects, mainly in the pages of the *British Photographic Journal*, and similar periodicals. He also wrote the article on photography in the series of volumes on "British Industries," published by Mr. Stanford. He was an occasional contributor to several of the scientific and technical journals, and wrote a good deal in the *Journal* of his own society, which, though not founded by him, was published from the beginning under his auspices, for he was on the Committee of Publications when it began, and his secretaryship commenced before the completion of its first volume. The older series of *Transactions*, it will be remembered, ceased some few years before the *Journal* was started. Mr. Foster was one of the founders of the Photographic Society, and served till a few years ago on its council. He was also President of the Quckett Club for a year. The manner of his death was startlingly sudden. Returning home after his day's work, he sat down to read the newspaper before dinner, when one of his family coming into the room after he had been by himself only a few minutes, found that he had fallen back from his chair dead. The cause of death was fatty degeneration of the heart. He died as we might all wish to die, at a ripe old age (nearly seventy), quietly and easily, after a good life's work, and in harness till the end.

He did not live to receive a testimonial which his friends had just collected for him, and these same friends now propose to do what they can to increase the amount for the benefit of those he has left behind.

DR. APPLETON

WE were only able last week to note briefly the loss which learning and science have sustained in the death of Dr. Appleton at the early age of thirty-eight years. Dr. Appleton was born at Reading, where, and at St. John's, Oxford, he received his education. His special bent lay more in a literary and philosophical than in a scientific direction; but, as we indicated, his services to the advancement of science in this country have been very great. He may, indeed, be regarded as the originator of the movement for the endowment of scientific research; and it is greatly owing to his unceasing activity and influence that anything has been done in this direction by Government. To quote the words of the memoir in the *Academy*, of which he was the founder, and which, for the sake of sound criticism and accurate knowledge, we trust will be a lasting monument to his energy, and the breadth of his culture:—"With an enthusiasm which nothing could chill, and a belief no opposition could shake, he endeavoured to inspire his countrymen with the same zeal for learning and science that he felt himself, and to rekindle among them the well-nigh extinguished love of disinterested study and research. Where others talked, he acted; where others wavered, he continued firm. Through good report and evil report he struggled on towards the goal he saw clearly before him, and the confidence he felt himself was communicated to those who worked with him. Gifted with the power of organisation, with boundless energy, and with the art of influencing others, he was marked out as the leader of a forlorn hope. Defeat was impossible for him, and disappointment only increased his courage and activity. It was in Dr. Appleton's hands that the movement in favour of the endowment of research took solid shape and organisation. His exertions brought about the meeting at the Freemasons' Tavern in 1872, which first drew public attention to the fact that the universities exist for something higher than the examination of young men. From that time forward Dr. Appleton took an active share in the agitation that resulted in the passing of the Universities Act of 1877, and none of the opportunities which his editorial position gave him were allowed to be lost. Besides letters in the *Times*, the *Pall Mall Gazette*, and elsewhere, he wrote two elaborate articles on 'The Economic Character of Subsidies to Education' and 'The Endowment of Research as a Form of Productive Expenditure,' both republished in the volume of 'Essays on the Endowment of Research,' of which Dr. Appleton was editor."

We are pleased also to be able to refer in this connection to an article in the *Athenæum*. Although there are some parts of this article which we certainly could not quote. In this it is acknowledged that Dr. Appleton had raised a great question, and given it a hold on public interest, "and there can be no doubt that the movement which he, more than any other single man, had set on foot had considerable effect on several of the provisions of the Universities Act passed by the present Government." . . . "For a man who died before he was thirty-eight it is no slight achievement to have forced such a question as this on the sluggish attention both of the public and of Parliament."

We are pleased not only that our contemporary should bear such hearty testimony to the energy and success of Dr. Appleton, in promoting the cause which he had at heart, but that it should be able to refer to the subject of endowment of research not only without bitterness, but with even some slight measure of approval. A cause which had so pure-minded, clear-sighted, and widely-cultured a man as Dr. Appleton on its side, must surely have some solid reasons in its favour.

Dr. Appleton is acknowledged by all who knew him to have been one of the most even-tempered of men. He was always cheerful and complaisant; opposition and even rudeness did not ruffle him; he returned to the charge smiling at every blow. He was a very quick and ready manager in such work as that of an editor, being full of suggestion, and prompt at meeting difficulties. He was a genuine philosopher, though he professed keen interest in all departments of knowledge, he did not make the mistake of over-estimating his own knowledge, or of pretending to an encyclopædiac mind. His great merit is that he really gave time and strength for "ideal" ends.

PRISON BREAD

IN two former papers[1] I discussed the dietetic value and chemical composition of brown bread and of aerated bread. The recent report[2] of the Committee appointed to inquire into the dietaries of the prisons in England and Wales having called public attention to the subject of the nourishment contained in different varieties of bread, the suggestions made in that report may be suitably considered at the present time.

On pages 21, 22, 23, 38, and 39 of the report will be found the statements and figures as to the bread question, which I propose to criticise on the present occasion. The committee begin by stating that "the flesh-formers in white bread amount to 7 or 8 per cent., according to the quality of the wheat of which it is made. In bread containing the envelopes (of the grain) they amount to about 10 per cent." Two or three years ago little fault could have been found with these statements; indeed, the Committee appear here as in other parts of their report, to have drawn some of their facts and figures from a work of my own on Food, published in 1876 for the Science and Art Department. Still I am not now prepared, in the light of the most recent analyses of wheat and its mill-products, to endorse the statement that brown bread, whether made so as to include all the flour, middlings, sharps, pollard, and bran, produced from a given weight of wheat, or with all these materials minus the coarse bran, will contain on the average 10 per cent. of flesh-formers. Why, there are some varieties of wheat, beautiful, plump, soft, white, floury wheats, which do not contain more than 8 per cent. of total nitrogenous matters of all kinds, including veritable flesh-formers. How then can a wheat of this kind, if simply ground up (whether the 4 per cent. of long bran it yields be included in or excluded from the bread), be made to yield a brown bread or whole meal bread containing more flesh-forming matter than 5½ per cent.? For the meal will have taken up nearly one half its own weight of additional water, and will now be proportionately more dilute as to all its nutrients.

And, again, I have previously pointed out that the coverings of the wheat grain contain, in varying, yet considerable proportions, nitrogenous compounds to which the flesh-forming property cannot be rightly attributed. Thus, it may easily happen that the inclusion of the 14 or 15 per cent. of mill products, usually rejected in bread-making (excluding the long bran), may not appreciably influence the proportion of flesh-formers in the loaf. These two considerations do not, in my opinion, lessen the desirability of substituting whole meal bread for white bread in our prisons, but they invalidate some of the Committee's calculations as to the amounts of flesh-formers supplied in the new prison-dietaries, and they further suggest a method of adjusting the nutrient ratio which should subsist between the nitrogenous and carbonaceous constituents of the day's ration. I will briefly discuss these two points.

We are told (on page 38) that 7 lbs. per week of bread will furnish the prisoner with 9·072 ounces of flesh-formers. Now, if the bread referred to be that recommended by the reporters, 7 lbs. should furnish, according to their own showing, no less than 11·2 ounces of flesh-forming nitrogenous matters. For they affirm such bread to contain on the average 10 per cent. of flesh-formers, and so the weekly allowance of 7 lbs. or 112 ounces of bread would furnish 11·2 ounces of these nutrients. They appear, however, to have assumed the bread in use to contain not 10, but only 8·1 per cent. of flesh-formers—at least, in the absence of direct analytical data, I deduce this figure from the calculated amounts of nitrogenous substance tabulated in the report. Indeed, I conclude that they have not made the fresh calculations rendered necessary by the altered composition of the proposed bread, but have adopted the old figures of Playfair and other writers on this subject. But taking average whole meal bread made as directed by the reporters, and from ordinary wheats, it would not be safe to reckon upon it containing as much as 8·1 per cent. of true flesh-forming material—my own experiments put it at a little above 7. But granted the higher figure, we then find that the prisoners with hard labour (with 7 days' confinement) receive no more than 14 ounces of flesh-formers to 96 of heat givers, reckoned as starch, during a week. The ratio here is 1 to 6·8, which differs too widely from the normal ratio (1 : 4½) to afford satisfactory sustenance to men expected to do hard work.

There are, however, two ways out of this difficulty. Why should not a part of the fine flour be excluded from the constituents of the meal for prison bread? Or again, why should not biscuit flour, tailings, and middlings be added to it from other sources? And the same result might be ensured, and the flesh-formers be at the same time more adequately represented in the bread, if care were taken to choose for prison meal the hard, horny and tail wheats, which are always more nitrogenous than the white, opaque and soft grains. It is true that some of these hard, translucent wheats, especially when they owe their character to unripeness or a wet season, contain a larger proportion than usual of non-albuminoid nitrogen, but in spite of this their percentage of true flesh-formers is always high. It would be quite easy, by chemical analysis of the samples of grain offered by contract to the authorities, always to secure a wheat containing 13 to 14 per cent. of true flesh-formers, and therefore capable of producing a bread with at least 9 per cent.

There are two other remarks suggested by reading the part of this report on Prison Dietaries which relates to bread. The Committee is clearly right when it urges the desirability of including most of the coarser mill products of wheat in the meal on account of the phosphates thus secured. And the proposed plan is a good one, of making the dough of the finer mill products only at first, and then introducing, when the dough is nearly ready for the oven, the middlings, sharps, and pollard; again, kneading the mass as quickly as possible, and then baking it. The excessive solidity and stickiness of most whole meal bread is thus avoided, since the ferments present in the seed coats of the grain have but little time to exert their action upon the starch of the flour. A. H. CHURCH

[1] NATURE, vol. xviii. p. 229. and vol. xix. p. 174.
[2] Report of Committee on Dietaries in Prisons, 1878

ISOMORPHISM

AT the regular meeting of the Berlin Chemical Society on February 10, Prof. Hermann Kopp, of Heidelberg, delivered an address upon "Isomorphism." Prof.

Kopp first proceeded to sketch the methods employed for determining the molecular and atomic weights of the elements. When an element can be volatilised conveniently, so that we can obtain its vapour-density, its molecular weight is readily decided. Those elements which enter with a large number of volatile, or gaseous bodies, like carbon, present but little difficulty. Those, like zinc, which form but one class of volatile compounds, leave much to be desired, for a series of homologous bodies are no better than a single member of the series. In this case, however, the specific heat of the element comes to our aid, and we can usually take such a multiple of its equivalent as will give, when multiplied by the specific heat, a product not far from six. Naumann's law also enables us to make use of the specific heat of salts as well as that of the elements, the product of the specific heat by the sum of the atomic weights being nearly equal for similar compounds, and usually six times that of the number of atoms in a molecule. But this fails in some cases, probably, because we cannot take the specific heat at a sufficiently high temperature, as in the case of ice. In many cases where the above tests fail, isomorphism holds good. But totally unlike bodies, containing an unlike number of atoms in the molecule, have the same crystalline form. To avoid this dilemma, Prof. Kopp proposes to limit the term isomorphous to those compounds which possess the same crystal-forming power, as proved by their ability to crystallise together, or, if unequal in solubility, the ability of one crystal to grow in a solution of the other. Both of these cases were beautifully illustrated by alums. If a trace of a chromalum solution be added to a solution of potash-alum, each crystal that forms will contain both, as shown by the reddish tinge, and the colour deepens as the quantity of chromalum added is increased. On the other hand, when a crystal of one sort of alum is placed in a solution of the other kind, it continues to grow. Fine specimens of such crystals were exhibited by the speaker, who is remarkably skilful in this matter of growing and nursing crystals. Many other isomorphous salts were exhibited, such as the sulphates of magnesia and nickel; in some cases two different salts had been deposited alternately over the crystal of a third salt. Most interesting were rhombohedra of calxspar covered with nitrate of sodium, thus proving these two bodies isomorphous. The professor acknowledged that he had had much difficulty in obtaining these, and had utterly failed to make a crystal of arragonite grow in a solution of nitrate of potash. Prof. Kopp said, in conclusion, that unlike number of atoms could not replace each other in a molecule of two isomorphous bodies. Sulphate of cadmium will crystallise with eight equivalents of water to three of the anhydrous salt. Sulphate of didymium crystallises with eight equivalents of water. Both have the same crystalline form, but two atoms of didymium seem to replace the three of cadmium:—

$$Di_2S_3O_{12} + 8H_2O;$$
$$Cd_3S_3O_{12} + 8H_2O.$$

But these salts will not crystallise together, and crystals of the latter, from a mixed solution, contain no pinkish tinge of didymium.

HER MAJESTY'S ASTRONOMER AT THE CAPE

MR. DAVID GILL has been gazetted successor to Mr. E. J. Stone in the direction of the Royal Observatory, Cape of Good Hope. The discrimination exercised by the First Lord of the Admiralty in this appointment, we are confident will be appreciated and applauded by astronomers generally. Obtaining his first experience in practical astronomy in the Observatory at Aberdeen, and in a private observatory which he erected in the same place, Mr. Gill was so fortunate as to be associated with Lord Lindsay in the designs and details of the large observatory founded by this nobleman at Dun Echt in 1870, taking the position of chief of the staff. He thus became engaged in the organisation of the expedition to the Mauritius fitted out by Lord Lindsay for the observation of the transit of Venus, on which occasion advantage was taken of the circumstance of a heliometer forming part of the equipment to determine the sun's distance by measures of the planet Juno, being the first trial of the method, and attended with satisfactory results; the details of this work were published by Lord Lindsay as the joint work of himself and Mr. Gill. In connection with the same expedition, Mr. Gill arranged and personally conducted the whole of the chronometric and telegraphic longitude determinations connecting Berlin, Malta, Alexandria, Suez, Aden, Bombay, Seychelles, Reunion, Mauritius, and Rodriguez. It was while engaged upon these operations that he undertook, at the request of the Khedive, the measurement of the first base line of the geodetic survey of Egypt. In 1877 Mr. Gill laid before the Royal Astronomical Society a proposal to determine the sun's distance by heliometric observations of the planet Mars about the very favourable opposition of that year, Lord Lindsay lending his heliometer for the purpose. The proposal met with the support of the Astronomer-Royal and Council of this Society, and was further aided in its execution by a grant from the government funds in the hands of the Royal Society. The Island of Ascension was fixed upon as a favourable station for these observations, and Mr. Gill proceeded to Ascension in June, being occupied there about six months in the necessary preparations and carrying out of the scheme. The reductions are still proceeding, but in proof of the importance attached to this attempt to obtain a reliable value of the solar parallax and the interest felt by the leading astronomers of different nations in his work, it may be mentioned that on asking for aid in the accurate determination of the positions of the stars observed with Mars, his request was cordially acceded to at the following observatories:—Greenwich, Oxford, and Liverpool, Albany, U.S., Berlin, Cambridge, Mass., Cordoba (the national establishment of the Argentine Republic), Königsberg, Leipsic, Leyden, Melbourne, Paris, Pulkova (the Imperial Observatory of Russia), and Washington.

We will express the hope that Mr. Gill may carry to his new sphere a continuance of the great energy he has hitherto shown and repeat our conviction that his nomination by the First Lord to the important position of "Her Majesty's Astronomer at the Cape," will be hailed with great satisfaction in the astronomical world. It is understood that Mr. Gill leaves England early in May, arriving at the Cape in good time to confer with Mr. Stone upon the future work of the Observatory.

OUR ASTRONOMICAL COLUMN

THE NAVAL OBSERVATORY, WASHINGTON.—The Report of Admiral Rodgers, superintendent of this great astronomical establishment, for the year 1878 has just been issued. The operations of the institution have been more than usually extended, involving expeditions for the observation of the transit of Mercury on May 8, and the total solar eclipse of July 29. The 26-inch refractor has been in charge of Prof. Asaph Hall, with Prof. Holden as assistant, and has been constantly employed in the observation of satellites, double stars, and nebulæ, and occasionally of comets. Admiral Rodgers mentions that many foreign astronomers visiting the United States on the occasion of the eclipse, took the opportunity of inspecting this instrument, expressing very generally an opinion that the mounting was too light, and in this opinion the superintendent to a certain degree coincides,

although it is pointed out that during the five years that the equatorial has been mounted, "the position of the pole of the instrument has changed only a fraction of a minute of arc." The observations of the satellites of Saturn refer mostly to Japetus, Hyperion, and Titan. The disappearance of the ring took place February 6; Bessel's elements were verified by observations of its angle of position on thirty-six nights by Prof. Hall, and on twenty nights by Prof. Holden. There are also observations of the satellites of Uranus and Neptune, besides the fine series on the two satellites of Mars which were placed in the hands of astronomers some time since. A good series of measures of the companion of Sirius was obtained, and the six stars in the trapezium of Orion have been measured in connection with observations of Mr. Otto Struve's selected list of stars for determining the personal errors of observers. Prof. Holden observed the Orion nebula on twenty-eight nights, also six others of the more interesting of this class of objects.

The transit-circle and the 9·6-inch equatorial have been in charge of Prof. Eastman; 3,450 observations were made with the former instrument during the year, while the equatorial has been occasionally employed for a very necessary auxiliary purpose when it is desired to observe the fainter or less accurately computed minor planets on the meridian, viz., in determining previously the approximate correction of the ephemerides; for want of this necessary preliminary observed at Washington, a considerable number of observations on the meridian have been put upon record as observations of faint minors, which have been found to belong to small stars, to the equal vexation of observers and computers.

During the transit of Mercury, seventy-two photographs of the planet upon the solar disk were made at Washington by Mr. Rogers, with one of the photoheliographs used for the transit of Venus. Prof. Harkness proceeded to Texas for the observation of this transit of Mercury, succeeding better with the later than the earlier half of the phenomenon. The compilation and discussion of the observations is proceeding under Prof. Eastman, and will soon be ready for publication.

With regard to the total solar eclipse, it is stated that the liberal appropriation authorised by Congress allowed of a number of separate expeditions being organised, and the co-operation of the leading astronomers of the United States was invited and cordially responded to; but, while the Observatory of Washington was enabled to assist in a financial point of view, the heads of expeditions were left free to arrange their own plan of observation. The report enters briefly into particulars of the stations and success of the observers, to which space will not allow further reference here. With respect to the search for an intra-Mercurial planet or planets, it is mentioned that the following, in addition to Prof. Watson, were so occupied, at least during a part of the time that the sun was obscured:—Prof. Asaph Hall at La Junta, Colorado, with a 5-inch Alvan Clark equatorial, power 150 diameters, sweeping south and following the sun to about 10° distance; Mr. O. B. Wheeler at the same place, with a similar instrument, sweeping below and preceding the sun; Prof. Newcomb at Separation, Wyoming, and Professors Holden and Pritchett at West Las Animas, Colorado, also conducted unsuccessful sweeps for an intra-Mercurial planet.

The Washington Observatory has made arrangements for dropping a time-ball in New York city, at noon daily, which took effect from September 10, 1877; there have been a few failures, the cause of which is explained. The volume of observations for 1875 was daily expected to be delivered from the press at the time the Report was drawn up: we presume there are few real astronomical workers who have not experience of the liberality with which the handsome volume annually issued has been distributed by the United States Naval Observatory.

TEMPEL'S COMET, 1867, II.—Since our last note referring to this comet, M. Gautier has published sweeping-ephemerides, in the calculation of which he first assumes the perihelion passage to occur May 10·9416 Berlin mean time (that being the epoch fixed by his calculations after taking into account the action of Jupiter during the present revolution, which has delayed the comet less than three days), and then varies this date by ∓ 4 days; he believes the error of his computation will not exceed these limits. The following are the positions taking T = May 10·9416 for midnight at Berlin, or roughly for 11h. Greenwich time, during the next period of absence of moonlight, or rather beyond it:—

1879.	Right Ascension. h. m. s.	North Polar Distance. ° ′	Log. Distance from Earth.	Intensity of Light.
March 10	15 56 1	98 54·4	0·0960	0·188
,, 14	16 1 41	99 10·5	0·0808	—
,, 18	16 7 2	99 26·2	0·0657	—
,, 22	16 12 2	99 41·6	0·0506	—
,, 26	16 16 39	99 56·9	0·0355	—
,, 30	16 20 51	100 12·6	0·0206	0·278

An acceleration of four days in the time of arrival at perihelion will alter the comet's position on March 10, + 10m. 1s. in R.A., and + 1° 4′ in N.P.D.; and on March 30, + 11m. 51s. in R.A., and + 1° 11′ in N.P.D.

BIOLOGICAL NOTES

NEW FISHES FROM CENTRAL ASIA.—The last number of the *Bulletin* of the Imperial Academy of Sciences of St. Petersburg contains an interesting communication from Prof. Kessler on the fishes obtained by Prjvalsky during his recent expedition to Lob-Nor, a district previously unvisited by any naturalist. Herr Prjvalsky's collection from Lob-Nor and the basin of the Tarim contained examples of eleven species of fishes, eight of which belong to the family of *Cyprinidæ*, and three to that of *Cobitidæ*. As might have been expected, nearly the whole of these are new to science, and belong to genera (*Diptychus*, *Schizothorax*, &c.) characteristic of the high lands of Central Asia. One of the Cyprinoides is so peculiar as to necessitate the institution for it of a new genus, which Herr Kessler proposes to call *Aspiorhynchus*. *Aspiorhynchus prjvalskii*, as Prof. Kessler names this fish, in honour of its discoverer, inhabits the lower Tarim and Lob-Nor, where it attains a considerable size and furnishes an excellent article of food. Prof. Kessler suggests that two of the fishes obtained by the late Dr. Stoliczka during Forsyth's expedition to Yarkand, which were referred by Dr. Day to the genus *Ptychobarbus*, probably belong to his genus *Aspiorhynchus*.

DREDGING OPERATIONS, GULF OF MEXICO.—The last *Bulletin* (No. 9) of the Museum of Comparative Zoology at Harvard College, Cambridge, Mass., contains an account of some wonderful new or rare forms of echini, by A. Agassiz, of corals by L. F. de Pourtalès, and of ophiurans, by T. Lyman, all the specimens having been dredged, during the survey of the United States steamer *Blake*, in the Gulf of Mexico. Preceding the technical descriptions there is a bibliographical notice of the publications relating to the deep sea investigations carried on by the United States Coast Survey from 1850 to the present time. Of the echini described and figured in the present number is a most interesting new species of Dorocidaris (*D. blakei*). While the recent Cidaridæ, so far as at present known, do not by any means show the great variety in the form of their spines, which is found so common among the fossil genera of the family; yet here we have at least one species in which the variety of the shape of the spines is extreme. Its long tapering spines would have indicated its position in Dorocidaris, but its extraordinary flattened fan-shaped spines seem nearly identical with those of the Jurassic genus Rhabdocidaris—when

alive these echini were of a brilliant vermilion colour. *Salenia pattersoni* spec. nov., is described as the most exquisitely coloured of the living Salenidæ, thus far found; the test was of a light cream colour, as well as the shafts of the primary spines. These are banded with a brilliant vermilion, the two colours nearly equally divided. The secondary spines are also cream-coloured, but separated at the base by dark violet lines which extend from the apical to the actinal system. Similar dark violet lines separate the genital and ocular plates. *Conoclypus sigsbei* is described as a magnificent species, by far the most striking sea-urchin which A. Agassiz had ever seen. The first time it was seen the dredge brought up half a dozen of the huge, brilliant lemon-coloured specimens. All these species, as well as the remarkable *Periaster limicola*, are figured from photographs. Count Pourtalés describes a number of new or rare forms of corals. As far as our present knowledge goes, he writes, no sea-bottom can rival in abundance of deep-sea corals the West Indian. It is not at all unfrequent for a single cast of the dredge to bring up a dozen different species represented by more or less numerous specimens of each. A very young specimen of Holopus was dredged from a depth of 100 fathoms. It has been sent for study to Sir Wyville Thomson, but a beautiful figure by A. Agassiz is here given. Several new species of Antedon are described by Pourtalés. A large number of new species and two new genera of ophiuroids are described by Theodore Lyman. The descriptions are accompanied by excellent figures.

United States Fish Commission.—Messrs. G. Brown Goode and Tarleton H. Bean give an account of some fifty species of fishes from the east coast of the United States, some of which are new to science and all of which are new to the fauna of that portion of the American States. Among the more interesting of the new forms may be mentioned *Phycis chesteri*, the largest specimens measured without the tail about eight inches in length; they were taken off Cape Ann. A new species of Dr. Günther's genus Haloporphyrus was taken on the outer edge of Le Have Bank at a depth of 400 to 500 fathoms. Two specimens of the rare *Remoropsis brachyptera* (Lowe) Gill, were obtained; one was found clinging to the side of a sword-fish, harpooned in the channel south-west of George's Bank, and the other on the deck of a Halibut trawler fishing to the north-east of George's Bank, at a time when sword-fish were being taken on the trawls. A specimen of *Nemichthys scolopaceus* was taken alive from the stomach of a cod caught on the same bank. *Amia calva* is reported from St. John's River, Florida, and from Spruce Creek, a tributary of Halifax River, about lat. 28°. Its range has not hitherto been recognised south of Charlestown, South Carolina, from whence Garden sent specimens to Linnæus (*American Journal of Science and Arts*, January, 1879).

American Œdogoniaceæ.—Dr. V. B. Wittrock has just published a revision of the species of Œdogoniaceæ found in America, as far as they are known (*Botaniska Notiser* utgifne af O. Nordstedt, November, 1878). The list contains twenty-three species belonging to the genus Œdogonium, and eight belonging to the genus Bulbochæte. Of these, nine are found in Greenland, five in Pennsylvania, one in California, five in Mexico, three in the West Indies, one in Venezuela, one in Bolivia, and seven in Brazil. It would seem very certain that this number constitutes but a small part of the species which will by further investigations be discovered; still it enables the author to draw, with a considerably high degree of probability, the following conclusions:—1. That the œdogoniaceous vegetation of America differs but little from that of the European. 2. That the species found towards the more northern portion of this area are perfectly identical with those to be met with in Northern Europe, while the species met with in the more southern portion of the same area are either species quite different from those met with in Europe, or, at most, extreme varieties of European forms. Only one of the South American species forms an exception to this (*Œdogonium crispum* (Hass.), Wittr.), which would seem to be nearly a cosmopolitan. 3. That the genus Bulbochæte has in America, as in Europe, most of its species indigenous to the cold temperate or arctic zone. Of the eight species known from America, five are natives of Greenland.

Chemico-Agricultural Stations in Italy.—Stations for the scientific observations of subjects connected with agriculture in its widest sense, have now been for several years established throughout Italy. These are under the general control of a Minister of Agriculture. We have lately received the reports (Atti) of the stations at Rome and Palermo, contributed by Prof. J. G. Briosi; they have, as might be expected, mostly to do with the subject of the diseases of the vine and the olive. Among the more important of these reports are the following: On the Phytoptus of the Vine (*Phytoptus vitis*), with figures; an account of the Marciume of the Vine (*Albinia wockiana*), with figures; on a Fungoid Disease attacking Lemons (*Fusisporium limoni*), with figures. At Messina a lemon-tree, in good condition, of fair size, will, it is reckoned, produce about 2,000 ripe fruit each year. These fruits are sold at from twenty to forty lire the thousand, according to size and quality, so that a lemon orchard is of great value, and a good deal of distress has been caused by the destruction of the lemon crops by this disease.

Asparagin in Plants.—The physiological *rôle* and distribution of asparagin in the plant kingdom have been lately studied by Herr Borodin (*Botanische Zeitung*, 51 and 52, 1878). He states, as the result of his researches, that whenever a vigorous part of a plant becomes poor in non-nitrogenous substances, asparagin occurs as a product of decomposition, and accumulates. This may be explained in either of two ways: either the presence of non-nitrogenous matters hinders the decomposition of albumen, while these alone are decomposed; or (conversely) in life albumen is always decomposed and asparagin constantly formed, but where carbohydrates are present albumen is regenerated, and it is only where these are deficient that asparagin accumulates. The former hypothesis supposes different processes of decomposition in life according as carbohydrates are present or not; Herr Borodin thinks it therefore the more improbable, and adopts the other, doing so the more readily that the regeneration of albumen from asparagin and carbohydrates certainly occurs, and is necessary for the transference of the albuminous matters. Not all carbohydrates are adapted for regeneration of albumen from asparagin, and therefore asparagin may accumulate even when carbohydrates are present. Such unsuitable carbohydrates are starch and the oils, whereas glucose is the suitable form.

THE PIC DU MIDI OBSERVATORY

OUR readers may remember that early in the year General de Nansouty, the hardy director of the Pic du Midi Meteorological Observatory, was cut off from communication with the world below, the severe weather having so affected the telegraph as to prevent it from acting. Fears were entertained for the General's safety, and M. Albert Tissandier resolved to organise a party for the ascent of the Pic and the succour of the veteran observer. An interesting account of this ascent appears in *La Nature*, to which we are indebted for the accompanying illustrations. The snow-storm having somewhat abated at Bagnères-de-Bigorre on January 9, M. Tissandier resolved to attempt the Pic next day, in company with three of General Nansouty's usual guides.

They set out at 9 A.M. on the 10th, and in spite of the deep snow and fallen avalanches, the ascent was at first not difficult. After equipping themselves for snow work at some huts occupied only in summer, the ascent was begun in earnest. The weather was grey and uncertain, the temperature 0° Cent., with a thick mist that prevented anything being seen beyond 300 metres. The snow became deeper and deeper as they advanced, and one of the guides went before to show the way, the others following the marks of his footsteps up the steep slope of the mountain side. Sometimes they were buried to the waist, and often they had to rest to recover breath. The ascent was slow and difficult, but they were often rewarded by the magnificent effects resulting from the play of light upon the snowy landscape beneath, or of the clouds advancing majestically into the midst of the snows. After attaining an altitude of 6,000 feet, they had got over the steepest part of the slope. But now the weather changed, the wind rose, and mists more and more obscured the sky. Squalls of snow were driven into their faces, and seriously hindered their progress. Alongside the track heaps of snow showed where avalanches had recently fallen from the rocks above. The telegraph posts, 7 metres high, were often buried; five or six of them were even broken by the violence of the recent storms, and the wires were broken. The weather got worse as they ascended, and M. Tissandier had all the symptoms of mountain-sickness, which he had not experienced before, even when ascending Mont Blanc. At last, however, the summit was reached, and, as might be expected, General de Nansouty gave the party a warm reception. A glorious fire and an excellent dinner soon set M. Tissandier all right again.

The establishment of the General is far from being luxurious, M. Tissandier tells us; although none of the usual necessaries of life are wanting, one is struck with the devotion which impels him, for the sole purpose of advancing science to accept an existence so isolated, so primitive, and that during eight months of the year.

The observatory of the Pic du Midi is most picturesque. We enter first a passage with glass doors at the sides, in order to protect as much as possible from the violence of the wind and the gusts of snow. The telegraphic office is at the bottom. A respectable provision of wood furnishes this passage; a few hens inhabit it; one of them was slaughtered in M. Tissandier's honour. A room adorned with an immense fireplace is next presented to the visitor's view; it is the vestibule. The guides sleep here on a camp bed, and have for messmates two dogs and two cats, presided over by the intendant, the faithful guardian of the observatory. All round this apartment, carefully arranged as on shipboard, may be seen a variety of provisions. The dining-room opens in this vestibule. In summer a separate part of the building is arranged for the reception of tourists, and a stable for horses is placed below the principal structure.

To the first storey there is no staircase, as there is no room for it; there is only a ladder with a knotted cord as balustrade. On ascending this, a small vaulted room is entered; a stove ruddy with fire heats the whole floor, and the cold of the outside is unknown in these hospitable chambers. The chief ornaments of this apartment consist of two sets of beds, one near the floor, used by M. Baylac, the second observer and devoted companion of General de Nansouty. Above is another bed, or rather shelf, to use the General's expression; this is for the use of visitors. It is reached by a ladder, and the mattress consists of an excellent sheepskin, on which, M. Tissandier declares, he slept so soundly, 8,000 feet above the sea, that he reluctantly left it on the morning after his arrival. On this first floor the General has a workroom in common with M. Baylac. This room is too small for the work which has to be done in it.

Everybody is up at daybreak; this is the inexorable order. The General then begins the day's observations. It is necessary to go outside to examine the thermometers and barometers, which are placed under a shelter constructed on a stone terrace. Every two hours, and oftener when the atmospheric conditions require it, the observations are renewed, precisely recorded, and preserved with care. Thus the whole day is passed, night alone putting an end to the work. M. Tissandier bears testimony to the energy and patience of the courageous observer of the Pic du Midi in carrying on his work.

FIG. 1.—Ascent of the Pic du Midi, January 10, 1879.

Happily the rather too primitive arrangement of the General will soon be changed for the better, thanks to the generous donations of those who love and desire to advance science.

During the small amount of leisure which can be found between the hours of observation, General de Nansouty directs his companion in a great variety of labours. A very interesting herbarium of the flora of the high regions of the Pic du Midi has thus been formed. M. Tissandier admired some rare plants, such as *Gentiana glacialis*, *Daphne cnæorum*, *Salix herbacæa*, &c. Mineralogical

Fig. 2.—Observatory of the Pic du Midi.

Fig 3.—The crests of Peune Longue (Pic du Midi) emerging above the clouds.

specimens are also collected and arranged. Traps are also laid by M. Baylac, and thus a fine collection of ermine skins has been formed.

The guides repaired the damage to the telegraph which had interrupted the General's communication for ten days. M. Tissandier says rightly that these accidents

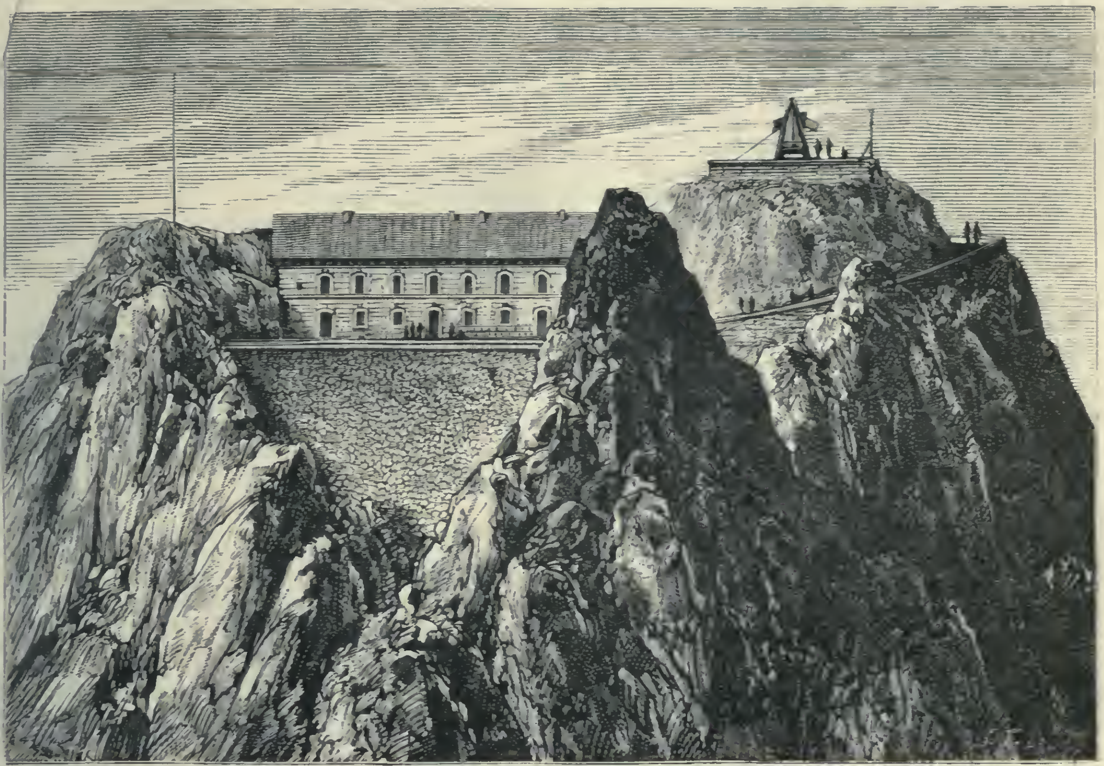

FIG. 4.—View of the New Observatory of the Pic du Midi, now building

should not be allowed to happen to a man who so generously devotes himself to the progress of a department of science that is of the greatest national utility. For at least a part of the distance between the summit and the plain the wires should be placed underground, and thus beyond the reach of injury from avalanches and

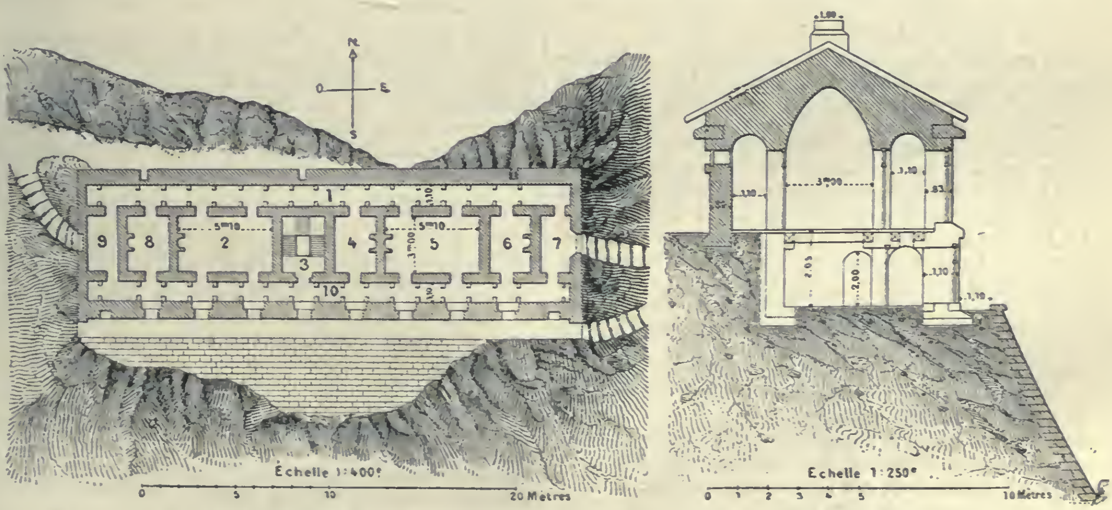

FIG 5.—Plan and section of the New Observatory. Plan of the first floor:—1, Passage, magazine; 2, *Salon*; 3, Staircase; 4, Dining-room; 5, Work room; 6, Guest-chamber; 7, Telegraph; 8 and 9, Bed-rooms. The ground-floor will be used for provisions.

storms. After M. Tissandier's visit, our readers may remember, telegraphic communication was again interrupted with the Pic. M. Tissandier bade the General good-bye on the 12th, and during his descent took several sketches. While it took him nine hours to make his ascent, he came down in four.

The improvements contemplated by General de Nansouty comprise an entirely new and much more solid and durable structure at the very summit of the mountain. A few generous friends of science have come to his aid and placed in his hands the means of carrying out the execution of his enterprise. M. Bischoffsheim gives 15,000 francs, the Minister of Public Instruction and the Minister of Public Works each 10,000 francs, the Academy of Sciences 1,200 francs; and large sums have been given by various other societies and individuals while many smaller subscriptions, down to one franc, have been placed at the General's disposal. There is every reason to believe, that though the work will be much more costly than originally expected, it will be thoroughly and promptly completed.

Our illustration (Fig. 4) shows the new observatory as it will appear when the works are completed; it is at present half built. To the right is seen, perched on a platform, the shelter for the instruments of observation. In the centre is the dwelling-house, the arrangements of which will be seen in the plan, Fig. 5. To the left is the lightning-rod, intended to protect the structure from the lightning which so frequently strikes the summit of the Pic. This lightning-rod, with its cable, which plunges 500 metres lower down in Lak Oncet, has cost 2,800 francs. The excavation of the hollow in which the structure is built has cost 2,500 francs; so much of the building as has been raised, that is one half, has cost 22,000 francs. No doubt all the necessary funds will be forthcoming; it is said that the Minister of Public Instruction will this year contribute another sum of 10,000 francs.

The example of General de Nansouty has already borne fruit in France. General Farre has installed an observatory at the foot of Infernet. In Provence a movement has been set on foot to place one on Mont Ventoux. With the fine observatory of the Puy de Dôme, France will possess an important net-work of high meteorological stations which cannot but render valuable services to a knowledge of atmospheric phenomena, and be of great practical value to national industry. Let us hope that in a very few months our own country will possess at least one of these lofty stations which the French Government, the French people, and French science think it their interest and duty to give substantial encouragement to.

GEOGRAPHICAL NOTES

AT the meeting of the Geographical Society on Monday evening Sir Rutherford Alcock announced that the Earl of Dufferin had formally resigned the office of president in consequence of his appointment to the St. Petersburg embassy. Mr. Clements R. Markham read a paper on the basin of the River Helmund and the smaller basin of the Abistada Lake, in Western Afghanistan, a region which is classic ground, and is the scene of many of the ancient Persian tales related in the pages of Ferdosi. Mr. Markham gave some interesting particulars respecting the formation of the river of Ghazni, which drains the eastern half of the remarkable isolated basin of Lake Abistada, on the east side of the western Sulimani Range. He afterwards read a paper by Lieut.-General Kaye, on the mountain passes leading to the valley of Bamian, based on that officer's recollections of his visit to the region north of Kabul, nearly forty years ago, supplemented by notes made at the time. With regard to the idols of Bamian, the limit of his journey, General Kaye mentions a curious fact, viz., that between the images and at their sides, peeping over their shoulders—and some even above their heads—were many caves in the cliff-side on which they are cut, having intricate connecting approaches and galleries cut within the rock; these formed dwellings for many Bamianchis and also for some camp-followers of the British. The two papers were illustrated by the large diagram of Afghanistan which has just been constructed for the Society.

THE London Missionary Society have received letters down to October 17 from their mission at Ujiji, on Lake Tanganyika, which announce the death from apoplexy of the Rev. Mr. Thomson, the leader of the party after the Rev. Roger Price's departure. The Arabs, though well disposed, refuse to allow the missionaries to settle away from Ujiji. Mr. Hore, the scientific member of the mission, has taken several observations with the view of settling the position of Ujiji.

IN consequence of the prevailing ignorance on the subject, Mr. E. F. im Thurn, of Demerara, has begun to draw up some notes on the Indians of Guiana. In the first instalment he remarks that the main tests by which to distinguish the various tribes are language, geographical position, physical features, and customs, as expressed in their characters, habits, and legends. In applying these tests to the tribes of British Guiana he thinks it best to look first at their geographical position. British Guiana consists of three regions—the coast region nearest the sea, within that the forest region, and within that again the savannah region, which passes without break into the great savannahs of Brazil. The coast region, in the north, towards the sources of the Orinocco, is inhabited by the Warau Indians, and further south by the Arawacks, while here and there are settlements and families of the Caribisi, a term which appears to be not strictly synonymous with Caribs. The forest region is almost entirely inhabited by the Ackawois, with a very few Carabisi settlements scattered among them. The Savannah region is peopled by a large number of tribes. Beginning from the north towards the Orinocco, the chief are the Arecunas, Macusis, Wapianas, and Atorais. Further south are the Tarumas and Woiowais, and the small remnants of the Maopityans, or Frog Indians, and the Pianoghottos. Here and there travellers report the existence of other tribes, but these Mr. im Thurn maintains to be groups of hybrids between two tribes. Of the Maopityans and the Pianoghottos nothing beyond a few details as to their peculiar personal appearance and manners is known, and of the Woiowais only the name is known. Mr. im Thurn next dwells at some length on the linguistic peculiarities of the other tribes mentioned, excepting the Tarumas, and he afterwards describes the way in which they most probably came into the positions they now occupy.

THE statue of Captain Cook, which has been erected in the Hyde Park, Sydney, was unveiled on February 25. The ceremony, which was of an imposing character, was performed by the Governor, Sir Hercules Robinson, in the presence of the Ministry, the public bodies of the city, detachments of the naval and military forces, and upwards of 20,000 spectators.

DR. EDWIN R. HEATH, of whose proposed exploration in South America we have already made mention, left New York on November 23, and reached Pará on December 19. He was to have taken a steamer up the Madeira on the 23rd, and thence to Exaltacion or else across to Reyes, on the Beni River, where he proposed to spend some time in making collections and the necessary preparations for descending the river. He expected to obtain Greenwich time at San Antonio, the latitude and longitude of which is well established, and to work his longitudes by them until arriving at the Beni, where he intended to correct it by "lunars." With a good outfit and apparatus he was to take observations of latitude and longitude at every suitable opportunity, as also to make records of the thermometer, barometer, and boiling-points. After completing all his preparations at Reyes, and having his *balsa* properly constructed and equipped, he proposed to commit himself to the current, and take his chances of what might happen.

THE Minister of Public Instruction at Paris has received an interesting communication from Dr. Jules

Crevaux (see NATURE, vol. xix. p. 298), written on October 30 from the River Kou, an affluent of the Yary, one of the lower tributaries of the Amazon. When he last wrote he had just crossed the crest of the Tumuc-Humac range. The Rouassir, an affluent of the Kou, was at length reached, after many difficulties, on September 27, but proved to be navigable for less than 250 yards; its course then led through a marshy country, in which it was divided into numerous streams, encumbered with a virgin vegetation, which had to be cut through. The party only reached the confluence of the Kou on December 2. Here Dr. Crevaux met some members of the Roucouyenne tribe whom he had seen before, and who were journeying towards the Oyapock River, in Guiana. They took his letters and some of his collections, while a few of them undertook to remain with him and guide him to the Yary, and thence to the Paru.

AT a recent meeting of the Geographical Society of Lyons, Capt. Baudot read a report on M. Duponchel's project of a railway from Algeria to the Senegal. He characterised the scheme as a dream and an illusion, and basing his remarks on his experiences gained during a long sojourn in Algeria, he enumerated the difficulties which rendered the project incapable of realisation in our time.

WE have received the first part of a new edition of Stieler's well-known Hand-Atlas, published by Perthes, of Gotha. A large number of new maps are promised; one of these, North-West Africa, is contained in the first part, and seems to us to be well up to date. It is only four years since the last edition was published, but much has happened during the interval to render a new one necessary.

A NEW Society of Geography has been established at Nancy, the head town of French Lorraine, and the first meeting took place on February 24. Another Society of Geography for Normandy has also been found at Rouen.

AT a recent meeting of the Berlin African Society, the sum of 2,000 reichsmark was awarded to the well-known traveller, Herr Ad. Krause, who is now in Northern Africa, for a special tour to the Ahaggar mountain range. A further sum of 20,000 mark will be distributed amongst several other travellers shortly. In the next part of the Society's *Mittheilungen*, interesting reports just come to hand from Drs. Gerhard Rohlfs and Buchner, will be published.

IT is stated that Major Butler, of the 9th Regiment, has returned to India from Turkestan, after completing a survey of nearly 6,000 miles of the country. In the course of his explorations he visited and held a conference with the Tekké Turcoman chiefs at Kizil Arvad, which was afterwards occupied by the Russians, but from which it is said that General Lomakin has found it necessary to beat a retreat.

IN the list of observations for fixing positions on the Amazons, taken by Commander Selfridge, U.S.N., which were recently published in the *New York Herald*, we learn that by an accidental error the longitude of Pará was given as 48° 59′ 15″, instead of 48° 29′ 15″, and that the latter will have to undergo a correction of 50″ for the difference between the meridians of the Rio de Janeiro Observatory and Fort Villegagnon, the distance having been erroneously calculated from the latter.

UNDER the title of "L'Amérique Equinoxiale" M. Ed. André has just commenced, in the *Tour du Monde*, a series of admirably illustrated papers on the United States of Colombia, Ecuador, and Peru, in which he travelled on a scientific mission from the French Government in 1875–6.

NOTES

FREDERICK SMITH, F.L.S., assistant-keeper of the zoological department of the British Museum, died on the 16th inst. at the age of seventy-three. Mr. Smith had devoted himself to entomology, and was one of the first living authorities on hymenopterous insects.

THE first *soirée* given at the Paris Observatory by Admiral Mouchez took place on February 21, and was very successful. More than a thousand persons belonging to influential circles visited the scientific exhibition of telephones, microphones, electric pens, Feil's new specimens of artificial gems, &c. A lecture was given by M. Wolf illustrating a new projection by electric light; the revolution of a radiometer could be observed for the first time on a screen. Admiral Mouchez had secured the services of the band of the Republican Guard, and a ball terminated the proceedings. Science seems to be somewhat more human and gay in Paris than in London; we do not think this does any harm to science, and is certainly a very effectual method of spreading an interest in it.

ENCOURAGING experiments were made at the British Museum on Tuesday night in lighting up the reading-room by means of the electric light. To-night further and more complete experiments are to be made, and we trust that as the result a considerable extension of working-hours will be possible for the hundreds who make the great room their daily workshop. A week or two ago the enterprising authorities of the Dundee public library made similar experiments with hopeful results. For such purposes there can be no question of the utility of the light, if suitable and safe arrangements could be made. The form of light used at the Museum was the modification of the Jablochkoff candle introduced by the Société Générale d'Électricité. By way of experiment the electric light has recently been introduced into the Vienna Art Exhibition at the "Künstlerhaus" and has enabled the directors to keep open their picture galleries until late at night. The experiment was a perfect success, and the new light will remain permanently established at the galleries.

THE subjects of the Croonian Lectures for this year are announced. Lecture I. will be on the physical basis of auscultation, Lecture II. on tension, Lecture III. on the rate of the heart's hypertrophy. All the lectures will be illustrated by means of physical experiments and oxyhydrogen projection. The lecturer is Dr. W. H. Stone.

ON Wednesday, March 5, Prof. Flower will give the first of his nine lectures at the College of Surgeons, on the comparative anatomy of man, in continuation of the course of last year, to be continued on Mondays, Wednesdays, and Fridays, at 4 o'clock, to March 24. The following are the heads of Prof. Flower's lectures:—Recapitulation of the best ascertained facts in connection with the subjects treated of in the last course, including the physical characters and geographical distribution of the Australian, Tasmanian, Melanesian, Papuan, Malay, and Polynesian races, with further illustrations from recent additions to the Museum; the inhabitants of the Andaman Islands, briefly touched upon last year, will next be treated of in detail, as typical examples of the Negrito race, and their osteological characters and relations to other races demonstrated from a series of skeletons and crania lately received; the Mongolian type and its various modifications, illustrated as far as the materials in the Museum permit; ethnology of Eastern and Southern Asia; the Ainos, a non-Mongolian people of Northern Japan; the Eskimos. The lectures are free to all who are interested in the subject.

A NEW society has been created at Paris for aëronautics. It is styled "Académie d'Ascensions météorologiques," and a

museum is being fitted up and will be opened in March for public inspection, admittance free. It contains all the apparatus devised for constructing or directing balloons or taking meteorological observations in the air.

We regret to see from the *Times* correspondent at Daka, that notwithstanding all that science has done for warfare, the Afghan war has been an unscientific one. "India," he states, "is unprepared for scientific war." "The enemy like ourselves possesses arms of precision and artillery. Their artillery at Ali Musjid and the Peiwar Kotal was probably equal if not superior to our own. Rockets, however, so easily carried over rough mountain roads, and so terrifying to barbarians from their eccentric course, exciting their astonishment more than any other appliances of art except the telegraph, have never been introduced in the campaign. Nor have any steam launches been sent to traverse the navigable Cabul river, explore its windings, and secure the left flank from gatherings of the enemy. No lime-lights or other lights, of which science boasts so many, have ever been supplied to prevent the enemy perpetually harassing our troops and disturbing their much-needed repose by creeping within range under cover of night and firing into our camp." This is rather disheartening, and we trust that in the campaign against the Zulus more attention will be paid to recent applications of science, and that for example night surprises will be made impossible by the use of one or other form of light which by a little ingenuity might be made to light up all the ground around any position.

An unusually brilliant meteor was seen in the north of England on Monday morning at about twelve minutes to three o'clock. It is described as a pear-shaped ball of fire in the northern heavens, which travelled slowly downwards towards the horizon, and emitting scintillations and a light of great brilliancy almost equal to that of day, so great indeed that it is said the smallest print could have been read. The light having disappeared, a sound, described by some as resembling the discharge of heavy cannon, and by others as that of the rumbling of distant thunder, was heard, but in all cases it seems to have been sufficiently violent to rattle windows, &c., and to have raised various speculations as to what could be the cause, some ascribing it to an earthquake, others to lightning, while others who saw the meteor set it to the account of that unearthly visitor.

A smart shock of earthquake, lasting about four seconds, was felt at North Unst Lighthouse, Shetland, on January 4, at five minutes past one o'clock in the afternoon. At 7.45 A.M. on Sunday week, a smart shock was felt at Milan and Brescia.

A simple and convenient way of demonstrating the vibratory movements of chords, is described by M. Schwedoff in a recent number of the *Journal de Physique*. The stationary waves of the chord are produced by means of an electric trembler (like that used for bells), the chord being attached at one end to the soft iron palette, and caused to vibrate transversely. The other end of the chord is attached to a stretcher for varying the tension. A movable runner allows of varying the length of the vibrating portion. A blackened board with figures on it is supported behind the chord.

By last accounts from China we learn that Mr. C. Moreno, the agent of the American projectors of a scheme for connecting China with the west coast of America by a submarine cable, is now at Tientsin for the purpose of soliciting the support of the Chinese Government. The Japanese are said to have promised assistance if the project finds favour at Peking.

An interesting archæological observation has recently been been made quite accidentally. It is well known that the urns found on Roman burial-grounds and containing the bone remains of cremated bodies are often covered with clay cups or dishes. The object of these dishes was supposed to have been to contain spices, which sent forth agreeable odours during the progress of the cremation. Herr Dahlem, a well known German archæologist, was able to verify this view in the following manner. He had obtained a dish of this kind which was broken, and after cementing it had placed it upon a stove for the purpose of drying the cement. Shortly afterwards he noticed a strong and by no means unpleasant odour proceeding from the heated dish. It seems therefore that the ingredients burnt in the dish some fifteen centuries ago had left traces behind, which announced their presence upon becoming heated. Herr Dahlem remarks that the odour was not unlike that of storax.

Prof. C. V. Riley, entomologist of the U.S. Department of Agriculture, reports that serious complaints have come from the Pacific slope during the year of a new insect that is killing many of the orchard and ornamental trees in that section of the country. Specimens received from Mr. A. W. Saxe, of Santa Clara, California, show it to be a species of *Dorthesia*, an abnormal bark-louse (family *Coccidæ*). It is an Australian insect (apparently *D. characias*, Westw.), and has of late years been introduced on Australian plants into South Africa, where, according to Mr. Roland Trimen, curator of the South African Museum, it has multiplied at a terrible rate, and become such a scourge as to attract the attention of the Government. It has evidently been introduced (probably on the blue gum or eucalyptus) to California, either direct from Australia or from South Africa, and will doubtless become a great evil, because most introduced insects are brought over without the natural enemies which keep them in check in their native country, and consequently multiply at a prodigious rate. The best remedy is a judicious use of kerosene or linseed-oil.

In the *Revue d'Anthropologie* for January, 1879, Dr. Gustave Le Bon contributes an important memoir, "Recherches anatomiques et mathématiques sur les Lois des Variations du Volume du Cerveau et sur leurs Relations avec l'Intelligence." One of the most interesting of his conclusions is that relating to the cranial differences between the sexes, both in weight of brain and dimension of skull. This question has long been studied by English anthropologists, and recently conclusions have notably been drawn by Mr. Darwin in his chapter on "Difference in the Mental Powers of the Two Sexes," in his "Descent of Man," and collaterally by Mr. Fras. Galton, in his work on "Hereditary Genius." Dr. Le Bon states as the result of his investigations that the female brain is not only less in weight than that of man, but that this inferiority exists "à âge égal, à poids égal et à taille égale," and that the cranial differences between the sexes are greater among the cultivated and more highly-developed races than among those in the most primitive condition, which he ascribes to the fact that the mental activity of civilised society is conducted in the aggregate by the male sex. These conclusions are highly corroborative of the views advanced in a paper read before the Anthropological Institute of London in 1874 (Distant, "On the Mental Differences between the Sexes," *Journal* of the Anthropological Institute, vol. iv. p. 78). Dr. Le Bon points out also the important fact that though the average capacity of the crania of the superior races is much greater than that of the less-developed ones, still what really constitutes the superiority of one race over the other is that the civilised races contain necessarily more largely-developed crania than can be found among the inferiorly developed races. As regards a strong opinion often held as to the superiority in size of the left hemisphere of the brain over that of the right, Dr. Le Bon can add nothing in confirmation. From a measurement of 287 crania he found inequalities indicated on either side in such proportion as to preclude his describing them as anything but a variable character: "sans qu'il soit possible d'assigner des raisons sérieuses à cette inégalité de développement."

ONE of the most interesting questions in American archæology has long been that of the age of the "mound-builders." Modern views seem now opposed to a prehistoric date for these people. Amongst other American workers who have inclined to the more recent date of these structures may be mentioned S. F. Haven, who considered the ancestors of the present Indians to have been the authors of these erections, and Dr. P. J. Farnsworth, who believed that the mound-builders were identical in race with the historical Indians of North America. On this subject a paper read before the Congrès International des Américanistes, 1877, by M. F. Force, has just been reprinted in pamphlet form by Clarke and Co., Cincinnati, 1879, entitled "To what Race did the Mound-builders belong?" The following are some of the author's conclusions:—That so far as indications are given by the growth of vegetation, it is not necessary to hold that any of the works were abandoned more than one thousand years ago. That the absence of all tradition concerning the mounds among the recent Indians is no proof of their great antiquity, as Indian tradition is short-lived and evanescent. Although the advent of De Soto with his armed followers, pillaging and ravaging the country, must have been calculated to make a deep impression, yet, when Europeans visited the country a century and a half later, they found not a vestige of a tradition of De Soto. Finally, Mr. Force considers that the mound-builders were tribes of Indians, more advanced than the Algonquins or the Dakotahs, but much less advanced than the Aztecs or the Peruvians, and on the same plane with the Pueblo Indians, and that they were living in full prosperity in the time of Charlemagne. Mr. Force reviews the evidence as to their antiquity derived from an examination of crania from these mounds, and endeavours to prove that either the skulls were not obtained from the mounds under consideration, or in other instances would not bear the conclusions based on their examination.

A CURIOUS thermo-magnetic motor, devoid, probably, of practical value, but having some scientific interest, has been devised by Prof. Houston and Thomson (*Journal* of the Franklin Institute). A disk or ring of thin steel is mounted on a vertical axis so as to be quite free to move with its edges opposite the poles of a horse-shoe magnet. The wheel of course becomes magnetised by induction. On heating a section of it, it begins to move. The reason is, that the heated section has its coercitive force increased, and so, being less powerfully magnetised by the induction of the adjacent pole, than the part next it, the attraction exerted by the pole on this latter part is sufficient to cause motion. A constant source of heat gives continuous rotation. The disk must be sufficiently thin to prevent its acquiring a uniform temperature. The heat may be applied at diametrically opposite parts, with similar effect. What renders the motor of little value is the amount of heat required being so enormous as compared with the force developed.

THE *Monats-Berichte der Berliner Akademie* (September and October 1878) contain some researches by M. Paalzow on the spectrum of oxygen: as, however, M. Paalzow has fallen into the old and common mistake of taking the spectrum of carbonic oxide for the spectrum of oxygen, he cannot be said to have made any decisive addition to our knowledge.

A CEYLON paper furnishes some interesting notes respecting the culture of the cinchona tree in the island. The variety known as *C. succirubra* yields a large quantity of bark, and is so hardy that, though the proper zone of elevation for its culture is from 2,000 to 4,500 feet, many planters are induced to try it at higher elevations. The zone for *C. officinalis* is from 4,000 feet upwards, and it has been grown on Dodabetta at a height of 8,000 feet, but in that case the bark of the unmossed tree becomes covered with lichens. *C. calisaga* will grow wherever the last-named variety does. *Cinchona officinalis* is highly recommended as a sheltering tree for coffee-shrubs against the effects of wind.

THE first number of the *Journal* of the Russian Physical and Chemical Society (both societies now united) contains an interesting paper by M. Beketoff on the specific heat of hydrogen when compounded with palladium; a paper by M. Ponomareff on derivatives from uric acid; additions and corrections, by Prof. Menschutkin, to his papers on etherisation of secondary alcohols; two papers on organic chemistry by MM. Kiabinine, Saytzeff, and Semlianitzin; and a paper by M. Lermantoff on the chemical and photographic action of light. Many very interesting notes give a very complete account of recent work in chemistry.

THE formation of hail and the various causes which contribute to it are still a very obscure question in meteorology. The following points on which information is desired have lately been indicated by M. Colladon:—1. Dates as exact as possible, and made comparable with the hour at Paris, Berne, or Geneva, of the commencement and end of the hail shower; extent of the surface covered. 2. Average and maximum dimensions of hailstones, their form, the average or maximum number of layers they present. Do the successive layers increase in thickness from the central nucleus? 3. Apparent form and elevation of hail clouds; have they the appearance of a vast continuous gyratory movement, or simply of movements of attraction and repulsion? Multiplicity of flashes, their average number per minute; are they, or not, accompanied by resounding noises and frequent descents of lightning on the ground? or are they mostly mute? Are there notable falls of hail without apparent and well-marked electrical phenomena? 4. Average temperature of the air before or during an electric storm, and temperature of the rain-water accompanying it, at the moment of its fall. M. Colladon has contrived an inexpensive apparatus for measuring the last item (*La Nature*, February 15). A funnel conducts the rain to a capsule holding the bulb of a minimum thermometer which has the upper part of its stem bent horizontally and a scale attached to this part.

IN a note on brewing contained in a report on Sapporo and Ishcari (Japan) we read that the beer is poor, weak stuff that will not keep. In course of time, however, it is fully expected that the art of brewing will succeed, more especially as a native director has spent several years in America and Europe devoting his attention to brewing. The hops used, it seems, are imported, and foreign hop seed has been sown, the plants raised from which appear to be doing well. The wild hops, which are found in great abundance on the road from Morarau to Sapporo, and have been found to be unsuitable for brewing in their wild state, are now being cultivated, as it is supposed that by care and attention they will prove to be as good if not better than foreign hops. Consequently great pains are now being taken with these hop plantations.

THE additions to the Zoological Society's Gardens during the past week include a Green Monkey (*Cercopithecus callitrichus*) from West Africa, presented by Mr. Douglas Murray; a Bennett's Wallaby (*Halmaturus bennettii*) from Tasmania, presented by Mr. W. E. Windus; a Common Hare (*Lepus europæus*), British Isles, presented by Mr. Alfred Withers; two Indian Barred Doves (*Geopelia striata*), a Chinese Turtledove (*Turtur chinensis*) from India, presented by Capt. H. Braddick; a Tayra (*Galictis barbara*) from Panama, two Grand Galagos (*Galago crassicaudatus*) from East Africa, three Australian Wild Ducks (*Anas superciliosa*) from Australia, two Cardinal Grosbeaks (*Cardinalis virginianus*) from North America, purchased; a Spotted Eagle Owl (*Bubo maculosus*) from Africa, deposited; two Prairie Marmots (*Cynomys ludovicianus*) from North America, received in exchange.

ON A NEW CHEMICAL INDUSTRY ESTABLISHED BY M. CAMILLE VINCENT[1]

"AFTER I had made the discovery of the *marine acid air*, which the vapour of spirit of salt may properly enough be called, it occurred to me that, by a process similar to that by which this *acid* air is expelled from the spirit of salt, an *alkaline* air might be expelled from substances containing the volatile alkali. Accordingly I procured some volatile spirit of sal-ammoniac, and having put it into a thin phial and heated it with the flame of a candle, I presently found that a great quantity of vapour was discharged from it, and being received in a basin of quicksilver, it continued in the form of a transparent and permanent air, not at all condensed by cold."

These words, written by Joseph Priestley rather more than 100 years ago, describes the experiment by which ammonia was first obtained in the gaseous state. Unacquainted with the composition of this alkaline air, Priestley showed that it increased in volume when the electric sparks are passed through it, or when the alkaline air (ammonia) is heated, the residue consists of inflammable air (hydrogen). Berthollet, in 1788, proved that this increase in bulb is due to the decomposition of ammonia into nitrogen and hydrogen, whilst Henry and Davy ascertained that two volumes of ammonia are resolved into one volume of nitrogen and three volumes of hydrogen.

The early history of sal-ammoniac and of ammonia is very obscure. The salt appears to have been brought into Europe from Asia in the seventh century, derived, possibly, from volcanic sources. An artificial mode of producing the ammoniacal salts from decomposing animal matter was soon discovered, and the early alchemists were well acquainted with the carbonate under the name of *spiritus salis urinæ*. In later times sal-ammoniac was obtained from Egypt, where it was prepared by collecting the sublimate obtained by burning camel's dung.

Although we are constantly surrounded by an atmosphere of nitrogen, chemists have not yet succeeded in inducing this inert element to combine readily; so that we are still dependent for our supply of combined nitrogen, whether as nitric acid or ammonia, upon the decomposition of the nitrogenous constituents of the bodies of plants and animals. This may be effected either by natural decay giving rise to the ammonia, which is always contained in the atmosphere, or by the dry distillation of the same bodies, that is by heating them strongly out of contact with air, and it is from this source that the world derives the whole of its commercial ammonia and sal-ammoniac.

Coal—the remains of an ancient vegetable world—contains about 2 per cent. of nitrogen, the greater part of which is obtained in the form of ammonia when the coal undergoes the process of dry distillation. In round numbers 6,000,000 tons of coal are annually distilled for the manufacture of coal-gas in this country, and the ammoniacal water of the gas-works contains the salts of ammonia in solution.

According to the most reliable data 100 tons of coal when distilled so as to yield 10,000 cubic feet of gas of specific gravity 0·6, give the following products, in tons:—

Gas.	Tar.	Ammonia Water.	Coke.	
22·25	8·5	9·5	59·75	Average.

This ammonia-water contains about 1·5 per cent. of ammonia; hence the total quantity of the volatile alkali obtainable from the gas-works in England amounts to some 9,000 tons per annum.

A singular difference is observed between the dry distillation of altered woody fibre as we have it in coal—and woody fibre itself. In the products of the first operation we chiefly find in the tar the aromatic hydrocarbons such as benzene, whilst in the second we find acetic acid and methyl-alcohol are predominant.

The year 1848 is a memorable one in the annals of revolutionary chemistry, for in that year Wurtz proved that ammonia is in reality only one member of a very large family. By acting with caustic potash on the nitriles of the alcohol radicals, he obtained the first series of the large class of compound ammonias, the primary monamines. Of these, methylamine is the first on our list:—

$$\left.\begin{matrix}CH_3\\CO\end{matrix}\right\}N + 2KOH = \left.\begin{matrix}CH_3\\H_2\end{matrix}\right\}N + CO\left\{\begin{matrix}OK\\OK\end{matrix}\right.$$

The years that followed, 1849-51, were prolific in ammoniacal discovery. Hofmann pointed out that not only one atom of hydrogen in ammonia can be replaced by its equivalent of organic radical, but that either two or all of the three atoms of the hydrogen in ammonia can be likewise replaced, giving rise to the secondary and tertiary amines by the following simple reactions:—

$$1.\quad CH_3I + \left.\begin{matrix}H\\H\\H\end{matrix}\right\}N = HI + \left.\begin{matrix}CH_3\\H\\H\end{matrix}\right\}N$$

$$2.\quad CH_3I + \left.\begin{matrix}CH_3\\H\\H\end{matrix}\right\}N = HI + \left.\begin{matrix}CH_3\\CH_3\\H\end{matrix}\right\}N$$

$$3.\quad CH_3I + \left.\begin{matrix}CH_3\\CH_3\\H\end{matrix}\right\}N = HI + \left.\begin{matrix}CH_3\\CH_3\\CH_3\end{matrix}\right\}N$$

To these bodies the names of methylamine, dimethylamine, and trimethylamine were respectively given. They resemble ammonia in being volatile alkaline liquids or gases, which combine with acids to form crystallisable and well defined salts.

Hitherto, these compound ammonias have been chemical curiosities; they have, however, recently become—as has so often been the case in other instances—of great commercial importance, and are now manufactured on a large scale.

We are all well aware that the French beet-root sugar industry is one of great magnitude, and that it has been largely extended in late years. In this industry, as in the manufacture of cane-sugar, large quantities of molasses or treacle remain behind after the whole of the crystallisable sugar has been withdrawn. These molasses are invariably employed to yield alcohol by fermentation. The juice of the beet, as well as that of the sugar-cane, contains, in addition to the sugar, a large quantity of extractive and nitrogenous matters, together with considerable quantities of alkaline salts. In our sugar-producing colonies, the waste liquors or spent-wash from the still—called *vinasses* in French—are wastefully and ignorantly thrown away instead of being returned to the land as a fertiliser, and thus the soil becomes impoverished.

In France it has long been the custom of the distiller to evaporate these liquors (*vinasses*) to dryness, and calcine the mass in a reverbatory furnace, thus destroying the whole of the organic matter but recovering the alkaline salts of the beet-root. In this way 2,000 tons of carbonate of potash are annually produced in the French distilleries. More than thirty years ago the idea was entertained of collecting the ammonia-water, tar, and oils which are given off when this organic matter is calcined, but the practical realisation of this project has only quite recently been accomplished, and a most unexpected new field of chemical industry thus opened out through the persevering and sagacious labours of M. Camille Vincent, of Paris.

The following is an outline of the process as carried out at the large distillery of Messrs. Tilloy, Delaune, and Co., at Courrières. The spent-wash, having been evaporated until it has attained a specific gravity of 1·81, is allowed to run into cast-iron retorts, in which it is submitted to dry distillation. This process lasts four hours, the volatile products pass over, whilst a residue of porous charcoal and alkaline salts is left behind in the retort. The gaseous products given off during the distillation are passed through coolers, in order to condense all the portions which are liquid or solid at the ordinary temperature, and the combustible gases pass on uncondensed, and to serve as fuel for heating the retorts.

The liquid portion of the distillate is a very complex mixture of chemical compounds resembling, in this respect, the corresponding product in the manufacture of coal gas. Like this latter, the liquid distillate from the spent-wash may be divided into—1. The ammonia water; 2. The tar. The ammonia water of the vinasses resembles that of the coal-gas manufacture, in so far as it contains the carbonate, sulphydrate, and hydrocyanide of ammonia; but it differs from this (and approximates to the products of the dry distillation of wood) by containing, in addition, methyl alcohol, methyl sulphide, methyl cyanide, many of the members of the fatty acid series, and, most remarkable of all, *large quantities of the salts of trimethylamine.*

The tar, on redistillation, yields more ammonia water, a large number of oils, the alkaloids of the pyridene series, solid hydrocarbons, carbolic acid, and lastly, a pitch of fine quality.

The crude alkaline aqueous distillate is first neutralised by sulphuric acid, and the saline solution evaporated, when crystals of sulphate of ammonia are deposited, and these, after separating and draining off, leave a mother-liquor, which contains the more soluble sulphate of trimethylamine. During the process of

[1] Lecture given at the Royal Institution by Prof. Roscoe, LL.D., F.R.S., February 21, 1879. Revised by the Author.

concentration, vapours of methyl alcohol, methyl cyanide and other nitriles, are given off, these are condensed and the cyanide used for the preparation of ammonia and acetic acid by decomposing it with an alkali.

Trimethylamine itself is at present of no commercial value, though we are not without hopes that a useful employment for this substance may soon be found. The question arises as to how this material can be made to yield substances capable of ready application in the arts. This problem has been solved by M. Vincent in a most ingenious way. He finds that the hydrochlorate of trimethylamine, when heated to a temperature of 260°, decomposes into (1) ammonia, (2) free trimethylamine, and (3) chloride of methyl:—

$$3NMe_3HCl = 2NMe_3 + NH_3 + 3MeCl.$$

By bubbling the vapours through hydrochloric acid, the alkaline gases are retained, and the gaseous chloride of methyl passes on to be purified by washing with dilute caustic soda and drying with strong sulphuric acid. This is then collected in a gasholder, whence it is pumped into strong receivers and liquefied. The construction of one of these is shown in Fig. 1. They consist of strong wrought-iron cylinders, tested to resist a pressure of 20 kilos per square centimeter, and containing 50, 110, or 220 kilos of chloride of methyl. The liquid is drawn from these receivers by opening the screw tap (D), which is covered by a cap (C) to prevent injury during transit.

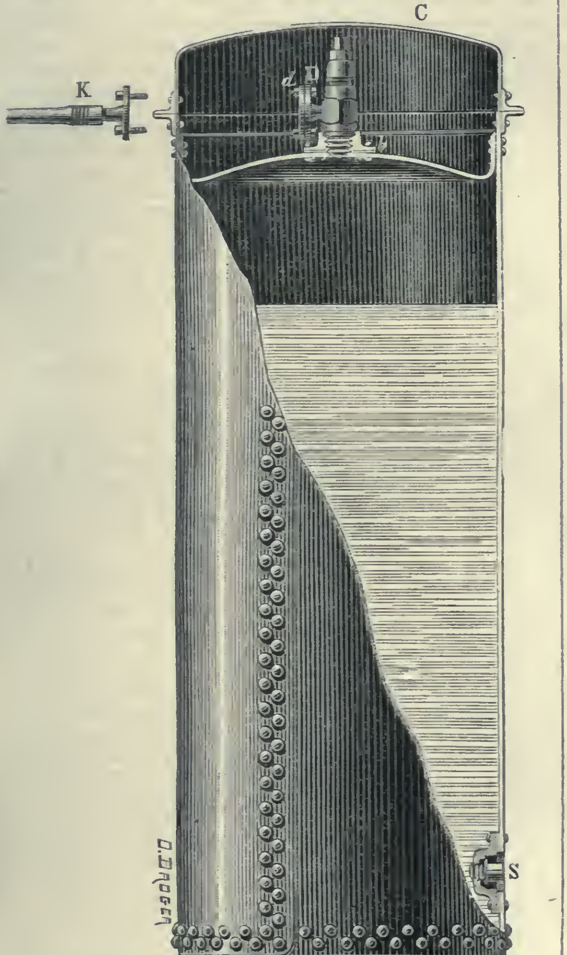

FIG. 1.

Both ammonia and chloride of methyl are, however, substances possessing a considerable commercial value. The latter compound has up to this time, indeed, not been obtained in large quantities, but it can be employed for two distinct purposes —1. It serves as a means of producing artificial cold. 2. It is most valuable for preparing certain methylated dyes, which are at present costly, inasmuch as they have hitherto been obtained by the use of methyl iodide, an expensive substance.

Methyl chloride was discovered in 1840 by MM. Dumas and Peligot, who obtained it by heating a mixture of common salt, methyl alcohol, and sulphuric acid. It is a gas at the ordinary temperature, possesses an ethereal smell and a sweet taste, and its specific gravity is 1·738. It is somewhat soluble in water (about 3 volumes), but much more in acetic acid (40 volumes), and in alcohol (35 volumes). It burns with a luminous flame tinged at the edges with green, yielding carbonic and hydrochloric acids. Under pressure, methyl chloride can readily be condensed to a colourless, very mobile liquid, boiling at −23 C. under a pressure of 760 mm. As the tension of the vapour is not high, and as it does not increase very rapidly with the temperature, the liquefaction can be readily effected, and the collection and transport of the liquefied chloride can be carried on without danger. The following table shows the tension of chloride of methyl at varying temperatures:—

At 0°	the tension of	CH_3Cl is	2·48	atmospheres.
,, 15°	,,	,,	4·11	,,
,, 20°	,,	,,	4·81	,,
,, 25°	,,	,,	5·62	,,
,, 30°	,,	,,	6·50	,,
,, 35°	,,	,,	7·50	,,

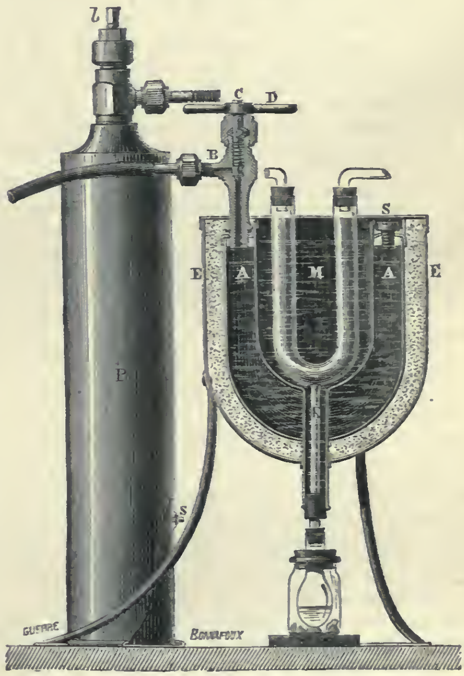

FIG. 2.

From these numbers we must of course subtract 1 to obtain the pressure which the vapour exerts upon the containing vessel.

As a means of producing low temperatures chloride of methyl will prove of great service both in the laboratory and on a larger industrial scale. When the liquid is allowed to escape from the receiver into an open vessel, it begins to boil, and in a few moments the temperature of the liquid is lowered by the ebullition below −23°, the boiling-point of the chloride. The liquid then remains for a length of time in a quiescent state, and may be used as a freezing agent. By increasing the rapidity of the evaporation by means of a current of air blown through the liquid, or better, by placing the liquid in connection with a good air-pump, the temperature of the liquid can in a few minutes be reduced to −55°, and large masses of mercury easily solidified.

The construction of a small copper receiver and of the freezing-machine employed by M. Camille Vincent is shown in Fig. 2. It consists of a double-cased copper vessel, between the two sides of which the methyl-chloride is introduced. The central space is filled with some liquid such as alcohol, incapable of solidification. The chloride of methyl is allowed to enter by the screw-tap (B), and

the screw (S) left open to permit of the escape of the gas. As soon as the whole mass of liquid has been reduced to a temperature of $-23°$ the ebullition ceases, the screw (S) may be replaced, and if a temperature lower than $-23°$ be required the tube (B) placed in connection with a good air-pump. By this simple means a litre of alcohol can be kept for several hours at temperatures either of $-23°$ or $-55°$, and thus a large number of experiments can be performed for which hitherto the expensive liquid nitrous oxide or solid carbonic acid was required.

M. Camille Vincent has recently constructed a much larger and more perfect and continuous form of freezing-machine, in which, by means of an air-pump and a forcing-pump, the chloride of methyl is evaporated in the freezing-machine, and again condensed in the cylinders. This enlarged form of apparatus will probably compete favourably with the ether- and sulphurous acid freezing-machines now in use, as they can be simply constructed, and as the vapour and liquid employed does not attack metal, is non-poisonous, and as the frigorific effects which it is capable of producing are most energetic.

The second and perhaps more important application of methyl-chloride is to the manufacture of methylated colours.

It is well known that rosaniline or aniline red, $C_{20}H_{19}N_3$, yields compounds possessing a fine blue violet or green colour, when a portion of the hydrogen has been replaced by the radicals, methyl or ethyl, and the larger the proportion of hydrogen replaced, the deeper is the shade of violet produced. Then we have triethyl rosaniline, or Hofmann's[1] violet, $C_{20}H_{16}(C_2H_5)_3N_3$.

By the replacing one or two atoms of the hydrogen of aniline by methyl, and by oxidising the methyl-aniline, Charles Lauth obtained fine violet colours, whilst about the same time Hofmann observed the production of a bright green colouring matter now known as iodine green, formed during the manufacture of the violet, and produced from this latter colour by the action of methyl-iodide.

In order to prepare aniline green from the pure chloride of methyl a solution of methyl-aniline violet in methyl-alcohol is placed in an iron digester, and the liquid rendered alkaline by caustic soda. Having closed the digester, a given quantity of liquid chloride of methyl is added by opening a tap, and the digester thus charged is placed in a water bath, heated by a jet of steam until the temperature reaches 95°, and the indicated pressure amounts to from 4 to 5 atmospheres. As soon as the reaction is complete the hot water is replaced by cold, and the internal pressure reduced by opening the screw-tap of the digester. The product of this reaction, heated and filtered, yields the soluble and colourless base, whose salts are green. To the acidified solution a zinc-salt is added to form a double salt, and the green compound is then precipitated by the addition of common salt. By adding ammonia to a solution of the methyl green salt, a colourless liquid is obtained in which cloth mordanted with tannic acid and tartar-emetic becomes dyed green (R. S. Dale).

If rosaniline be substited for methyl-aniline in the preceding reaction, Hofmann's violet is obtained. The application of methyl-chloride to the preparation of violets and greens is, however, it must be remembered, not due to M. Vincent; it has been practised for some years by various aniline colour makers. M. Vincent's merit is in establishing a cheap method by which perfectly pure chloride of methyl can be obtained, and thus rendering the processes of the manufacture of colours much more certain than it has hitherto been. By the use of th's material the aniline can be methylated in simple cast-iron boilers heated by steam, and under a pressure much more moderate than is otherwise required.

In reviewing the new chemical industry of the beet-root vinasses one cannot help being struck by the knowledge and ability which have been so successfully expended by M. Camille Vincent, on the working out of the processes. Here again we have another instance of the utilisation of waste chemical products and of the preparation on a gigantic scale of compounds hitherto known only as chemical rarities. All those interested in the progress of scientific research must congratulate M. Camille Vincent on this most successful issue of his labours.

ILLUMINATION IN SPECTROSCOPY[2]

AFTER having shown how intrinsic brilliancy of the light operated on was the chief visual step to excellence in spectroscopic observations, the author proved that the temperature of the light must be kept constant, or we might be landed in a totally different class of physical phenomena of a most confounding character.

Coming, then, practically to *flame*-spectroscopy, he described the results hitherto obtained by all the leading spectroscopists respecting the peculiar lines and bands, all of them very faint, of the blue-grey blowpipe flame of coal-gas and common air; and then showed how, by merely looking at one and the same flame *end-on*, in place of transversely, according to the usual custom, all the features hitherto chronicled may be seen some five times brighter; while many other details not dreamt of before come into view, and the temperature remains undisturbed.

Next applying the same principle to the electric-spark illumination of gas-vacuum tubes, a still greater proportional improvement was obtained. But not until the author had invented or arranged a new description of such tubes, which rendered the application of the end-on principle possible. Examples of these new tubes, as prepared lately for the author by M. Salleron, 24, rue Pavée au Marais, Paris, were exhibited; and several proofs of their superior brightness of illumination were given. The last being that in a narrow and critical region of a rather faint and difficult carbonaceous spectrum, where the Royal Society, London, has published eight lines only, and those dark ones—the new tubes showed thirty-one lines, and all of them bright ones. As yet the author had only been able to get twelve different gases thus prepared; but with such decided improvement of spectroscopic vision in every case, that he hopes so increased a demand may soon flow in upon M. Salleron, as will make it worth his while to prepare similar end-on tubes of all known volatile products; and the result can hardly but prove most favourable to the progress of spectroscopic science.[1]

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

DR. J. H. BALFOUR, Professor of Botany in the Edinburgh University, has resigned his chair, which he has filled since 1845, on account of failing health. The patronage of the Chair of Botany is vested in the curators of the University. Among the candidates for the chair, we learn, are Mr. Carruthers, Prof. Dickson, of Glasgow, Mr. J. Bailey Balfour, and Prof. McNab, of Dublin.

THERE was much fine talk last Wednesday at the Mansion House on the subject of University extension in London, and it was pleasing to see a prince take an apparently genuine interest in the intellectual advancement of the people. We sincerely hope that the movement may lead to a substantial and durable result, though we very much doubt it. What we want most in London is a true university after the German model, not a "Cambridge extension." We are glad that Prince Leopold, in his really able address at the Birkbeck Institution on Tuesday, insisted so strongly on the weak point of the British workman, and that he can only hope to hold his own by the side of the foreign workman by starting with an equally good education.

AT the annual meeting of the trustees of the Birmingham Science College, under the presidency of the founder, Sir Josiah Mason, who celebrated on Monday his eighty-fourth birthday, it was announced that the college building, a handsome Gothic structure in the rear of the Birmingham Town Hall, is rapidly approaching completion, and the formal opening will probably be made on the founder's next birthday. Nearly 150,000*l*. has been expended on the college building and endowment.

SCIENTIFIC SERIALS

American Journal of Science and Arts, February.—We have here two interesting papers on acoustics. Mr. Jacques has inquired into the velocity of loud sounds, measuring the velocity at different short distances from a cannon by means of a series of membranes electrically connected with a chronograph. He finds that the velocity of sound is a function of its intensity, and that experiments in which a cannon is used contain an error, probably due to the bodily motion of the air near the cannon. Immediately in the rear of the cannon the velocity was less than at a distance, but, going from the cannon, the velocity rose to a maximum considerably above the ordinary velocity, and then fell gradually to the rate usually received. When the cannon was pointed

[1] Hofmann, *Proc.* Roy. Soc., xiii. 13 (1863).

[2] Abstract of paper upon "End on, in Place of Transverse, Illumination in Private Spectroscopy," by Mr. Piazzi Smyth, Past President of R. Sc. Soc. Arts. Edinb., February 10, 1879.

[1] Tubes similar to those referred to are already well-known in England; Dr. Monckhoven has in fact pointed out the value of such tubes, and sent specimens to several observers in England.—ED.

at right angles to its first position, the maximum velocity came nearer it, and had the cannon been pointed towards the membranes, the retardation would probably have become an acceleration.—Dr. Ihlseng has measured the velocity of sound in wood, both by Kundt's method and the graphic method, in which latter a blackened glass plate was drawn rapidly in a horizontal direction (across the direction of the rod's length), by a falling weight, and a pen attached to the rod wrote its vibration on the plate, which also registered those of a tuning-fork. This method was found one of considerable accuracy. Its results were slightly below those by Kundt's method, and (when the plate was moved in a different direction) it demonstrated the existence of transverse along with longitudinal, and gave their ratios.—Mr. Pumpelly writes on the relation of secular rock disintegration to lœss, glacial drift, and rock basins; Mr. Fontaine continues his notes on the mesozoic strata of Virginia; and Mr. Hawes describes a group of dissimilar eruptive rocks in Compton, New Hampshire.—In a method of determining dip, devised by Mr. Hodges, a compound bar is used consisting of two joined at right angles at a point near their ends; when placed so that the two branches make equal angles with the line of dip, the two joined poles neutralise each other, and any needle suspended near that point is unaffected. A slight turning of the compound bar renders the field round the needle a north or a south, and the needle moves correspondingly.—Some notices of recent American earthquakes are furnished by Prof. Rockwood, Jun.

Journal de Physique, January.—This number opens with M. Joubert's researches on the rotatory power of quartz and its variations with the temperature; they prove that quartz constitutes a thermometer of extreme sensibility.—A new and simple regulator of velocity, for electric motors especially, described by M. Deprez, rests on the principle of centrifugal force acting on one end (loaded) of a flexible metallic strip, and (with a certain intensity) breaking contact of an adjusting screw at that end with a metallic piece, and so stopping a current which actuates the motor.—M. Witz studies the thermal effects of the walls of an inclosure on the gases it contains.—M. Pellat describes an apparatus for effecting the synthesis of compound colours, the very colours of the spectrum being taken in the desired proportions and mixed completely: and M. Schwedoff one for studying the vibratory movements of cords, the cord being set in motion by means of an electric trembler at one end.

THE *Sitzungsberichte der naturwissenschaftlichen Gesellschaft Isis in Dresden* (1878, part 1, January to July) contain the following papers of interest:—On Heligoland and Norderney from a geological point of view, by C. D. Carstens.—On the tertiary flora of the Klein Purberg near Czernowitz, by Herr Engelhardt.—On amber, by Dr. O. Schneider.—On the saltpetre and the guano from the Atakama Desert, by Herr Weis.—On fossil man, by Herr Engelhardt.—On some prehistoric remains discovered on the Hradischt in Bohemia, by W. Osborne.—On palm leaves, by Herr von Biedermann.—On the largest elm tree of Germany, by C. F. Seidel. The tree in question stands in the village of Schimsheim near the railway station of Armsheim in Rhenish Hessen, and measures 30 metres in height, its trunk 15·07 metres in circumference, while its age is estimated at close upon 600 years.—On the colour which a gas flame assumes in the vapour generated by a mixture of permanganate of potash and sulphuric acid, by Carl Bley.—On the formation of crude coralline and of resorcine-oxalëine, by Dr. Schmitt.—On the action of ethyl mercaptan on diazo-compounds, by the same.—On a curious occurrence of tape-worms, by Herr Ebert.—On a Chinese work on insects, by C. F. Seidel.—On the origin of organic life upon the earth, by Dr. Steil.—On the red gneiss near Freiberg in Saxony, by Dr. Geinitz.—On the natural history of the Caucasus countries, by Dr. Oscar Schneider.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, January 30.—"On the determination of the Rate of Vibration of Tuning Forks," by Herbert McLeod, F.C.S., and George Sydenham Clarke, Lieut. R.E. Communicated by Lord Rayleigh, F.R.S.

The paper contains a description of some experiments made with a view to determine the absolute pitch of tuning forks by means of a method proposed by the writers in a previous paper (*Proc.* Roy. Soc., 1877, xxvi. 162).

It commences with a description of the time-measurer adopted, consisting of a compensated pendulum, worked by electricity, the impulse being given by a driver depending for its action on gravity alone. The pendulum is arranged to give second contacts, driving a clock-wheel with sixty teeth. This wheel has a platinum pin giving minute contacts, but it is used merely as a switch, the circuit being closed by the pendulum itself. The current works a relay, and closes the circuit required.

The tuning-fork apparatus consists of a brass drum resting on friction-wheels, and driven by a weight and train. Uniformity of motion being of great importance, an air-regulator, consisting of a fan inclosed in the lower compartment of a cylindrical box, is employed. By means of a diaphragm and vanes the fan can be made to do more or less work by pumping air from the lower into the upper compartment. The fan spindle carries a pulley driven by a thread passing round the drum.

Round one end of the drum are wrapped strips of paper on which white equidistant lines have been so ruled that they are parallel to the axis of the drum when the strips are in position. The strip most frequently used has 486 lines round the complete circumference of the drum. Opposite this graduated strip is placed a microscope with its axis horizontal. In the substage is placed a 2″ objective, producing an image of the graduations at the focus of the object-glass of the instrument. At the common focus of the two lenses is placed the tuning-fork, the stem of which is held vertical in a vice. The fork is partially inclosed in a glass case, and is so adjusted that the image of one of its limbs seems to cut the image of the graduations at right angles. The fork is set in motion by a suspended double-bass bow. If, when the fork is in vibration the drum is made to rotate with such a velocity that one of the graduations passes over the interval between two adjacent graduations in the time of one vibration of the fork, a stationary wave is seen of length equal to the length of that interval. To determine the number of vibrations of the fork in a given time, it is only necessary, therefore, to be able to count the number of graduations which pass in that period. As a perfectly uniform rotation has not been obtained, a regulator under the control of the operator is employed. This consists merely of a piece of string which passes round the axis of the drum, and also round a pulley which can be turned by the operator's left hand. An upward or downward motion of the wave denotes that the drum is going too fast or too slow, and by means of the pulley a gentle check or acceleration sufficient to keep the wave steady is given to the drum.

An electric counter gives the number of complete revolutions accomplished by the drum in any given period, and a fine-pointed tube, containing magenta, is carried by a saddle above the drum, and being actuated by an electro-magnet, makes a dot on a piece of white paper wrapped round the drum at the beginning and end of the experiment. The distance apart of these dots gives the additional fraction of a revolution accomplished by the drum during the period of the experiment. Electric circuits are so arranged that a reverser turned a few seconds before the minute at which it is intended to begin the experiment, causes a current to be sent exactly at that minute by the clock relay, which starts the electric counter, and also makes a dot on the drum. Just before the expiration of the last minute of the experiment the reverser is turned in the opposite direction, and at the expiration of that minute the counter is stopped, and a second mark made on the drum.

Some of the results obtained with different forks are given. The results of further experiments made to determine the effect of temperature, of continuous and intermittent bowing, and of the mode of fixing the fork are appended.

An optical method by which two slightly dissonant forks may be compared without altering the period of either, is described.

Figures and diagrams fully explaining the apparatus employed accompany the paper.

February 13.—"Note on the Development of the Olfactory Nerve and Olfactory Organ of Vertebrates." By A. Milnes Marshall, M.A., D.Sc., Fellow of St. John's College, Cambridge. Communicated by W. S. Savory, F.R.S., Surgeon to, and Lecturer on Surgery at, St. Bartholomew's Hospital.

In the course of an investigation into the development of the cranial nerves of the chick, certain facts came to light indicating that the olfactory nerve, instead of being, as usually described, a structure differing totally in its mode of origin from all the other nerves in the body, in reality "exactly corresponds in mode of development with the other cranial nerves, and with the posterior roots of the spinal nerves." [1]

[1] *Proc.* Roy. Soc, March 8, 1877, p. 50, and *Quarterly Journal of Microscopical Science*, January, 1878, pp. 17-23.

The present paper contains the results of further investigations on this point; it deals also with some features in the development of the vertebrate olfactory organ, and with certain questions of a more general nature affected by the conclusions arrived at.

The Development of the Olfactory Nerve

The olfactory nerve of an adult vertebrate is usually described as consisting of three parts—a proximal *tractus olfactorius*, an intermediate *bulbus olfactorius*, and a distal *nervus olfactorius*, connecting the bulb with the olfactory organ. Of these parts the two former are commonly said to arise as a hollow diverticulum of the cerebral hemisphere—the so-called olfactory vesicle or olfactory lobe. The third part, the *nervus olfactorius*, is described as arising at a later stage either from the olfactory lobe, from the olfactory organ, or from the intervening mesoblast. In consequence of these peculiarities in its mode of development, the olfactory nerve is said not to bear the slightest resemblance to the other cranial nerve, and to be in no way comparable with them. Dr. Marshall, however, finds, from an examination of a large number of vertebrate embryos—chick, dogfish, salmon, trout, axolotl, frog, and lizard—that the *nervus olfactorius* is the first part to be developed; that it arises at the same time as the other cranial nerves and in the same manner; that it appears before the cerebral hemispheres, and consequently arises from the original fore-brain. He finds further that there is no trace whatever of an olfactory vesicle in the chick till the end of the seventh day, or in the dogfish till stage O of Balfour's nomenclature; in the salmon and trout there is no trace of an olfactory vesicle up to the time of hatching, nor indeed, for some time afterwards. Mr. Marshall maintains that the olfactory vesicle must therefore be regarded as a structure of merely secondary importance; and that the olfactory nerves, since in their early stage they do not differ embryologically in any respect from the segmental cranial nerves, must be regarded as the first or most anterior pair of true segmental nerves.

The Development of the Olfactory Organ

This will, in the absence of figure, be treated very briefly; those points only being noticed which are of special interest in connection with the conclusions arrived at in the preceding part of the paper.

The olfactory pits appear at almost the same time as the visceral clefts; or, to speak more accurately, they first become conspicuous objects at, or very shortly after, the time when the anterior visceral clefts become open to the exterior. This occurs about stage K in the dogfish, and about the fiftieth hour in the chick.

In their early stages the olfactory pits present a striking resemblance to the visceral clefts in position, shape, size, and general relations; their external apertures elongate and become slit-like, and the direction of the slit, like that of the visceral clefts, is at right angles to the longitudinal axis of the head. These facts are best illustrated by the study of whole embryos, and of longitudinal vertical sections.[1] They come out with great clearness in all the types of vertebrates examined, but with especial distinctness in the axolotl and salmon.

The development of the Schneiderian folds presents several points of great interest, which can be most favourably studied in the elasmobranchs. Attention has already been directed by Balfour[2] to the very early appearance of these folds. The important point, so far as the present question is concerned, is that these Schneiderian folds appear at the same time as, or very shortly after, the first rudiments of the gills. In addition to this identity in time, there is also identity in structure; in both cases development consists in the formation of a series of equal, closely apposed folds, mainly epithelial, but involving the underlying mesoblast to a certain extent. These folds are in the two cases—gills and Schneiderian folds—of the same width, the same distance apart, have epithelium of the same thickness and same histological character, involve the mesoblast to exactly the same extent, and in exactly the same manner; in a word, are structurally identical.

In the later stages the Schneiderian folds, like the gills, receive a very abundant supply of blood-vessels; and the relations of these vessels to the folds, which are very peculiar and characteristic, are identical in the two cases. Even in the adult elasmobranch there is a remarkable histological resemblance between the gills and the nose.

[1] For figures of whole embryos illustrating the points referred, *vide* Parker, "On the Structure and Development of the Skull in Sharks and Skates," *Trans.* Zool. Soc., vol. x. part iv., 1878; Pl. 25, Fig. 1; Pl. 39, Figs. 1 and 2; Pl. 40, Fig. 1; and Balfour, *op. cit.*, Pl. 7, Stage L.

[2] *Op. cit.*, p. 184, and Pl. 44, Fig. 14.

The facts above recorded concerning the development of the olfactory nerve and olfactory organ point towards the same conclusions as to the morphology of these structures, viz., that the olfactory organ is a visceral cleft; that the olfactory nerve is the segmental nerve supplying that cleft in a manner precisely similar to that in which the hinder clefts are supplied by their respective nerves; and that the Schneiderian folds are gills.[1]

These conclusions, if accepted, will considerably simplify our conception of the segmentation of the vertebrate head. As there are no nerves or clefts in front of the olfactory segment, the olfactory nerve must be taken as the most anterior nerve, and the nose as the most anterior cleft. The next cleft is that in front of the maxillo-palatine arch, of which a part probably persists in the adult as the lachrymal duct: the segmental nerve corresponding to this cleft is the *third*, or oculomotor nerve. Next comes the mouth cleft, supplied by the *fifth*, or trigeminal nerve; and then in succession the clefts supplied by the facial, glossopharyngeal, and pneumogastric nerves. This view of the constitution of the vertebrate head is found to accord well with the later researches of Prof. Parker on the morphology of the skeletal elements of the head.

Some at least of the labial cartilages will probably prove, on this view, to be homologues of the extrabranchials, a comparison that has already been made by Prof. Parker.[2]

If the olfactory organs are visceral clefts, they must originally have communicated with the mouth cavity. Indications of a former connection of this kind are by no means wanting; thus in salmon embryos the alimentary canal extends forwards, so as to underlie the nasal sacs; as development proceeds, this anterior prolongation of the mouth cavity gradually shrinks; it persists for a short time as a pair of cæcal diverticula, which ultimately disappear altogether.

In conclusion, it may be noted that the Schneiderian folds afford an instance, on the theory here maintained, of structures originally hypoblastic in nature becoming, from changed circumstances, epiblastic.

"On an Extension of the Phenomena discovered by Dr. Kerr and described by him under the title of 'A New Relation between Electricity and Light.'" By J. E. H. Gordon, B.A., Assistant Secretary of the British Association. Communicated by Prof. Tyndall, F.R.S.

In November, 1875, Dr. Kerr announced in the *Philosophical Magazine*, that he had discovered a new relation between electricity and light. He showed that when glass is subjected to an intense electrostatic stress that a strain is produced which causes the glass to act like a crystal upon polarised light.

On Wednesday, February 5, 1879, I was working at this experiment in the Royal Institution, and endeavouring, by means of the electric light, to project the effect on a screen, in preparation for a lecture on the next day.

In the experiment as described by Dr. Kerr, and which was shown plainly on the screen, on February 6, the light is extinguished by the Nicols, and reappears when the coil is set going.

In the projection experiment a patch of moderately bright white light, about 3 inches diameter, appeared on the screen when the coil was worked. The images of the points inside the glass were about 1½ inches apart. On Wednesday, however, the electrostatic stress was accidentally allowed to become strong enough to perforate the glass. Immediately before perforation there occurred the effects which are the subject of the present communication.

First appeared a patch of orange-brown light about six or seven inches diameter. This at once resolved itself into a series of four or five irregular concentric rings dark and orange-brown, the outer one being perhaps fourteen inches diameter. In about two seconds more these vanished and were succeeded by a huge black cross about three feet across, seen on a faintly luminous ground. The arms of the cross were along the planes of polarisation, and therefore (the experiment being arranged according to Dr. Kerr's directions) were at 45° to the line of stress.

The glass then gave way, and all the phenomena disappeared except the extreme ends of the cross, and the discharge through the hole, where the glass had been perforated, was alone seen.

The phenomena were seen by Mr. Cottrell, by Mr. Valter (the second assistant), and by myself. A fresh glass plate was

[1] Cf. Dohrn, "Ursprung der Wirbelthiere," p. 23.

[2] *Proc.* Zool. Soc., vol. x. part iv., 1878, p. 212.

at once drilled in hopes of repeating the phenomena in the lecture next day, but owing to sparks springing round we did not succeed in perforating the glass, and therefore saw only the faint return of light described by Dr. Kerr.

Some more glasses have been prepared and their terminals insulated, and I now propose to make another attempt to repeat the new effects before the Royal Society.

Zoological Society, February 18.—Prof. W. H. Flower, F.R.S., president, in the chair.—The Secretary exhibited, on behalf of the Rev. T. O. Morris, an example of *Bombyx quercûs* with malformed antennæ.—Mr. Sclater exhibited a new humming bird from Northern Peru, which he had received for identification from M. L. Taczanowski, C.M.Z.S., and which he proposed to name *Thaumatius taczanowskii*.—Mr. Sclater exhibited a living amphisbænian (*Bronia brasiliana*) lately received by the Society from Monte Video.—A communication was read from Mr. E. L. Layard, C.M.G., F.Z.S., containing a note on *Pachycephala icteroides*, Peale, with the description of a supposed new species of the genus from Ovalau, Fiji group, proposed to be called *P. neglecta*.—A communication was read from Dr. A. Günther, F.R.S., containing a description of four new species of chameleons from Madagascar, proposed to be called *Ch. malphe, Ch. brevicornis, Ch. gularis*, and *Ch. globifer*.—A communication was read from Mr. Edgar A. Smith, F.Z.S., containing a description of a large collection of mollusca from Japan, formed by Capt. H. C. St. John, R.N., of H.M.S. *Sylvia*.—Messrs. Godman and Salvin read descriptions of a number of new species of butterflies from Central and South America.—A second communication from the same authors gave an account of a collection of butterflies made by the Rev. G. Brown in New Ireland and New Britain.—Mr. A. G. Butler gave an account of the Heterocera contained in a collection from the same locality.—A communication was read from Mr. W. A. Forbes on the systematic position of the genus *Lathamus*, in which, from a study of its pterylosis, osteology, and other points in its external and internal structure, he showed that this parrot must be referred to the neighbourhood of the *Platycercidæ*.—Mr. R. Bowdler Sharpe read a note on *Heliodilus soumagnei*, Grandidier, of which a specimen had recently been acquired by the British Museum.—Mr. Sharpe likewise pointed out the characters of a second species of the genus *Dromæocercus*, from Madagascar, proposed to be called *D. seebohmi*.—A communication was read from Mr. A. Boucard, C.M.Z.S., containing descriptions of two supposed new species of South American birds.—Dr. F. Day read some remarks on the occurrence at Southend of the little gurnard, *Trigla pœciloptera*.

Meteorological Society, February 19.—Mr. C. Greaves, president, in the chair.—Eleven new Fellows were elected and thirteen candidates proposed.—The following papers were read:—Diurnal variations of barometric pressure in the British Isles, by Frederick Chambers. The object of this paper is to show that differences of types of the diurnal variations of pressure at inland or sea-coast stations are due to the superposition, on a common type of diurnal variation at all the stations, of a distinct diurnal variation of barometric pressure, such as is required to satisfy the convection-current theory which explains the well-known diurnal land and sea breezes. To show this, all that is necessary is to take the differences of the corresponding hourly inequalities of the barometric pressure at pairs of inland and coast stations, and to exhibit these differences in the form of curves, which are then found to closely resemble the curves of diurnal variation of air temperature.—On a standard cistern siphon barometer, by Frederick Bogen.—On the relation existing between the duration of sunshine, the amount of solar radiation, and the temperature indicated by the black bulb thermometer in vacuo, by G. M. Whipple, B.Sc., F.R.A.S. The author has instituted a comparison between the duration of sunshine, as determined by Campbell's sunshine recorder, and the amount of solar radiation, as ascertained from the readings of the black bulb thermometer in vacuo, for the year 1877, at the Kew Observatory. It is evident that there is a close relation between these phenomena, but owing to the great range of the black bulb thermometer, the exact nature of the connection is not immediately evident. The author says that it may be safely concluded that the measure of solar radiation as given by the black bulb thermometer is only to be considered at any place as an indication of the relative presence or absence of cloud from the sky at the locality, and so its use as a meteorological instrument may with advantage be set aside in favour of the sunshine record, which has not the elements of uncertainty attached to it, inseparable from the former instrument.—Results of meteorological observations made at Buenos Ayres, by William B. Tripp, Assoc. Inst. C.E.

Anthropological Institute, February 11.—Prof. W. H. Flower, LL.D., F.R.S., vice-president, in the chair.—The election of Sir Henry Sumner Maine, K.C.S.I., LL.D., F.R.S., as a Member, was announced.—Prof. W. H. Flower, LL.D., F.R.S., exhibited and described a scaphocephalic cranium from Fiji, and Mr. A. L. Lewis exhibited a series of implements and photographs from Australia.—Mr. John E. Price read a paper on the Australian Aborigines, by Mr. D. Macallister. After describing their social and domestic observances, traditions, and religious notions, the author concluded that he had no doubt that had the continent of Australia remained undiscovered by Europeans for a few thousand years longer, the climatic and general physical changes which would doubtless have occurred, together with the contact at intervals with their more civilised Polynesian neighbours, would have constituted an environment more favourable to progress than any which has ever existed, and would have tended to an improved condition of the people. As it was, the total absence from the continent of ferocious or powerful animals, the comparative ease with which the poor and limited quantity of their food was obtained, and their national isolation, may have been a patent cause for the non-progressive character of the people.—The director also read a paper by Capt. W. E. Armit, F.L.S., on the customs of Australian Aborigines.

Entomological Society, February 5.—Sir John Lubbock, Bart., V.P.R.S., president, in the chair.—Messrs. H. W. Bates, J. W. Dunning, and F. Smith, were nominated vice-presidents for the ensuing year.—Mr. H. J. Elwes exhibited a collection of lepidoptera from a small island at the mouth of the River Amur.—Mr. Waterhouse exhibited a remarkable spider from West Africa, *Gasteracantha Cambridgei*, Butt.—A specimen of *Harpalus oblonguisculus*, taken at Weymouth, was exhibited by Mr. Champion.—The Rev. A. E. Eaton remarked on the peculiarities in the neuration of the wings of most of the *Ephemeridæ*, and exhibited drawings of wings of *Trichoptera* and *Tineina*, to show the homologies in the neuration of the same.—The Secretary read a note from Dr. Fritz Müller, recording a remarkable case of mimicry in the Brazilian butterfly, *Eueides pavana*, which mimics *Acræa thalia*. It is, however, in the male sex of *E. pavana* that the greatest resemblance to the *Acræa* is found.—The following papers were also communicated: On the lepidoptera of the Amazons, &c., Part iii., Noctuites, by A. G. Butler.—Description of a new genus of rhyncophorous coleoptera, &c., by C. O. Waterhouse; and descriptions of the species of the lepidopterous genus Kallima, by F. Moore.

Institution of Civil Engineers, February 18.—Mr. Brunlees, vice-president, in the chair.—The paper read was on the construction of heavy ordnance, by Mr. J. A. Longridge, M. Inst. C.E.

BOSTON

Society of Natural History, May 15, 1878.—The Devonian brachiopoda of the Province of Para, Brazil, by R. Rathbun, late assistant geologist to the Geological Commission of Brazil.

PHILADELPHIA

Academy of Natural Sicences, November 5, 1878.—Descriptions of Ichneumonidæ, chiefly from the Pacific slope of the United States and British North America, by E. T. Cresson.

November 12.—Descriptions of a new species of Delabella from the Gulf of California, with remarks on other sp cies, by R. E. C. Stearns.

November 26.—On the structure of the gorilla, by Dr. Chapman, dealing with the muscles of the extremities as found in a male of two years old.

BERLIN

Chemical Society, February 10.—At the close of Prof. Kopp's remarks (see p. 387), Herr Frank exhibited a mass of infusorial earth saturated with bromine. As this form of silica will take up eight or ten times its own weight of bromine, he claimed that this would be a convenient form of handling, weighing, and using this corrosive liquid. The speaker also stated that he had found petroleum to be a specific for the burns and stains of bromine.—Herr Baumann then exhibited a specimen of hydroquinon found in the form of hydroquinon-sulpho acid in

the urine of a dog poisoned with carbolic acid. This remarkable conversion, in the system, of a mono-phenol into a di-phenol, was less remarkable than the statement of the speaker that he had also found a compound of paracressol in the urine of a horse, where it had been produced from the ordinary food.

Vienna

Imperial Academy of Sciences, December 19, 1878.—The following, among other papers, were read:—Explanations of some orographic and topographic details of European Turkey, not rightly understood by geographers hitherto, by Dr. Boué.—Preliminary remarks on the formation of rational plane curves on one another, by Dr. Weyr.—Researches on the relations of nutritive matters to the transpiration of plants (second series), by Dr. Burgerstein.—On some chemical constants, by Prof. Peschka.—The theory of electrotonus, by Dr. Fleischl.—On the orbit of the planet (153) Hilda, by Herr Kühnert.

January 9.—Critical researches on the species of the natural family of *Cervi* (concluded), by Dr. Fitzinger.—On direct muscle-excitation with the muscle-current, by Prof. Hering.—On the magnetic behaviour of pulverised iron, by Prof. Waltenhofen.—Spectroscopic researches, by Herr Ciamician.—Determination of coefficients of elasticity from bending of a bar, by Prof. Pscheidl.—On a new water-wheel, by Herr Kersovini.—On a new problem of ballistics, by Dr. Simony.—The daily period of the velocity and direction of the wind, by Dr. Hann.—On the action of nitrous acid anhydride on protocatechuic acid, by Dr. Gruber.

January 16.—Natural history of the Flagellata (the third part of a work on Infusoria), by Prof. Ritter v. Stein.—On Dr. Rosicky's experiments with Geissler tubes, by Prof. Mach.—On the summation of stimuli by the heart, by Prof. Ritter v. Basch.—On condensation-products of gallus acid, by Prof. Oser and Herr Böcker.—Report on the results of investigations and excavations by the prehistoric commission during the past year.

Paris

Academy of Sciences, February 17.—M. Daubrée in the chair.—The following papers were read:—Meridian observations of small planets at the Greenwich and Paris Observatories during the fourth quarter of 1878, communicated by M. Mouchez.—Determination of the coefficient of elasticity of different substances and of their limit of elasticity, by M. Phillips. The method suggested is based, like a previous one, on the theory of a regulator spring, but the influence due to inertia of the spring is suppressed. The coefficient of M. Deville's new alloy of iridium is given.—New researches on electric fish; characters of the discharge of the gymnotus; effects of a torpedo's discharge sent through a telephone, by M. Marey. He finds the discharge of the gymnotus pretty similar to that of the torpedo, and it is similarly affected by temperature. Using the telephone, a gentle excitation of a torpedo produces a short croaking sound, each of the small discharges consisting of only a dozen fluxes, and lasting hardly $\frac{1}{15}$th of a second. But the sound from a prolonged discharge, caused by pricking the electric lobe of the brain, lasts three or four seconds, and is a kind of moan, the tonality being near *mi*, (165 vibrations).—On the project of the interior sea in Algeria, by M. Favé. The topographic levellings at Suez, on land, comparable to that of Sahara, were proved (M. Favé urges) to have sufficient exactness.—Does the didymium of samarskite differ from that of cerite? by M. Lecoq de Boisbaudran. Both, he finds, give the same three blue lines.—New spectral lines observed in substances extracted from samarskite, by the same. He finds new lines or bands (not described by MM. Delafontaine, &c.), both of emission and absorption, which correspond together (at least the principal), and belong apparently to some new body. He expresses high admiration of Prof. L. Smith's generosity in distributing to chemists in France and America, rare and arduously elaborated products which he had not completed the examination of.—On the measures taken by the Sanitary Intendance of Marseilles, in the fear of invasion by the plague, by M. de Lesseps. He argues that it is foolish and useless to hamper the commerce of Marseilles with quarantine, &c., as the disease is not contagious but infectious, spreading by emanations carried by the air; and it would not be likely to attack such a town. He points out that the plague in Lower Egypt in 1834-5 did not spread to Upper Egypt, though the communications were not interrupted. M. Bouley contended that where the plague had appeared in Western Europe, it had come by diseased persons or objects in contact with them. M. D'Abbadie thought M. Bouley too absolute in asserting that the Oriental plague always spread by contagion.—On the Foucault's top transformed into a gyroscopic pendulum, by M. Gruey.—On the determination of the number of double points of a space defined by algebraic conditions, by M. Saltel.—Application of the direct potentials of Lamé to calculation of the equilibrium of elasticity of an isotropic and indefinite homogeneous solid, solicited in a finite extent by any exterior forces, by M. Boussinesq.—On unequal propagation of light polarised circularly in bodies submitted to the action of magnetism, according to the nature of the magnetisation and the direction of the luminous vibrations, by M. Becquerel. The fact here stated he demonstrated experimentally. The displacement of interference fringes under the magnetic influence, was the criterion employed.—Researches on the compressibility of gases at high pressures, by M. Amagat. The method (in which a deep pit is resorted to has been already described. Under a pressure of 430 atmospheres (the greatest reached), the volume of nitrogen is nearly a fourth greater than that deduced from Mariotte's law; this corresponds to a difference of nearly 100 ctm. in the pressure necessary to get the reduction of volume deduced from this law.—Note on the phenomenon observed by M. Duter, by M. Korteweg.—Improvements in Harrison's electric lamp, by M. Ducretet. Apparatus inclosed in the supporting case regulates automatically the consumption of the carbons and keeps the luminous arc constant.—On the relations which unite tetric and oxytetric acids and their homologues to succinyle, malyle, and other radicals of bibasic acids, by M. Demarçay.—Bromocitraconic acid, by M. Bourgoin.—On the respiratory innervation in the poulpe, by M. Fredericq. The integrity of visceral nerves, the subœsophagean masses, and the palleate nerves, seem alone indispensable to normal production of respiratory movements.—On the functions of the ganglionic chain in decapod crustaceans, by M. Yung.—On the existence of Saigas in France in the age of the reindeer, by M. Gaudry. M. Lartet, several years ago, announced the discovery of horns of the animal, but thought these had been brought as arms by a strange people. Jaw-bones and bones of the limbs have now been found.—Geological study of strata traversed by a tunnel of 14,400 metres, for directly connecting the Fuveau basin of lignite with the sea, by M. Dieulafait.

COAL AND COAL-MINES

A Treatise on Coal, Mine-Gases, and Ventilation. By J. W. Thomas. (London: Longmans, 1878.)

MR. THOMAS is known to chemists by reason of the numerous and excellent analyses of the gases inclosed in various coals which he published some time ago in the *Journal* of the Chemical Society. Marsilly in France, and Meyer in Germany, first broke ground on this subject, but it is to Mr. Thomas, who very greatly improved the method of research, that we owe our most exact knowledge of the character of these occluded gases. The matter is of considerable importance from a twofold aspect. It not only serves to throw light upon the scientific question of the formation of coal, but also affords us information on the very practical question of the nature of the influence of the atmosphere upon the deterioration of coal. These observations attracted sufficient attention from mining engineers and persons connected with mining to induce the author to reprint them together with other matter relating to the general subject, and the result is the volume before us—a work which it is not too much to say ought to be in the hands of the manager and sub-officers of every colliery in the kingdom. Although the subjects of gases in coal and of the deterioration of coal by atmospheric influences are treated at considerable length, the relative or connected matter occupies by far the greater portion of the book, and we have chapters on the Diffusion and Transpiration of Gases, Explosions in Mines and Ships, Combustion, Ventilation, &c.

The opening chapter is occupied by a discussion of that most vexed of questions, What is Coal?—a question which has already cost some people much patience and more money to get answered, but hitherto without success. We are bound to say our author does not help us towards a solution; we are apparently as far off as ever from a scientific definition of this everyday commodity. His remarks on the classification of coals are extremely just. It is not surprising, from the author's connection with the South Wales Basin, that the particular subject of anthracite should receive special attention at his hands. The origin of this form of mineral fuel has given rise to much discussion in the past, but it is only within recent time that the opinion that it is not necessarily the oldest transition-product in the decay or alteration of vegetable matter has begun to gain ground. Our author throws considerable light on the process which has been at work in the formation of anthracite, from a study of the composition of the gases which are found inclosed in this class of coal. He regards the process of the formation of coal (after the first or primary decomposition which ensued during the time the vegetable matter was in the act of being buried) to have taken place in four ways, viz.:—

1. The dry process aided by heat, leading to the production of anthracite.
2. The dry process without much abnormal heat, to which the production of steam coal and Wigan cannel is due.
3. The wet process with heat, to which may belong the production of Scotch cannel and the more dense varieties of bituminous or house coals.
4. The wet process without long-continued heat, to which we may assign the formation of ordinary bituminous (house coals) and lignite.

With respect to the nature of the material from which coal has been originally derived, Mr. Thomas has little or nothing to add to what is commonly stated in popular works on the subject. To dismiss the spore-theory in some six or eight lines, with the assertion that "there is little evidence of a weighty character to confirm this hypothesis," is, in the light of existing facts, scarcely just to the researches of Carruthers, Morris, and Huxley. To say that all coal has been derived from lepidodendroid spores would unquestionably be incorrect, but to assert that many coals have been largely derived from such material is undoubtedly true. This much, we suppose by this time, is conceded by the majority of authorities on the subject: the difference between them is rather as to the proportionate part played by the spores.

As regards the character of the gas occluded in coal, this depends not merely upon the structure of the coal, but upon the conditions under which its formation has occurred and the depth below the surface at which it is situated. On the whole Mr. Thomas's analytical results agree fairly well with those of Dr. Meyer, in spite of the somewhat faulty method adopted by the latter; but the inferences which the two experimenters draw from their observations are not unfrequently opposed. There seems to be a decided difference between the gas inclosed in lignites and that found in coals of the older formations. Zitowitsch first detected carbonic oxide in some specimens of Bohemian lignites, and the author has detected the same gas in appreciable quantity in the well-known lignites of Bovey Heathfield, in Devonshire. On the other hand, no coal of the carboniferous period has been found to contain this gas. Another characteristic difference between the coals of the carboniferous and tertiary periods is seen in the absence of all hydrocarbons among the gases occluded in the latter varieties.

The presence of carbonic oxide in "after-damp" has been frequently surmised, but Mr. Thomas brings direct evidence to prove the fact. Until quite recently it was the general belief among chemists that when marsh-gas—the "fire-damp" of the miners—is mixed with less air than is required for complete combustion, only as much of the hydrocarbon is burnt as the oxygen present can convert into carbon dioxide and water. It is now found that when marsh-gas is exploded with a quantity of oxygen or air insufficient for complete combustion, the *whole* of the marsh-gas disappears into carbonic oxide, carbon dioxide, water, and free hydrogen. The importance of this observation is obvious. It has not unfrequently happened that after an explosion the expressions of the countenances of the victims, who have been found sitting or leaning in the most natural positions, have worn no trace of fear or intense anxiety, such as we should suppose would come upon them amidst the roar and wreck of the disaster. These men have not been asphyxiated by carbonic acid or drowned in excess of nitrogen: they have been struck down by the infinitely more deadly carbonic oxide. Instances too have occurred in which the explorers after an explosion have been almost as suddenly

overwhelmed, even when their lamps were burning freely. These facts point to an entirely different mode of treating those who have been rescued and who are still suffering from the effects of after-damp, from that which has been hitherto adopted. It is not too much to say that many a life could have been saved if, acting on Hoppe-Seyler's observations, artificial respiration could have been maintained for some time after apparent death.

There is much in this book that we should have liked to have dwelt upon had space permitted, for almost on every page we discern evidences of originality and freshness such as might be expected from one who, as we have seen, has brought the researching spirit to bear upon his subject. Whilst chemists are wearying themselves and others with vain speculations as to bonds and atomic-groupings, far too many of the common matters of every-day life are thrown aside as unfruitful or worked out. No one, however, could take up this book and not see that in the matter upon which it treats there are fifty problems waiting for solution—some of them most pressing in the interests of humanity, and any one of them capable of yielding a rich harvest of facts. T. E. THORPE

THE MORPHOLOGY OF THE ECHINODERMS

Morphologische Studien an Echinodermen. Von Dr. Phil. Hubert Ludwig, Director der naturwissenschaftlichen Sammlungen in Bremen. 1 Band mit 23 Tafeln und 5 Holzschnitten. (Leipzig: Verlag von Wilhelm Engelmann, 1877-79.)

WITHIN the last three years very numerous researches have been made on that most interesting group, the Echinoderms, to which, we are glad to see, the rank of a distinct sub-kingdom is now generally assigned. Greeff, Götte, Lange, Ludwig, Simroth, and Teuscher, in Germany; Perrier in France, Théel and Lovèn in Sweden, Agassiz, Lyman, and Pourtalès in America; and in our own country Sir Wyville Thomson, Duncan, Sladen, and the two Carpenters, father and son, have each contributed more or less to our knowledge of the morphology and physiology of the group.

Of the many observations made and recorded by the above-mentioned naturalists, those of Dr. Ludwig ("Ei-bildung Ludwig," as we have heard him called by embryologists) seem to us to be among the most important, alike from their variety, and, as we are strongly inclined to believe, from their general accuracy. We are not so sure, however, that all Dr. Ludwig's conclusions are as correct and reliable as his observations are trustworthy, for there are certain points on which we have very strong grounds for dissenting from his views.

The volume before us, representing the result of three years' work, mostly microscopic, is the first of a promised series of studies in Echinoderm morphology, and consists principally of memoirs on the anatomy of Crinoids and Starfishes.

It contains much that is new, or rather that was so when the individual memoirs were first published in the *Zeitschrift für wissenschaftliche Zoologie*, and much that is to be found, stated more or less correctly in the writings of other workers, both before Ludwig and contemporaneous with him.

The first paper in the series, forming about one-third of the whole volume, is devoted to the anatomy of Comatula. While generally confirming Dr. Carpenter's results, respecting the canals of the arms and the chambered organ, Ludwig (whose observations on this type were contemporaneous with those of four other observers, two in Germany and two in this country) publishes several new and interesting anatomical details.

Among the most important of these is the presence of blood-spaces around the genital organs, and also of a system of blood-canals ventral to the water-vascular system. Both of these systems probably communicate with the vascular "axial prolongation" of Dr. Carpenter, which runs up into the disc from the chambered organ situated in the calyx, and represents the "heart" of the Starfishes.

Ventral to the radial blood-canal is the fibrillar sub-epithelial band, to which Dr. Ludwig assigns a nervous character from its resemblance to a similar and similarly placed structure, that is generally, though not universally, supposed to be the nerve of the arm of a Starfish.

Ludwig's views have been completely adopted by Gegenbaur, in spite of the fact that this band is absent from half, or sometimes from more than half, the arms of many Comatulæ. We scarcely think that Ludwig has taken this fact sufficiently into consideration in his discussion of Dr. Carpenter's suggestion that the axial cords of the skeleton constitute the chief nervous system of Comatula; and we are not altogether satisfied with the purely diagrammatic manner in which he figures this axial cord, and with the meagre description which he gives of it. He makes no mention whatever of the regular manner in which it gives off branching bundles of fibres to the muscles and other structures in the middle of every arm-joint, except in quoting their discovery by others, though he cannot well have helped seeing them, and he does not deny their existence. At the same time he seems inclined to admit the probative force of Dr. Carpenter's experiments at Naples, which tend to show that these axial cords are the *motor* nerves, at any rate of the complex Crinoid organisation, permeated though they may be by a coagulable fluid. Should this view be the true one, it is another argument in favour of Leuckart's separation of the Crinoids and their allies from the other Echinoderms, to form a distinct class, the Pelmatozoa.

Until lately the Crinoids have not been credited with an ambulacral system homologous with that of the other Echinoderms. Götte, however, has shown that, as far as development is concerned, this is not the case, and the true water-vascular ring of the adult Comatula was first described by Ludwig, though its radial branches in the arms have long been known. Depending from it into the cœlom are numerous small tubules which Ludwig describes as open at the ends, and compares to the sand-canals of the other Echinoderms, more especially of the Holothurians.

After finishing his researches on the anatomy of Comatula, Ludwig turned his attention to Rhizocrinus, and found that it corresponds with Comatula in all essential points of structure. This was the first stalked Crinoid in which the presence of a chambered organ was determined. It has since been found in Pentacrinus and Bathycrinus, and Ludwig's discovery that its chambers are continued down the axis of the stem as five blood

canals disposed around a central axis, has received abundant confirmation.

The curious genus Rhopaladina has been supposed by some writers to be the type of a new group of Echinoderms, with mouth, anus, and genital opening at the centre of one of the poles of the body. Ludwig shows, however, that it is merely an aberrant Holothurian, much bent on itself, owing to the almost complete disappearance of the medio-dorsal inter-radius, an exaggeration, in fact, of a condition very commonly met with in Cucumaria. Ludwig's memoirs on the Asterids contain several novelties, two of the most important of which are as follows:—

1. The pores in the madreporic plate have no communication with the cœlom, but lead solely into the sand canal. The same fact has been noted by Perrier for the Echini, and it is the more singular because the body cavity of the Crinoids is in free communication with the exterior.

2. The genital glands do not discharge their products into the body cavity, but are provided with longer or shorter ducts that open directly on the exterior of the body. Around the glands are blood spaces, just as in the Crinoids, and these are connected with a very complicated blood-vascular system, which Dr. Ludwig describes exceedingly well, clearing up many points which had hitherto been very obscure and scarcely understood. This is especially the case with the remarkable genus Brisinga, which Sars supposed to be without a blood-vascular system. Ludwig contributes many valuable observations to the anatomy of this type, and shows that in all essential features it is a true Asterid, though he does not share Sars' views of its relationship to Protaster.

The volume closes with a striking paper on the Ophiurids, in which it is shown that the whole of the oral skeleton of the disc is the result of modifications of the first two arm-vertebræ and of the adambulacral and superambulacral plates corresponding to them. But the chief novelty in this paper relates to the genital clefts. These have been hitherto supposed not only to let the genital products pass out of the cœlom, but also to admit water into it. Ludwig shows, however, just as in the case of the Asterids, that both these hypotheses are incorrect. The sexual products are not discharged into the cœlom, nor does water enter it by the clefts, but the latter open into pouches or bursæ which are merely involutions of the general integument of the body, and receive the short ducts of the genital glands, probably serving also as a respiratory apparatus. Their inner surface, that turned towards the cœlom, is curiously folded, and their whole structure is so very similar to that of the hydrospires of the Blastoidea that Ludwig is led to suggest a homology between these two sets of similarly placed organs. Billings considered the hydrospires to be respiratory in function, and found them to be connected with the "spiracles" or genital openings, which would thus be homologous with the genital, or, as Ludwig prefers to call them, "bursal" clefts of the Ophiurids.

Should further investigation confirm this interesting discovery of Ludwig's, and the conclusions he has drawn from it, we quite agree with him in regarding it as one of great importance respecting the relations of the various echinoderms *inter se*.

We shall look with great interest for the publication of Dr. Ludwig's promised researches on the Echini and Holothurians at, we trust, no distant time; and also for his concluding work on the comparative morphology of the sub-kingdom as a whole, which will not, we imagine, be altogether a pillar of strength to Haeckel's celebrated "Worm Theory of the Echinoderms."

OUR BOOK SHELF

Jornal de Sciencios Mathematicas Physicas e Naturaes. Publicado sob os auspicios da Academia Real das Sciencias de Lisboa. No. xxiii. agosto de 1878. (Lisboa, 1878.)

Giornale di Matematiche: ad uso degli Studenti delle Università Italiane. Pubblicato per cura del Professore G. Battaglini. Vol. xvi. (Napoli, 1878.)

WE have not seen any previous numbers of the first of these publications, but from the specimen before us we should certainly conclude that this Society is doing good work. In fifty-two octavo pages we have specimens of work in all the lines indicated in the above title. The opening paper, by C. A. Moraes de Almeida, is an "estudo geral dos espelhos curvos" (continuation, 11 pages); Chapter IV. treats of spherical, elliptical, and parabolical mirrors of very small aperture; Chapter V. discusses some cases of practical difficulty in the formation of images. The second paper is a mathematical one by L. F. Marrecos Ferreira; 1st part, on the geometrical properties of the intersections of right cones, derived from the principle of the homological transformation; 2nd part, on the properties of conics tangential to the sides of an angle and their application to the study of surfaces (18 pages). Both papers are neat, and contain interesting properties.

Zoology follows, with two contributions by J. V. Barboza du Bocage, first with a list (the sixteenth) of the birds in the Portuguese possessions in West Africa (15 pages), next under the title "Mélanges Ornithologiques," remarks on new species of Angola (*Nectarinia anchietæ*[1]) and on individual birds of the families Certhiidæ (*Hylypsornis Salvadori*), Paridæ (*Parus rufiventris*), Laniidæ (*Lanius Souzæ*, *Nilaus affinis*).

The last two pages contain a slight account of 111 plants, collected in Caconda by Signor Anchieta. Remarks are made on the points of contact between some of the plants in this collection and that got together by the late Dr. Welwitsch

The second journal maintains its reputation for its contributions to the study of geometry. Where there is so much to praise we must limit ourselves to giving here the bare titles of some of the longer papers:—Ricerche geometriche sopra alcune proprietà dei sistemi di rette nel piano e dei sistemi di circoli che passano per un punto sul piano e sulla sfera, per T. Fuortes (56 pp.); Sulla riforma dell'insegnamento geometrico, nota di G. Fiedler seguita da tre lettere inedite dell' autore (13 pp.); Sull' infinità circolare non Euclidea, per G. Battaglini (7 pp.); Relazione fra l'area e il perimetro, fra il volume e la superficie, fra i momenti, fra le coordinate dei centri di gravità per gli spazi limitati da linee e superficie che hanno l'equidistante della stessa natura per U. Dainelli (20 pp.); Sulla teoria delle quadriche omofocali del punto di vista sintetico per F. Maglioli (36 pp.); Nozioni preliminari per la geometria projettiva dello spazio rigato, Nota i di F. Aschieri (19 pp.); Sopra le curve piane del 3° ordine con un punto doppio, per P. Anelli (14 pp.).

The History of Coal. By the Rev. T. Wiltshire, M.A. F.G.S., &c. (E. and F. N. Spon, Charing Cross and New York. Pp. 36, 1878.)

THIS pamphlet is the introductory lecture which the

[1] So named from the finder, who met with a single specimen, October, 1877, in the interior of Benguella.

author, as Dean of the Evening-class Lectures at King's College, London, delivered before the Principal, the staff, and students, at the commencement of this Winter Session.

It deals with the antiquities of coal, and as might have been anticipated, shows much patient scholarship and research amongst the works of those classical and mediæval writers who are not usually troubled by geologists. Prof. Wiltshire considers that there is evidence to show that ignition of coal, which had been selected as hut-making material with the help of palæolithic and neolithic implements, occurred and probably accidentally; the mineral not having been selected for its now well-known qualities. Nevertheless, he admits that "the general non-employment of the coals and lignites, in the stone and bronze ages, is well evidenced by the absence of allusion to their use, both in myths and traditions of that date and in the manuscripts which followed not long after." Noticing the silence of Homer on the use of coal, the author very properly places the Levitical coals and those of the Gospels amongst charcoals derived from wood, and he shows that the "carbo" of Pliny and the "anthrax" of Theophrastes were identical. Searching over the dreary pages of this last-named author, Prof. Wiltshire shows that this Greek first noticed and recorded that certain stones were obtained from the ground, and that, broken in pieces, they burn like anthrax (charcoal), and that they come from Liguria and Elis.

The tertiary strata in those localities are lignitic, and true palæozoic coal does not exist there. As years rolled on many coal-like minerals were used, and fancies environed them. Certain it is that during the Roman occupation of Britain, coal was stored and used, for it has been found beneath the ruins of villas in Warwick, Shropshire, Yorkshire, Lancashire, and Durham. The gradual extinction of the Romano-British was followed by hundreds of years of forgetfulness of coal, and then we find the Abbot of Peterborough leasing ground, a part of the rent to be paid in coal, about the time of Alfred. About 1190 the Edinboro' coal-field began to be used, and in 1239 a monopoly of the sale of coal was granted to the Newcastle people.

This interesting lecture is most readable, and well worthy of the accomplished editor of the Palæontographical Society's volumes. P. M. D.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

Quarantine in Italy

ALLOW me to say a few words in defence of the prohibitive measures taken by the Italian Government against the introduction into our country of that pest, the phylloxera, and which, though subjected to much unreasonable criticism and selfish opposition here and abroad, have at least been hitherto perfectly successful in protecting our vineyards. Certainly at first sight it would seem that the only necessary measure to be taken ought to be a restriction on the importation of foreign vines, and of the plants (such as fruit-trees) usually cultivated along with them in nursery-grounds, and on whose roots some stray insects might probably occur; and to such a restriction did the Government at first limit itself. But it was soon found out to be quite ineffectual, as it only gave occasion to smuggling on a grand scale, encouraged, I am sorry to say, by certain horticultural firms that did not fear to compromise their respectability by so doing. We all know what ingenious persons smugglers can be; they began introducing the prohibited plants in their leafless state labelled as choicest exotics, to the utter confusion of the Custom House officials, who, being neither naturalists nor scientific men to any degree, were at a loss how to act, until the Government was obliged at last to send the order that no live plant should pass the frontier; a simple rule that anybody can understand, and not to be regretted when one has seen in France and elsewhere thousands of acres of what were once flourishing vineyards blasted by the pest, and has heard of the millions of money lost that way. I shall not mention such petty annoyances as being obliged to leave a bouquet at the Custom House; but surely it is better that our gardens should be deprived of those novelties and rarities that are not obtainable through seeds, rather than run the slightest risk of diminishing one of the principal resources of our impoverished country. Though myself a director of a botanic garden, I own I cannot push my love for flowers to that extent to sacrifice to it much greater interests.

Pisa, February 26 T. CARUEL

Captain Cook's Accuracy

Apropos of your article on the centenary of Capt. Cook's death in NATURE, vol. xix. p. 334, it may be interesting to call attention to his remarkable accuracy in determining the positions of places laid down in his charts. There is a great contrast between his accuracy and the evident carelessness of some more recent navigators. Some years ago when I was sailing in the Pacific we were one day approaching the recorded position of an island which no one on board our vessel had seen. I was conversing with the captain, and asked him whether he expected to find it in its recorded place. To this he replied: "It is sure to be there, for Capt. Cook determined its position; and although I have been now a good many years in the Pacific, I have never yet found him wrong. Had it been the United States Exploring Expedition which determined its place, I should have thought the chances just about equal as to whether it is right or wrong."

There is, unfortunately, too much ground for the remark about the observations of Admiral Wilkes's Expedition. Those who have had opportunities to test the work done by it know that it is often most inaccurate. Quantity of work rather than the quality of it appears to have been the rule with the navigators who conducted that expedition. I believe all Cook's work was worthy of his reputation.

As this is a serious charge to make against such an expedition, it may be well to give some examples to substantiate it. The particulars of the first I take from Findlay's "South Pacific Directory," pp. 633-34. Respecting Vatoa, or Turtle Island, south-east part of the Fiji Archipelago, he says: "A singular mistake crept into the survey by the United States' Expedition. On May 5, 1840, the *Vincennes* 'had a sight of Turtle Island, and determined it to be in lat. 19° 48′ S., long. 178° 33′ W. It has the appearance of a small rounded knoll.' This would seem to be circumstantial, and is further confirmed by a foot-note on the same page. In a subsequent passage the *Porpoise* is said to have determined it to be in lat. 10° 50′ S., long. 178° 37′ 45″ W. 'It was found to be three miles long, by one and a quarter mile wide. The reef extends all around the island, and is from one and a half to two miles wide.'"

If we suppose that in the above 10° is a misprint for 19° there will be only 2′ in lat. and 4′ 45″ in long. difference between the two determinations. But it appears that both of these are about 30′ in error in their longitude. On this Findlay remarks: "This singular variation in longitude from that assigned to it by the great discoverer Cook (178° 0′ W.), or 37′ in error, is startling, because the accuracy of Cook in this instance had been confirmed by other navigators." He then gives an account of an examination of it made by Capt. Worth in H.M.S. *Calypso* in 1848, when he made the island to be "apparently about six miles in length," its centre twenty-nine miles eastward of Wilkes's position, and, instead of the reef from one and a half to two miles wide all around, on the south-west a reef five or six miles wide, with "a large oval coral patch detached from it lying north and south, eight or nine miles in length."

My second example of inaccuracy shall be one in cartography. Some years ago I was about to make a trip into the mountains of Savaii, the largest of the Samoa Islands. Before starting, with Wilkes's chart in my hand, I took a few bearings of points which might serve for comparison when I reached the mountains. I was standing at Tuasivi, a place on the eastern end of the island which may be seen marked in Grundemann's map. To my surprise I found I could see from that place to Tafua point, the south-east extremity of the island, whereas the chart made

the land to project very considerably between the two points. On further examination, I found that, instead of making the land trend inward to a very deep bay at Sapapali'i and Iva, as it does in reality, it had been made to extend seaward in a series of headlands. This error is perpetuated in all the maps I have seen, including Grundemann's, and that published in the *Journal des Museum Godeffroy*, both of which are based on Wilkes's chart.

My third and last example shall be one of a different kind. In 1870 I visited an island north of Samoa known as Quiros or Gente Hermosa. Wilkes' expedition described it as being *without a lagoon*. I found it to be barely four miles in diameter, but with a *deep fresh-water lagoon in its centre about three miles in diameter*. Now as the ring of land around this lagoon is only about one-third of a mile across, I cannot imagine how any members of the expedition could have landed without seeing the water. Such an inaccuracy as this would have been bad enough in the description of an ordinary traveller. It is inexcusable in an expedition specially fitted out for scientific observation.

S. J. WHITMEE

Cook's Collections

IN NATURE, vol. xix. p. 373, a remark of Dr. Hamy, of Paris, is reproduced, concerning "the fate of Cook's collections in being buried in an Austrian museum." It will be of general interest to make known that, what there is in Vienna of ethnographical objects in relation to Cook, consists of 260 numbers, chiefly originating from Cook's third voyage. These objects were bought by order of the Emperor Franz in the year 1806, at the auction of the Parkinson Museum in London (previously Lever Museum), and now form part of the large ethnographical collections, which will be accessible to the public in a few years in the new, nearly completed, Imperial Natural History Museum of Vienna. This museum will become one of the greatest and most complete on the continent, uniting all mineralogical, geological, palæontological, prehistoric, anthropological, ethnographical, zoological, and botanical imperial collections of Vienna under the charge of Prof. Hochstetter. Royal Zoological Museum, Dresden, February 28

Magnetic Storm, May 14, 1878

THERE appears to have been a slight error in my note (vol. xix. p. 148); in the sixth line, it should read 14th instead of 15th.

With this exception the observations are correctly reported, and the period during which the greatest trouble was experienced in working on the Persian Gulf cable covers the time at which the magnetic storm was observed at Stonyhurst to be at its height (vol. xviii. p. 617).

I cannot quite agree with Mr. Preece when he suggests (vol. xix. p. 173) the advisability of recording earth-currents in Webers. Comparatively few of the readers of NATURE would appreciate the magnitude of an earth-current if expressed in those terms, while every one, I think, will understand me when I say that the earth-current passing through the line equalled that which would be produced by a certain number of cells connected to the same circuit.

The systematic observation of earth-currents in different parts of the world is no doubt very desirable, but to be of value it must be regulated and collated by some central authority. I feel convinced that if the Society of Telegraph Engineers invited assistance in this matter, and pointed out what was actually required, the appeal would be very readily responded to.

Kurrachee, February 6 HENRY C. MANCE

Intellect in Brutes

IF Mr. Henslow will read my letter again he will find it distinctly stated that the "several occasions" on which the leakage took place were referred to in connection with the agency of rats only. The plumber informs me that in none of the cases (four or five) was there any sign of injury to the pipe by frost. In the specimen which I have, the rats have made two *ineffectual* attempts to perforate the lead, and have succeeded in two distinct places. Had a frost crack existed, with consequent escape of water, there would have been no necessity to make two fruitless attacks on the pipe elsewhere. The specimen may be seen by any one interested at the office of *The Country*, 170, Strand. Metaphysicians will probably think that Mr. Henslow has stumbled into a quagmire in his discussion of "practical" and "abstract" reasoning. Does he believe that brutes and boys in common have nothing but the faculty of "practical" reason? When a boy finds the value of x in a simple equation, is he not dealing with "abstract" ideas? ARTHUR NICOLS

I AM not opposed to Dr. Darwin's teachings, nor do I care much whether science proves that man is descended from Adam or from some extra clever race of monkeys, so long as the *truth* is established. In regard to the explanation given at p. 365 of the rats eating the pipe to get at the water because they "heard the water trickling," I am inclined to look at the matter in a simple matter-of-fact way, and so feel inclined to think they cut the pipe because it was somehow in their way. Lead and block-tin gas-pipes are found cut in a similar way. Now, are they cut to get at the *gas?* Lead waste-pipes are also often found so cut, both from the outside and inside. I happen to be a practical plumber myself, and have had to deal with rats in many ways, but I scarcely think that "the reasoning power of the rat" in this case has been properly reasoned out.

21, Renfrew Street, Glasgow, March 1 W. P. BUCHAN

I BELIEVE "that the reasoning faculty in man and animals differs in degree only." But I do not think Mr. Nicols' plumber's lead-pipe case (NATURE, vol. xix. p. 365) a well-tested instance of rat sagacity. We have not sufficient proof that the rats gnawed the pipe for the purpose of getting at the water; though, of course, they used the water after having come upon it. It seems more likely that they gnawed the pipe because it obstructed their tunnelling operations; else why did they cut it in two separate places? Mr. Nicols says "a rat will not drink foul water." Neither will I when I can get better, but I am afraid I should need to put up with the foul if I lived in a sewer.

Cambuslang HENRY MUIRHEAD

It is somewhat difficult to understand Mr. Henslow's remarks on the above subject in NATURE, vol. xix. p. 385. He tells us that if the dog that rang the bell to fetch the servant to let him out of a room in which he was shut up, *had not been taught to ring the bell*, "it would have been *abstract reasoning*, but it was only practical." Further on he says that brutes never acquire "abstract reasoning."

The Arctic fox, by Mr. Henslow's own showing, appears to have used "abstract reasoning," because it had never been taught to cut the line attaching the bait to the trigger of the gun before taking the bait (of which I have seen several cases), or to dig a trench in the snow to avoid the shot. Can Mr. Henslow be a sportsman? If so, he ought to know that in the case referred to, to pull the bait downwards *out of the line of fire* was the only safe way for the fox to have acted, so as to get his head out of danger. Had he used what Mr. Henslow calls "abstract reasoning"—which, I presume, means pulling the bait, not the line, to *one side* out of the line of fire, the fox would certainly have been shot, as the bait could not have been moved more than four or five inches from the wooden stake through which the bait-line passes.

If Mr. Henslow really means that the fox should have shown his powers of "abstract reasoning" by going up to the line of fire between the gun and the bait, and then pulled the string until the gun went off, I think the chances of reynard's ever eating the bait would be very small indeed. I have known him do what showed equal or greater intelligence, namely, cut the bait-string, as already mentioned. JOHN RAE

Royal Institution, February 28

MR. HENSLOW, in his letter on this subject, complains that "brute reasoning is always *practical*, but never *abstract*." As an instance of what appears to me abstract reasoning in a dog, I beg to offer the following: A few years ago we had in our possession a terrier gifted with a propensity (probably instructive) for worrying the sheep that were put to graze in a field separated from our house by another field. Coming out of the house one day I observed this dog crossing the latter field, evidently intent upon a little amusement. I called him back, he obeyed; but when he came to a patch of brushwood which hid him from view, he cut straight across the field, under cover of the brushwood, to behind a hedge, and then pursued his course

towards the sheep field. What taught him that he could thus reach his game unobserved? A. J. A.

HERE is an instance of "instinct" which shows, I think, that there is no difference whatever between the reason of animals and that of men.

A mare here had her first foal when she was ten or twelve years old. She was blind of one eye. The result was that she frequently trod upon the foal, or knocked it over when it happened to be on the blind side of her, in consequence of which the foal died when it was three or four weeks old. The next year she had another foal; and we fully expected that the result would be the same. But no; from the day it was born she never moved in the stall without looking round to see where the foal was, and she never trod upon it or injured it in any way. You see that reason did not teach her that she was killing her first foal; her care for the second was the result of memory, imagination, and thought, after the foal was dead and before the next one was born. The only difference that I can see between the reasoning powers of men and of animals, is that the latter is applied only to the very limited sphere of providing for their bodily wants, whereas that of men embraces a vast amount of other objects besides this.

The above limitation does not, I think, apply strictly to domestic animals, dogs especially, which seem to acquire some perceptions beyond mere animal ones.

Hull, February 28 C. W. STRICKLAND

Parhelia

ALLOW me to record the occurrence of parhelia here this morning. The phenomenon lasted about twenty minutes, and was fairly brilliant. No halo was apparent, merely a mock sun on either side of the true one, and the line passing through the three, dipped towards the south at an inclination of 2° to 3° to the horizon. E. W. PRINGLE

Uxbridge, March 4

Unscientific Art

As a specimen of Unscientific Art, let me bring to the notice of your readers a two-page engraving in the last number of the *Illustrated London News*, entitled "Capture of Sirayo's Stronghold."

If there is any truth in the laws of perspective the Zulus flying before the cavalry are indeed "sons of Anak."

Scientific Club, March 2 E. W. PRINGLE

Bees' Stings

IN NATURE, vol. xix. p. 385, a correspondent asks whether the identity of bee-poison with formic acid has yet been determined. Some sixteen years ago I made a few experiments with the poison from wasp-stings, and found, to my astonishment, that it was invariably alkaline instead of acid. A living wasp, duly held in the cavity of a perforated cork, was easily induced to sting a piece of turmeric paper; a brown-red spot immediately appeared. A. H. CHURCH

Cirencester, March 1

A NEW PROCESS IN METALLURGY[1]

LONG before human art acquired the knowledge of metal-making, prehistoric man had learned to make fire of the dry stems and branches of trees; in the charred fragments of half-burnt wood we recognise a form of carbon, the first simple elementary body produced by man from the complex natural bodies with which he was surrounded. In the knowledge of the use of fire, then, was the first dawn of art, particularly of that art which deals with the reduction of simple bodies from compound minerals. To convert metallic compounds into metallic elements is the domain of the metallurgist, and the means by which this is effected constitute the basis of metallurgic art. Carbon was thus a necessity to metallurgy—with the knowledge of fire the world emerged from the stone age. From those early times down to the present day, no fusion has been effected without using carbon, which in the form of wood, coal, or charcoal, has been the substance invariably used by the metallurgist for the production of heat, and to enable him to decompose and to smelt metal-bearing materials.

The new process, however, we are about to describe, has for its object the smelting of metalliferous substances without the employment of carbonaceous fuel. The sulphides of iron, lead, and zinc are known to be combustible substances of almost universal occurrence, and when burnt under favourable conditions give rise to a great evolution of heat. We have calculated the relative temperatures thus produced, from which it appears that the temperature at which iron pyrites (bisulphide of iron) burns in air under the conditions most favourable to the development of a high temperature is over 2,000° C., protosulphide of iron burning at about 2,225° C. Zinc sulphide, or blende, gives a temperature of 1,992° C., and galena 1,863° C.; while calculations made in a similar manner with coal, assuming it to be completely burnt, show the temperature attainable to be 2,787° C. These mineral sulphides, which are therefore natural and almost inexhaustible sources of heat and energy, can under certain circumstances be burnt more economically than their heat-giving equivalent of coal.

The best means, however, of utilising this heat-producing property of metallic sulphides is not so apparent as would appear at first sight. Only iron pyrites is sufficiently combustible at a low temperature to burn in the open air, the mass being raised to the temperature at which the oxidation takes place solely by the union of the sulphur and iron with aerial oxygen. In Spain this is carried on in vast heaps of hundreds of thousands of tons, and the operation extends over many months. The oxide of iron that remains is typical of those mineral substances which, once burned in the primeval operations of nature, gave up their stores of heat and force, and became, as it were, inert bodies.

Going back now to the combustion of carbon, it is well known that it burns at widely varying temperatures, as, for example, in our bodies, in a common coal fire, or in a powerful furnace. A great deal of attention and thought has been spent upon the subject of the economy of carbonaceous fuel, and great advances have been made in this direction, yet the expenditure of coal or coke necessary, say, to melt a given quantity of metal, still far exceeds the theoretical limit. The main causes of this discrepancy may be accounted for as follows:—(1) That only a fractional part of the oxygen of the air passed into the furnace acts upon the material to be burnt. (2) That the oxygen is not brought in contact with the combustible matter with sufficient rapidity to attain the necessary temperature for the operation. (3) That gases pass off hot and unburnt; these are now, however, frequently utilised.

There is one metallurgical operation in which the first two sources of loss are perfectly avoided—namely, by blowing air through molten crude iron, as in the Bessemer operation, where, by the burning of small quantities of carbon and silicon contained in the crude iron a very high temperature is attained, which is not the case in the process of puddling, where the oxidation is spread over a considerable period of time, although the same constituents are frequently burnt in similar proportions. But even in the Bessemer process the carbon is only half burned, and a large amount of heat escapes with the carbonic oxide and nitrogen. When, however, we blow thin streams of air through molten sulphide of iron lying upon a tuyère hearth, a high temperature is produced by the perfect combustion which ensues in the midst of the sulphides, and no unburnt gases excepting sulphur vapour escape from the surface of the molten mass. Hot nitrogen and sulphurous acid being the only gaseous products

[1] A paper with full details of the process was read by John Hollway at the Society of Arts on February 12, 1879; Prof. H. E. Roscoe, F.R.S., in the chair.

of the operation (excepting the small quantities of hydrogen from the aqueous vapour of the air), these may be caused to act upon iron pyrites and other mineral matter. When pyrites is thus heated, an atom of sulphur held in feeble combination is in great part expelled, and thus is obtained protosulphide of iron, with which the operation commences, and which can exist in the molten state. Sulphide of zinc thrown into this bath of molten sulphide is converted into oxide: the sulphides of copper, nickel, and silver do not burn at all so long as sulphide of iron is present, and, accordingly, if oxides, silicates, or carbonates of these latter metals are introduced into the molten sulphide of iron, the iron present will take away the oxygen with which the metals are combined and concentrate them into a regulus of sulphides. But the question then arises, How, after fractional decomposition by oxidation, we can separate the sulphides from the oxides? This is accomplished by the addition of siliceous matter introduced into the furnace with the charge of sulphides, so that in the manner explained are obtained from crude materials five principal classes of products, viz.:—(1) sulphur; (2) sublimates of volatile sulphides and oxides; (3) a slag of silicates of certain more oxidizable metals, principally iron; (4) regulus containing the nickel, copper, and silver; (5) sulphurous acid and nitrogen. Under certain circumstances a sixth class of products may be obtained consisting of the metals copper and lead. Thus, when the sulphides of iron and copper present in the bath are treated continuously with the blast of air without the addition of combustible sulphides, a point at length arrives when the whole of the iron present is oxidised, and the regulus in the bath consists of subsulphide of copper. If now a limited supply of air is introduced, the copper is reduced to the metallic state, with the evolution of sulphurous acid. Further experience in the matter may lead to the adoption of this continuation of the process. Again, sulphide of lead present in the bath may be caused to yield metallic lead by partial oxidation. The sulphurous acid can be made into sulphuric acid in chambers or condensed to the liquid state. Thus we have in this new process a metallurgical operation, the necessary heat for the decomposition and fusion being entirely obtained by the combustion of the iron and sulphur contained in the materials operated on.

Some large experiments have been made in order to prove the more important points here enunciated. They are all to be found described in the paper upon the subject in the *Journal* of the Society of Arts, dated February 14 and 21, 1879. A brief record of some of the phenomena witnessed at the February experiments at Penistone may not be uninteresting. At seven in the morning on February 12 last a small party of gentlemen arrived at Messrs. Cammell & Co.'s Penistone Steel Works, in order to see the operation from its very commencement. Two Bessemer converters were ready for the experiments; one of these was charged at 10 A.M. with some molten protosulphide of iron (made by fusing some pyrites in a cupola), and a blast of air was driven through the tuyères. Lumps of sandstone were continuously thrown in together with cupreous pyrites. A flame of the burning vapour of sulphur expelled from the pyrites passed from the converter mouth to the chimney shaft; it was from 6 to 10 feet long, blue at the edges and greenish in the body of the flame. About noon this experiment broke down through an accident, after which the product was taken out. An experiment was then commenced by setting fire to some sulphide of iron by means of about 2 cwt. of coal thrown into the vessel to start the combustion; pyrites and sandstone were then thrown in, in lumps, which rapidly melted, this being continued until midnight (over eight hours). The molten mass in the vessel remaining perfectly liquid, was from time to time partially poured out to make room for the addition of further similar materials. During the whole of the eight hours not an ounce of coal was used, the converter being "fed with stones," and "vomiting forth fire and brimstone," as a gentleman present graphically expressed it. In this latter experiment about eighteen tons of raw pyrites was thus treated, and over four tons of sulphur was distilled and afterwards burnt. More than half a million cubic feet of sulphurous acid and nitrogen left the mouth of the converter at a high temperature, taking away with them a considerable fraction of the heat produced by the oxidation. This was very unfavourable to the success of the experiment, as will be readily understood when this great loss of heat is taken into account. With a suitable plant the heated gases would be utilized to drive off sulphur from pyrites, so as to produce the molten protosulphide required to continue the operation. Heat is not only obtained by the oxidation of the metallic sulphides, but also by the oxidation of iron protoxide to peroxide when the contents of the vessel are over-blown. In an experiment made in July last the oxidation was thus purposely continued. "As soon as the subsulphide of copper began to burn a splendid emerald green flame suddenly appeared, lasting about a minute, and all the lines except those of copper and sodium left the spectrum. During the last few minutes of the blow the mouth of the converter was dull and without flame."

Some of the products of these experiments were shown at the Society of Arts; they consisted of crystalline masses of ferrous silicate and blocks of 50 per cent. copper regulus. No sulphur was collected, it being impossible to do so with Bessemer plant, which, in actual operations, will not be used for the process. These experiments, however, enabled those present to witness, in the course of a few hours, the principal effects produced. "A remarkable spectrum was obtained from the burning sulphur vapour; viewed through a small direct vision spectroscope, many absorption bands were seen occurring at apparently regular intervals from the red to the violet. The lines of sodium, lithium, and thallium were recognizable, but the majority of the lines are of (as yet) unknown origin, though they are the most important, since the changes furnish indications of the progress of the chemical changes taking place in the vessel. The lithium was, probably, derived from the sand introduced with the pyrites."

The process is peculiarly suitable—(1) For the treatment of metalliferous substances which cannot be advantageously utilised by other processes. For the extraction of sulphur by distillation, and simultaneously for the concentration and separation of copper, silver, and nickel from such materials in the form of a metallic regulus; while lead, zinc, arsenic, &c., accrue in the sublimates. (2) For the treatment of cupreous pyrites, large quantities of which exist in many parts of the world where fuel is scarce, and where the present mode of treatment by the cementation (wet) process involves not only the loss of vast quantities of sulphur, which is burnt to sulphurous acid, but causes the destruction of all vegetation within its influence. For example—About one million tons of pyrites, too poor in copper to pay for shipment to the United Kingdom, are annually treated in Spain by the cementation process. Such ores thus treated, containing 1½ per cent. of copper, leave only a small profit, whereas it is calculated that similar ores by this new process will yield a profit more than five times as great. (3) For the treatment of copper and nickel ores, so as to produce a concentrated regulus without employing carbonaceous fuel.

It is therefore obvious that this process will effect a great revolution in the treatment of metallic sulphides, such as iron, cupreous and nickeliferous pyrites, also copper and nickel ores and the refuse gangue of mining operations, which can thus be smelted without the employment of carbonaceous fuel, the necessary heat being obtained by the oxidation of the metallic sulphides.

ON THE FREEZING OF LAKES[1]

In pursuance of investigations, now extending over some years, into the natural conditions of our seas and lakes, I took advantage of the recent frost to make some thermometric observations in fresh-water lakes covered with ice.

Most of the observations were made with one of Negretti and Zambra's "half-turn" deep sea thermometers, which proved to be a useful instrument for this species of inquiry. It was necessary however to fit it with a suitable inverting contrivance, as the apparatus supplied for this purpose by the makers is quite useless. When this thermometer was accidentally disabled, thermometers on the Millar-Casella type with certain improvements introduced by myself were used.

Observations were made in Linlithgow Loch at different dates, and in Loch Lomond on January 28 and 29. The results are given in the accompanying tables.

[1] Substance of two papers read before the Royal Society of Edinburgh on January 20 and February 17, 1879.

Had the freezing of the loch taken place according to the commonly received idea, that is, had its waters been first reduced uniformly throughout its depth to the temperature at which the density of water is a maximum, and the surface layer then cooled further until a covering of ice was formed, we should have expected to have found the *remains* of this uniform temperature on examining the water after a firm coating of ice had formed. Distilled water reaches its maximum density at 39·2° Fahr., and I naturally expected to meet with a considerable stratum of water at or near this temperature. Both in Linlithgow Loch and in Loch Lomond there was a tendency to uniformity in the temperature of the water, but in Linlithgow this temperature was approximately 37° F. and in Loch Lomond 34° F. A single glance at the curves of the observations in these two lakes shows that they could never have been developed, if at the time of the formation of the first coating of ice the bulk of the water had been at a uniform temperature of 39·2° F.

In order to explain the existence of this unexpectedly low temperature, I at first imagined that there might be sufficient saline matter dissolved in the water to lower its temperature of maximum density. The presence of five parts of common salt in one thousand parts of water would have sufficed to lower this temperature to about 37°, and as the water of Linlithgow Loch was otherwise excessively foul, it appeared at first sight to be a likely explanation. It was not however verified by experiment. Although possessing a most offensive odour, the water was remarkably free from saline ingredients, and when its change of volume at low temperatures was compared with that of distilled water in the same dilatometer no difference could be detected. Seeing then that the temperature of maximum density was the same as that of distilled water, it was evident that, before being covered with ice, the whole of the water had been cooled down much below that temperature, and that this effect had been produced in a still more marked manner in Loch Lomond.

Let us consider what would be likely to take place during the cooling and freezing of a lake such as the frozen part of Loch Lomond. The water would be cooled down gradually by radiation from the surface, and we may admit that at some date, probably early in December, the whole water from surface to bottom would have a sensibly uniform temperature of 39·2° F. I believe that even in a very small lake there would be no date when the whole of the water would be uniformly at the temperature of maximum density, but it is a condition to which it would approximate in a greater or less degree, according to local circumstances. As the cold continued, circulation would be completely stopped, and cooling would be confined to the surface-layer, supposing the climate of the surface to be absolutely identical all over the surface of the lake. It is impossible that this condition can be fulfilled for more than an instant of time, for it would be disturbed by the slightest movement of the atmosphere. As a matter of fact there is great diversity of climates even at points close to each other, causing among other effects great variations in the temperature of the surface water. Did lakes cool absolutely uniformly throughout their whole extent, there would be no reason why ice should begin to form in one part more than another, and the ice would begin to form at one and the same moment all over the lake, which is contrary to experience.

Let A B C (Fig. 1) represent the bed of a lake in section, D E the surface of the water. At the date when the water has approximately the uniform temperature 39·2° F. D E will represent the isothermal of 39·2. Now let the cooling go on and let the first ice appear, as it naturally would, at the edge. Let E F represent the first piece of ice, which for simplicity's sake we may suppose to have been formed suddenly, and let us consider the effect of its

presence. This effect would be expressed graphically by the dipping of the isothermal of 39·2, as at G, and the generation of those of temperatures intermediate between it and 32° F. This alteration in the temperature means also an alteration in the density; and if we consider a vertical section through the ice at H K and through the middle of the lake at L B we shall find the mean density at L B greater than at H K, and the result would be the production of convection currents. What takes place at E would take place on the other side at A also, and we should have a system of circulation which in broad outline would consist of surface currents from the sides towards the middle, and under currents from the middle towards the sides, somewhat after the manner indicated in Fig. 2. The length of time that these currents would continue to flow before the lake was covered over with ice would depend on a number of local circumstances. The shape, size, and position of the lake would have much influence, and also the severity of the frost. However low the temperature of the air, the strength of the currents would always diminish as the water got cooled down, for the lowest available temperature is 32° and the highest 39·2°. Hence the convection currents would be the strongest at the first formation of the ice, and would gradually, and at an increasing rate, get weaker as the general temperature of the water got lower. When the whole of the water was cooled to 32° they would stop altogether.

It is therefore certain that in the water of a frozen lake we must find a tolerably uniform temperature, and this temperature must lie between 39·2° and 32°. In order that either of these extreme temperatures should

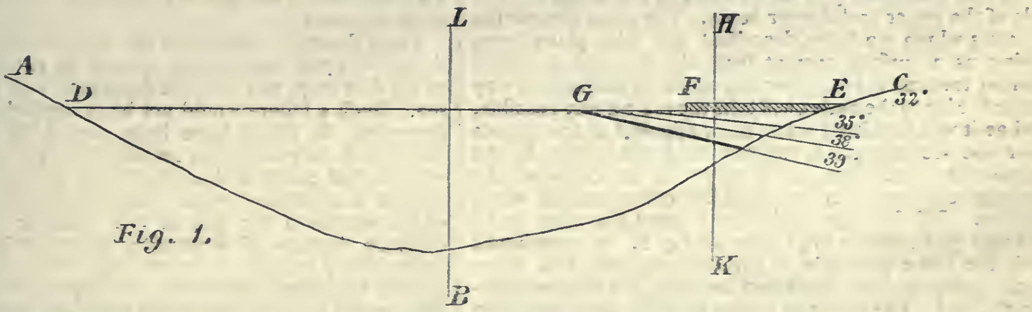

Fig. 1.

prevail, the weather would require to be of a very exceptional character. Admitting that the water had been cooled to a uniform temperature of 39·2°, this temperature could be *fixed* only by a sudden frost of extraordinary and probably unknown intensity. As the convection currents become weaker the more nearly the temperature of the water approaches 32° it would require the least possible frost during an infinite winter to reduce the temperature of the water to 32° before it was covered with ice. The uniform temperature of 32° however could be produced in another way, namely by the cooling of the water after it was covered with ice. This condition is probably not uncommon in shallow lakes in very cold climates.

In general, in climates such as our own, an intermediate temperature would prevail. In the Balloch basin of Loch Lomond this temperature was found to be about 33·9° F. In Linlithgow Loch it was much higher, about 37° F. The lake will remain open with an ice-fringe along the side as long as the water leaves the ice-edge with sufficient velocity to mix with the warmer water off shore before freezing under the influence of surface radiation. As soon however as this velocity is reduced so far as to enable the frost to overtake the water as it leaves the ice-edge before mixing with the warmer water the propagation of ice from the fringe out into the middle of the lake will take place with great rapidity, and a single night will often be sufficient to cover a large lake.

From the moment of the formation of the complete ice covering, the water is subjected to a uniform climate, its surface being everywhere in contact with ice; and it is only under these conditions that the whole of the lake can be said to be exposed to an identical climate.

Hence we see that, even admitting that a uniform tempe-

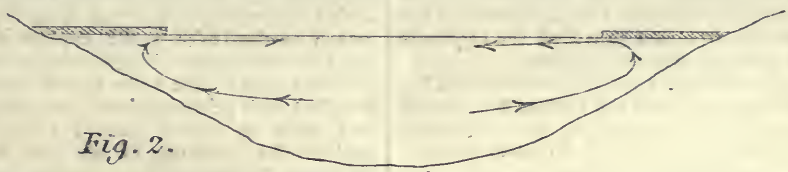

Fig. 2.

rature of 39·2° had previously existed, the whole of the water would be very considerably cooled down before it could be covered with ice, and the extent of this cooling would depend on local circumstances of position and climate, so that the final temperature of the water would be different for different lakes in the same winter, and for the same lake in different winters. The body of the water of a lake would be cooled more when it has been frozen by a moderate and comparatively long continued frost, than when the ice has been frozen quickly by very severe frost. For the more severe the frost the sooner will it be able to overtake the water leaving the ice fringe; in other words, the stronger will be the current which it will be able to arrest, and the greater the *head* which it will be able to stem. But the head which causes the current, is caused by the higher temperature of the open water as compared with that under the ice. Hence the more severe the frost, the higher will be the temperature which it will be able to fix. Let us now consider the causes which would tend to alter the temperature fixed by the ice covering.

In the first place there is alteration in the thickness of the ice and conduction from it downwards. The effect so produced would be concentrated in the surface layer, and its nature can be easily imagined.

In a large lake like Loch Lomond there is, even in severe weather, a considerable amount of change of water going on. The river Leven, which leaves it at Balloch, is navigable for small vessels, and a number of not inconsiderable streams fall in at different parts of the loch. The ice extended from the lower end at Balloch up to Luss, where it terminated in a miniature cliff which swept in a curve from the Dumbartonshire shore to the island of Inchlonaig and thence in another curve to the Stirlingshire shore. It is easy to see that the streams which fall

into the lake in its lower part when it is covered with ice, must supply water at 32° F; for even if it were at a higher temperature while forming part of the stream, it would, by impinging on the edge of the lake ice, be cooled down before being able to mix with its waters. It would thus enter the lake at 32° and would spread itself out immediately under the ice, and its effect on the temperature of the water would be similar to that produced by the thickening of the ice and conduction from it.

The excess of water which falls into the upper and open part of the lake must also find its way under the ice to the outlet. In order to estimate its effect, we must consider the conditions obtaining at the terminal edge of the ice stretching across the lake. We have already discussed what takes place when the first ice fringe forms at the sides of a lake, and we may look on the ice covering the lower and shallower part of the lake, as the fringe on that side of the upper and deeper basin. The same convection currents which we have described will take place here, giving us a surface current from the ice, and an under current towards the ice, now the water in finding its way under the ice to the outlet, will take the easiest way possible, and as it will find itself retarded or opposed at the surface near the ice edge, and assisted near the bottom by the convection circulation, its supply will be delivered by preference as an under and therefore comparatively warm current. Off the edge of the ice I found the water at 8½ fathoms 37·2°, and in 17½ fathoms 37·4° F. In accordance with the same principle of greatest easiness, this water would penetrate into the frozen basin by the deepest existing channel. The lower or frozen basin is separated from the upper and open one by a remarkable chain of islands separated from each other by channels everywhere less than there, and indeed hardly anywere more than two fathoms deep. The two channels however next the main land are each five fathoms deep, and it is through them that the bulk of the water finds its way. This was shown in a very singular way by the existence of a space of open water stretching from the main land to the nearest island over the shallowest part of the channel on the Dumbartonshire shore, there being thick strong ice over the deep water on both sides. In its passage over the ridge which rises very steeply, the warm water is thrown up near the surface and its supply is sufficient not only to preserve this space of open water, but also to raise the temperature of all the water of a depth greater than five fathoms in the lower basin.

In the case then of a lake only partially frozen, the temperature of the water under the ice is lowered by the drainage entering where it is frozen and is raised by the water supplied from the open part provided the channels connecting the two parts are not too shallow.

In Linlithgow Loch which was entirely frozen over, the very great rise of temperature near the bottom was caused by the immense quantity of filth contained in its water and in the mud at the bottom. J. Y. BUCHANAN

ON THE BURSTING OF THE GUN ON BOARD THE THUNDERER [1]

IN the interval which elapsed between the bursting of the gun and the report of the Committee much thought and some trouble has been expended in divining the possible causes which might, under one set of circumstances or another, have led to such a result. It now appears, however, that, different as have been the various suggestions, they all resembled each other in one particular, namely, that they were all wrong.

It is to be hoped, however, that all the ingenuity that has been expended will not have been thrown away, and that some improvement may result from the pointing out of such numerous defects. That in some respects, such as the increasing twist and the sudden steps or shoulders on the outside of the gun, the present system is defective, is shown quite apart from the recent accident; and although it now appears that the moving forward of the shot as the rammer was withdrawn had probably nothing to do with this accident, it cannot be considered satisfactory that this moving forward should be so much the rule as it is shown to have been in the experiments recently undertaken.

Although at first sight it may appear that the fact of the gun having been loaded with two charges of powder and two shot is amply sufficient to explain the bursting, it may not be useless to examine somewhat closely into what would result under such circumstances. The bursting of a 38-ton wrought-iron gun is an experiment of which we should make the most as we cannot expect to have it often repeated.

From the first accounts of the accident it appeared as though the gun had simply broken in two, like a carrot, at the first step, and that the front half had gone into the sea. Such a failure would not have implied an excess of pressure. It might have been caused by a great end strain such as would have resulted had the shot jammed when in full career and carried away the fore part of the gun, or it might have resulted from the gradual weakening of the section of the gun at the shoulder owing to the different degrees of expansion immediately before and immediately behind. One or other of these causes appeared to afford the most probable explanation of the phenomena as described in the early accounts. In various subsequent reports, however, it was stated that fragments of the fore part of the gun were blown about in all directions. So that the gun, instead of having simply broken in two, must have burst like a shell in front of the first shoulder. This fact placed the phenomena in an altogether different light. The explosive bursting of the zone of the gun into fragments implied an enormous excess of pressure at this point of the gun.

In order to cause the tube of the gun to burst longitudinally at all would require several times the normal pressure, and the breaking up of the wrought-iron tube into fragments would show that the force was largely in excess of what was necessary to burst it.

After seeing these reports it appeared certain that the gun had been subjected, at the point of rupture, to a pressure enormously excessive, and the question became whence could such a pressure have arisen? To me it appeared that nothing short of such an action as might, with a detonating fuse, result from the explosion of gun-cotton or dynamite would explain the breaking of the gun into fragments. Had the shot become jammed the pressure might have been raised sufficiently to burst the gun, but with pebble powder even this seemed doubtful, and such an action seemed altogether inadequate to explain the breaking of the gun into fragments. It appeared, therefore, that there was but one conclusion to be drawn—there had been something abnormal in the loading. Had the gun been loaded with small grained powder, gun-cotton, or dynamite, instead of pebble powder, such a result might have been produced; but then, the gun would, if it had burst, have burst at the breach unless the shot had slipped forward, and that there should have been two accidents appeared highly improbable. Besides, it was necessary to consider what sort of a mistake was most likely to have occurred; and the only possible mistake that could have been made on the spot appeared to be that of double loading.

The fact that if two complete charges were put into the gun, the powder of the second charge would be directly beneath the point of rupture appeared in favour of this the easiest mistake. But would, supposing the powder to have been pebble powder, the pressure from the two charges have been sufficient to cause the result? At first

[1] Read before the Lit. and Phil. Society of Manchester on February 18, by Prof. Osborne Reynolds, F.R.S., Professor of Engineering, Owens College, Manchester.

it seemed to me that even supposing that the second charge had been ignited by the first, which was doubtful, this would not explain the suddenness or magnitude of the pressure. But on further consideration it appeared certain that the second charge would not be ignited by the fire from the first; and it then became clear that in this very fact we should have an amply sufficient explanation of the excessive pressure.

My object in writing this paper is to point out the probability of this explanation, and so, if possible, to induce the authorities to test it. It occurred to me several days before the report of the Committee appeared, and in spite of the improbability of such a mistake as double loading, I could not shake off the conviction that it afforded the true explanation. As I have pointed out, the blowing into fragments of a wrought-iron tube implied an explosive action such as might result from guncotton or dynamite, but which could not be produced by the slow burning of pebble powder. The point to be explained, then, is how the second charge could be brought into such a condition that it would explode like gun-cotton. To understand this, it must be remembered that in the usual way the grains of gunpowder burn from their outside only, so that the thicker the grains the longer will be the time occupied in burning, and for the same weight of powder the slower will the gas be given off. The reason why gun-cotton is so much more destructive than gunpowder is not that it gives off more gas weight for weight, but that when ignited by a flash it burns so much quicker. If, therefore, by any means the whole mass of gunpowder could be heated up to the firing point at the same instant, so that the grains fired simultaneously inside as well as out, the action of the powder would be as quick or quicker than the gun-cotton. And, still further, if besides being heated the powder was compressed into a fraction of the space it usually occupies, the gases so confined would be capable of a still greater pressure.

Now if the after cartridge were fired and the forward cartridge were not ignited by the flash, and considering the length and fit of the shot, it could hardly have been so ignited, then the after shot would be driven forward closing on to the forward shot and compressing the powder between until the pressure on the forward shot was at least half as great as the pressure of the gases behind the after shot, which would be between ten and twenty tons on the square inch. Thus the powder would be subjected to a squeeze between the two shot such as would result from a blow. It would be compressed to a fraction of its former volume. The cubes would be crushed into a cake and the work of compression would be sufficient to heat the powder far beyond its point of ignition. Thus the entire mass of powder would be simultaneously ignited in a highly compressed and heated state. The force of such an explosion would be practically unlimited and would be located at the very point at which the gun burst. Hence in such an action we have ample cause for the effect produced.

But it will be asked why does not the same thing happen when a rifle is doubly loaded? It is said that in that case the second cartridge is generally blown out before it ignites, and this may be so, for in the rifle the intensity of the pressure of the gas on the shot can never exceed above a twentieth part of what it is in the 12-inch gun, and hence in the case of the rifle the pressure may well be insufficient to ignite the powder between the shot.

This view of the action resulting from the firing of powder by percussion appears to me to be one which it would be well worth while to test, for if proved it would completely re-establish confidence in the strength of the guns, which has been somewhat rudely shaken.

Let a 12-inch gun be loaded with a double charge of powder and a double charge of shot, or a shot of double weight, and fired. If, as is probable, the gun does not burst, confidence in the gun will be re-established. Then let it be loaded twice over with the powder between the shot so as to ascertain whether the action of the powder when fired by percussion would not produce an effect similar to that which we are here considering. The destruction of one gun for the purpose of establishing confidence in all the rest would not seem to be an unworthy sacrifice.

MOSELEY'S NATURALIST ON THE "CHALLENGER"[1]

THIS is certainly the most interesting and suggestive book, descriptive of a naturalist's travels, which has been published since Mr. Darwin's "Journal of Researches" appeared, more than forty years ago. That it is worthy to be placed alongside that delightful record of the impressions, speculations, and reflections of a master-mind, is, we do not doubt, the highest praise which Mr. Moseley would desire for his book, and we do not hesitate to say that such praise is its desert. The same argus-like power of observation, the same readiness to appreciate the true interest and significance of every seemingly little fact, the same energy and indomitable perseverance in gathering information and material from every source in the short space of time at the circumnavigator's disposal which distinguished Mr. Darwin, characterise also his disciple and follower in many a distant ocean land and tropical forest.

Before the *Challenger* expedition set sail, Mr. Moseley was known as an accomplished biologist, trained in the laboratories of Stricker, of Vienna, and of Ludwig, of Leipzig. He had taken part in the eclipse expedition to Ceylon, and besides making valuable spectroscopic observations on the sun, had found time when there to study and collect specimens of the land Planarian Worms, the structure of which was the subject of a memoir by him in the *Philosophical Transactions* (published after the *Challenger* had left in 1874) which threw altogether new light on such important matters as the nature of metameric segmentation and the origin of the blood-lymph space, cœlom, or body-cavity of higher organisms generally.

During the *Challenger* expedition, and since its return in 1876 (when he was by special statute elected to a "research" fellowship by the members of his old college of Exeter, in Oxford), Mr. Moseley has, apart from this volume and its varied contents, produced a series of original memoirs published chiefly by the learned societies of London, which have been the means of making known the most important of the results to which the *Challenger* expedition has led in the field of biological science. It is to his industry and skill, combined with the opportunity afforded by the *Challenger's* cruise, that we owe the thorough description of the anatomy of the worm-like land-living Peripatus, and its development, studied by him at the Cape of Good Hope (*Philosophical Transactions*, 1874), whereby a totally new light is thrown upon the relationships of the great group of Hexapodous and Myriapodous insects, and the origin of tracheæ; to him we are indebted for the discovery and description of the most remarkable among the many pelagic or surface animals taken by the *Challenger* on the high seas, the transparent Pelagonemertes (*Annals* and *Mag. Nat. Hist.*, 1875), as well as for the detection of the only really markedly aberrant form of life dredged by the *Challenger* in deep waters (*Linnean Transactions*, 1878), the Ascidian, Octacnemus bythius. The colouring matters, also, of various marine animals have been studied by him with the spectroscope and the spectra, carefully recorded in the *Quart. Journ Microsc. Sci.* 1877. But of still greater importance and merit was Mr. Moseley's study of corals allied to Millepora and

[1] Notes by a Naturalist on the *Challenger*. By H. N. Moseley, M.A., F.R.S., Fellow of Exeter College, Oxford.

Stylaster, previously unknown (or nearly so) in the living state, although familiar as dry and bleached museum specimens. These, when freshly dredged by the *Challenger*, were treated by Mr. Moseley with those subtle devices known only to trained histologists, and as a result, he has been able to give the full anatomy of the soft parts of these corals, to show that they are compound organisms with variously differentiated "tentacular

FIG. 1.—The bird and the rat living together in the same hole.

polyps" (dactylozooids) and "mouth polyps" (gastrozooids), and that they constitute a new group of hydroids, and do not belong to the Anthozoa or ordinary coral-producing class of polyps. The results of this elaborate investigation, forming the Croonian lecture for 1878, have been recently published, illustrated with twelve quarto plates by the Royal Society.

Whilst thus actually producing the chief zoological

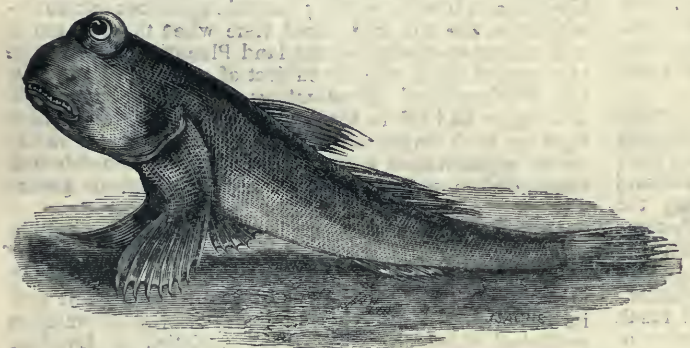

FIG. 2.—*Periophthalmus Kolreuteri* (on land; in the act of leaping).

results of the expedition, Mr. Moseley had specially undertaken the collection of plants, since no professed botanist was attached to the *Challenger*. The *Journal* of the Linnean Society, vols. xiv., xv., xvi., xviii., contain a large series of papers by Professors Oliver and Dickie, the Rev. M. J. Berkeley, and others, on the plants thus collected by Mr. Moseley's own hands on the islands visited by the *Challenger*. Not content with zoology

FIG. 3.—*Peripatus capensis* (natural size).

and botany alone, or rather, one should say, bringing his powers to bear on selected samples of the whole range of biology, Mr. Moseley has published the only anthropological memoir which has come to us from the *Challenger* staff—namely, an elaborate and careful account of an undescribed people—the inhabitants of the Admiralty Islands.

The results of all these researches are lightly sketched and often illustrated by woodcuts in the pages of the present volume, of which, however, they form but a limited portion. A still further development of biological science, namely, sociology—the history of civilisation, of manners, customs, and beliefs, is what the reader will find largely occupying Mr. Moseley's note-book, now published. And indeed, most entertaining and striking notes they are; the sayings and doings, the clothes and the amusements, the religions and the physical surroundings of Polynesians, Malays, Brazilians, Japanese, Chinese, seal-fishers, and English colonists, being set down as they impressed the observant mind of the author, accompanied by most trenchant comparisons and ingenious reflections which are characterised by a singular humour peculiar to him. Mixed with these, according to locality, we have, literally innumerable observations and suggestions with regard to such matters as basaltic columns, antarctic glaciers, flying-fish, fur-seals, phosphorescence, penguins, cockroaches, Kerguelen cabbages, land-crabs, and whales.

A few extracts will suffice to show that whilst Mr. Moseley's note-book will have special value for the professed naturalist, it is also eminently readable, and is likely to obtain great popularity amongst all those who have imaginations sufficiently vivid to allow their possessors to experience that intense form of pleasure which a good book of travels can generate. An enumeration of the titles of the chapters, to begin with, will show something of the distribution of matter in the book.

We have—I. Teneriffe, St. Thomas, Bermuda; II. Azores, Madeira, Cape Verdes; III. St. Paul's Rocks and Fernando do Norhona; IV. Bahia; V. Tristan da Cunha, Inaccessible Island, Nightingale Island; VI. Cape of Good Hope; VII. Prince Edward Island, the Crozet Islands; VIII. Kerguelen's Land; IX. Heard Island; X. Amongst the Southern Ice; XI. Victoria, New South Wales; XII. New Zealand, the Friendly Islands, Matuku Island; XIII. Fiji Islands; XIV. New Hebrides, Cape York, Torres Straits; XV. Aru, Ke, Banda, Amboina; XVI. The Philippine Islands; XVII. China, New Guinea; XVIII. The Admiralty Islands; XIX. Japan, the Sandwich Islands; XX. Tahiti, Juan Fernandez; XXI. Chile, Magellan's Straits, Falkland Islands, Ascension; XXII. Life on the Ocean Surface and in the Deep Sea, Zoology and Botany of the Ship, Conclusion.

Take the following description of a Penguin rookery at Tristan da Cunha (p. 120) as an example of Mr. Moseley's style. "It is impossible to conceive the discomfort of making one's way through a big rookery, haphazard, or 'across country,' as one may say. I crossed the large one here twice afterwards with seamen carrying my basket and vasculum, and afterwards went through a larger rookery still, at Nightingale Island. You plunge into one of the lanes in the tall grass, which at once shuts out the surroundings from your view. You tread on a slimy black damp soil composed of the bird's dung. The stench is overpowering, the yelling of the birds perfectly terrifying; I can call it nothing else. You lose the path, or perhaps are bent from the first on making direct for some spot on the other side of the rookery. In the path only a few droves of penguins, on their way to and from the water are encountered, and these stampede out of your way into the side-alleys. Now you are, the instant you leave the road, on the actual breeding-ground. The nests are placed so thickly that you cannot help treading on eggs and young birds at almost every step. A parent bird sits on each nest with its sharp beak erect and open ready to bite, yelling savagely 'caa, caa, urr, urr,' its red eye gleaming, and its plumes at half-cock, quivering with rage. No sooner are your legs within reach than they

are furiously bitten, often by two or three birds at once, that is, if you have not got on strong leathern gaiters, as on the first occasion of visiting a rookery you probably have not.

"At first you try to avoid the nests, but soon find that impossible: then, maddened almost by the pain, stench, and noise, you have recourse to brutality. Thump, thump goes your stick, and at each blow down goes a bird. Thud, thud, you hear from the men behind as they kick the birds right and left off the nests, and so you go on for a bit, thump and smash, whack, thud, 'caa, caa, urr, urr,' and the path behind you is strewed with the dead, and dying, and bleeding.

"But you make miserably slow progress, and, worried to death, at last resort to the expedient of stampeding as far as your breath will carry you. You put down your head and make a rush through the grass, treading on old and young haphazard, and rushing on before they have time to bite.

"The air is close in the rookery, and the sun hot above, and, out of breath, steaming with perspiration, you come across a mass of rock fallen from the cliff above, and sticking up in the rookery; this you hail as 'a city of refuge.' You hammer off it hurriedly half a dozen penguins who are sunning themselves there, and are on the look-out, and, mounting on the top, take out your handkerchief to wipe away the perspiration and rest awhile, and see in what direction you have been going, how far you have got, and in which direction you are to make the next plunge. Then, when you are refreshed, you make another rush, and so on.

"If you stand quite still, so long as your foot is not actually on the top of a nest of eggs or young, the penguins soon cease biting at you and yelling. I always adopted the stampede method in rookeries, but the men usually preferred to have their revenge, and fought their way every foot. Of course it is horribly cruel thus to kill whole families of innocent birds, but it is absolutely necessary. One must cross the rookeries in order to explore the island at all, and collect the plants or survey the coast from the heights."

Here is an example (p. 213) of the many observations which the book contains on the habits of birds and other animals:—

"An idea of the relations of the various birds to one another in the struggle for existence will be gained from the following incident:—I saw a cormorant rise to the surface of the water, and, lifting its head, make desperate efforts to gorge a small fish which it had caught, evidently knowing its danger, and in a fearful hurry to get it down. Before it could swallow its prey, down came a gull, snatched the fish after a slight struggle, and carried it off to the rocks on the shore. Here a lot of other gulls immediately began to assert their right to a share, when down swooped a skua from aloft, right on to the heap of gulls, seized the fish and swallowed it at once. The shag ought to learn to swallow under water, and the gull to devour its prey at once in the air. The skua is merely a gull which has developed itself by fighting for morsels."

Mr. Moseley has a great deal to say about the structure and natural history of icebergs in the chapter on the southern ice, and has illustrated this part of his book with two coloured plates and numerous woodcuts. The *Challenger* was in some danger here. "As the weather became worse, we were in a rather critical position. We were surrounded by bergs, with the weather so thick with snow, that we could not see much more than a ship's length, and a heavy gale was blowing. The full power of steam available was employed. Once we had a narrow escape of running into a large berg, passing only just about 100 yards to leeward of it by making a stern board, with all the sails aback, and screwing full speed astern at the same time. The deck was covered with frozen powdery snow, and forward was coated with ice from the shipping of seas. On February 28 again there were forty icebergs in sight at noon. It came on to snow thickly at about 4 P.M., and another gale came on. The plan adopted by Capt. Sir G. Nares was to lay down the bearings of the adjacent bergs before the weather became too thick for them to be seen, and then steaming with all the power of the ship against the gale, to hang on as long as possible under the lee of a large iceberg, and, when driven away from that, to steam rapidly across to the lee of another, the position of which was known by the bearings taken. So we went on steaming backwards and forwards through the whole of a thick, dark night."

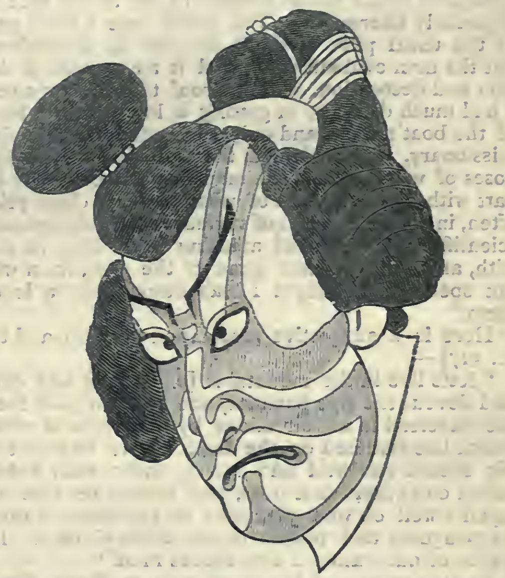

FIG. 4.—Face of Japanese Actor. (To show the mode of painting the face. From a Japanese Theatrical Picture-book.)

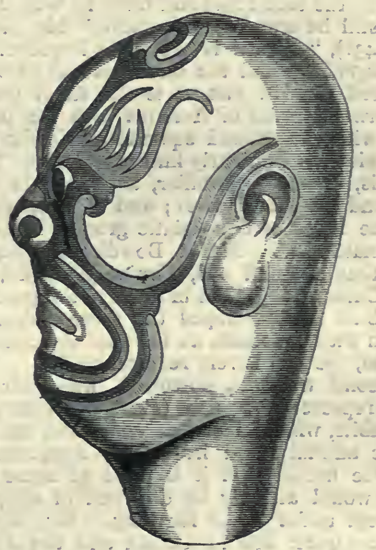

FIG. 5.—Head of figure burnt at Chinese funerals, made of paste-board. (To show the mode of painting the face.)

In warmer climes anthropology occupied, as we have said, much of the traveller's attention. The Tongans interested him by their expressive faces and gestures. A boat full of them was commanded by a noble, degraded from his rank by the missionaries, as a punishment for habitual drunkenness (p. 285).

"The coxswain of the pilot's boat, the ex-member of the nobility, wore, as I have said, a pea-jacket; a photograph was taken of the boat's crew. I could not persuade the coxswain to take off the pea-jacket, in order to make the group uniform [the others were quite naked, except a cloth round the waist]; he would only promise that if he were photographed with the jacket on in the group, he would allow himself to be taken with it off, separately afterwards. The jacket was a thick garment of the usual pilot cloth, fit only for an English winter, but the man evidently regarded it as a mark of distinction and decoration, and a proof that he was coxswain. I had much difficulty in getting a lock of hair from one of the boat's crew, and only succeeded by the help of a missionary, who explained that I did not want it for purposes of witchcraft. The man was also evidently loth to part with a single lock of what was his chief pride. I often, in collecting hairs of various races, subsequently, for scientific purposes, had amusing difficulties to contend with, and I suspect that some of the girls, from whom I got specimens, thought I was desperately in love with them."

Here is a suggestive association of man and the pig (p. 517)—

"Rats live in the mountains [of Tahiti], and climb up and devour the ripe bananas, and the groves of the trees are traversed in all directions by the tracks of wild pigs, which likewise feed on the fruit. It is strange that the pig should run wild and thrive, under such widely different conditions as it does, and should be able to exist equally well on wild plantains in the warm Tahiti, and on penguins and petrels in the chilly Crozets. In this power of adaptation it approaches man."

In his account of his short visit to Hong Kong and Canton, Mr. Moseley has much to say about the habits of the Chinese and their literature, medicines, and amusements. He reproduces several curious woodcuts from a Chinese work on natural history, the "Shan Hoi King." One of these (Fig. 1) represents, according to the description in the margin, "The Bird and the Rat which live together in the same hole. They come from the mountain of the tailed rats and birds in Wai Une, where they may still be seen." "No doubt," Mr. Moseley remarks (p. 431), "the rat is the ground squirrel (*Spermophilus mongolicus*), and the bird must be an owl, which is associated with it, just as is the small ground owl (*Speotyto cunicularia*) of America with the prairie dog and also with the ground squirrel of California, in the holes of which, as familiarly known, it lives. The genus Speotyto is, however, peculiar, as far as is known, to America and the West Indies; and the fact that an owl lives in the holes of the Asiatic ground squirrel is not known to naturalists. Mr. R. Bowdler Sharpe, however, tells me that a small owl, *Carine plumipes*, exists in northern China, which lives in holes in the ground. Possibly this bird has developed the same curious habit of association with a rodent, as has the American ground owl. If so, the fact is very remarkable."

Our second woodcut, borrowed from Mr. Moseley (Fig. 2), represents a fish (*Periophthalmus*) of very strange habits, which, like the land-crabs, though allied to aquatic animals, and irresistibly suggesting to the observer the notion that it is most at home under the water, yet would actually be drowned in all probability were it kept under water for long. Mr. Moseley has chased these queer fish in Ceylon and the Fiji Islands (p. 296). "They are very nimble on land, and difficult to catch. They use their very muscular pectoral fins to spring with, and, when resting on shore, the fore part of their body is raised and supported on these. There seems to be no figure of this very remarkable fish, which shows it at all in the attitude which it assumes when alive. The accompanying woodcut has been drawn from a specimen kindly lent to me by Dr. Günther, and I have put the fish as nearly in the natural position which it assumes when on land, as I can from memory." Space does not allow us to reproduce the excellent account of the Pearly Nautilus which follows here in the chapter on Fiji.

A good figure of Mr. Moseley's *protégé*, Peripatus, is given on p. 159, and is transferred to these pages (Fig. 3). A clear and intelligible account of the points of interest in the anatomy and habits of this caterpillar-like creature is given in the chapter on the Cape, and we read how both the author and von Suhm (one of the three other naturalists of the expedition, the other two being Sir Wyville Thomson and Mr. Murray) hunted high and low for specimens near Cape Town. Von Suhm "was unsuccessful; but I was lucky enough to find a fine specimen first under an old cart-wheel at Wynberg. Immediately that I opened this one I saw its tracheæ, and the fully-formed young within it. Had my colleague lighted on the specimen he would no doubt have made the discovery instead." It was, however, we take leave to assert, in spite of Mr. Moseley's modesty, no chance which brought the Peripatus to his hands, but, simply enough, the unwearying energy and ingenuity which characterised his proceedings throughout the voyage. At the Island of St. Thomas (p. 15) the party "heard of" Peripatus, but did not procure any. In New Zealand (p. 279) we again find mention of Peripatus; this time brought to Mr. Moseley's hands by a local naturalist, Mr. Locke Travers, F.L.S. Another result of Mr. Moseley's exertions at the Cape was his discovery of two specimens of the skull of the excessively rare and curious Ziphioid whale, *Mesoplodon Layardii*.

Tattooing and the use of paint as an ornament in China and Japan are amongst the subjects which Mr. Moseley discusses at length (p. 489), bringing a variety of facts together from his observations of Polynesians, as well as other races. The painting of the face by Chinese and Japanese is not similar to that practised by European ladies. "An even layer of white is put on over the whole face and neck, with the exception in Japan of two or three angular points of natural brown skin, which are left bare at the back of the neck as a contrast. After the face is whitened, a dab of red is rubbed in on the cheeks, below each eye. The lips are then coloured pink with magenta, and in Japan this colour is put on so thickly that it ceases to appear red, but takes on the iridescent metallic green tint of the crystallised aniline colour. In modern Japanese picture-books the lips of girls will sometimes be seen thus represented green. I suppose the idea is that such thick application of paint shows a meritorious disregard of expense. It is curious that the use of aniline colour should have so rapidly spread in China and Japan. In China, at least, such was not to be expected, but it seems to have supplanted the old rouge, and it is sold spread on folding cards, with Chinese characters on them, at Canton and in Japan."

"This form of painting the face seems to be exactly of the same nature as savage-painting, and possibly is a direct continuation of it. It is like the painting of our clowns in pantomimes. In China the faces of men (as opposed to women) seem not to be painted at the present time either on the stage or elsewhere; but in Japan, actors in certain plays are painted on the face with bright streaks of red paint, put on usually on each side of the eyes. The kind of painting is exactly that of savages (Fig. 4). It is a curious fact that this form of painting, surviving in adults on the stage, is still used elsewhere for the decoration of young children. It is quite common to see children on festive occasions, when elaborately dressed by their parents, further adorned with one or two transverse narrow streaks of bright red paint, leading outwards from the outer corners of their eyes, or placed near that position."

"Such a form of painting possibly existed in ancient

times in China. When a man of distinction was buried in China in former times, a certain number of servants were buried with him. Now, figures made of pasteboard and paper, about three feet or so high, are burnt at the funeral service, in small furnaces provided for the purpose in the temples, together with cartloads of similar pasteboard gifts, which are thus sent by the survivors for the use of the dead in the next world. Earthenware figures were similarly buried with great men in old times in Japan.

"The pasteboard heads of these funeral servants and retainers are painted with streaks, some of which are put on in almost exactly the same style at the angles of the eyes as those of modern Japanese actors. It seems a fair conjecture that the streaks on these heads (Fig. 5) are a direct survival of an actual former savage form of painting which was once in vogue in China, probably used to make fighting-men hideous. It is well known that primitive customs survive in connection with funerals all over the world with extreme tenacity. The numerous interesting survivals existing in the case of English funerals are familiar."

In connection with colour and decoration, we must draw the attention of breeders of poultry to the important experiment on sexual selection suggested on p. 373. Mr. Moseley in fact proposes to test the existence of a preference for colour on the part of hen-birds, by variously dyeing and manipulating the colours of two of more cock-birds kept with her.

The last chapter is one of the most interesting in the book, since here Mr. Moseley does not compress his wonderful richness of material into the short space which is necessary where he adopts the method of telling the reader all that he saw and thought about in one locality after another of the long list visited by the *Challenger*. Here he launches out more fully into discussion and gives a summary, intended for the general reader, of the most striking features presented by the life of the ocean surface, of the deep sea, and of the colony of cockroaches, rats, and other animals and plants which established themselves or were introduced on board-ship.

The significance of colour in marine animals is very suggestively treated, and the origin and use of phosphorescence likewise considered in an original manner. He says (p. 590):—

"The light emitted by phosphorescent animals is quite possibly in some instances to be regarded only as an accidental product, and of no use to the animal producing it; although of course, in some cases, it has been turned to account for sexual purposes and may have other uses occasionally. There is no reason why a constant emission of light should be more beneficial than a constant emission of heat, such as takes place in the case of our own bodies, and it is quite conceivable that animals might exist to which obscure heat rays might be visible, and to which men and mammals generally would appear constantly luminous."

The concluding paragraph contains a suggestion which could be carried into effect without expense by the Government, and there can be no question as to the naturalist best fitted to direct such an undertaking. Mr. Moseley says:—

"The urgent necessity of the present day is a scientific circumnavigating expedition which shall visit the least known inhabited islands of the Pacific, and at the same time explore the series of islands and island groups which yet remain almost or entirely unknown as regards their botany and zoology. These promise to yield results of the highest interest, if only the matter be taken in hand in time, before introduced weeds and goats have destroyed their natural vegetation; dogs, cats, and pigs, their animals and their human inhabitants have been swept away, or have had their individuality merged in the onward press of European enterprise. There is still, to the disgrace of British science, even in the Atlantic Ocean, an island, the fauna and the flora of which are as yet absolutely unknown. The past history of the deep sea, of the changes of depression and elevation of its bottom, is to be sought to a large extent in the study of the animals and the plants inhabiting the islands, which rear their summits above its surface. These insular floras and faunas will soon pass away, but the deep-sea animals will very possibly remain unchanged from their present condition long after man has died out."

Besides numerous woodcuts, Mr. Moseley's book is illustrated by two coloured plates of antarctic icebergs, and a track-chart of the world, with contour-colours of the sea-bottom. A very copious and carefully prepared index is appended. Throughout the book the references to literature of all kinds bearing upon the myriad topics touched upon are very abundant, and form one of the most intrinsically valuable features of the work.

E. Ray Lankester

METEOROLOGICAL NOTES

From the third annual Report of the Forest Meteorological Stations of Germany, being the Report for 1877, we learn that this system of inquiry into the influence of forests on weather and climate now includes fourteen stations scattered over a region extending over 7° of latitude and 5° of longitude, the stations being at heights ranging from 10 to 3,051 feet above the sea. The instruments and observations have been planned on satisfactory and comprehensive principles, and in a few years results eminently *ad rem* may be looked for. In the meantime the thermometric observations point to highly important results. Each station has three sets of thermometers for air temperature, similarly protected—one set in the wood, the second set high up in the crown of a tree, and the third set in an open space outside the wood, while earth thermometers are placed both in the open and in the wood, on the surface of the ground, and at depths of 6, 12, 24, 36, and 48 inches. The results show in every case a lower air temperature inside the wood as compared with the open country outside, the mean difference amounting to 1°·3. As regards the temperature of the surface of the ground, the mean deficiency in the wood shaded by the trees is 2°·5, an amount which gradually diminishes with the depth to 2°·0 at 48 inches, the lowest depth observed. It would be a problem of great interest to ascertain how deep this cooling of the earth's surface extends when it is screened by trees from solar and terrestrial radiation. What are called the "true means" of atmospheric pressure are calculated from the observations at 8 A.M. and 2 P.M., the formula being

$$\frac{\text{VIII.} \times 2 + \text{II.} \times 5}{7}.$$

Since the stations range in height from 10 to 3,051 feet, and otherwise differ in their physical conditions, it is scarcely necessary to point out that the method of reduction adopted is very faulty.

Some years ago a good deal of writing appeared in the periodical press depreciatory of the climate of Rome on account, as alleged, of the exposure of that city to the pestilential malaria of the Campagna. Many of the opinions then expressed will not bear scrutiny when confronted with the facts of the mortality and health of Rome. It was to counteract these opinions, which obtained wide currency, that a book entitled "The *Times* Newspaper and the Climate of Rome," by S. A. Smith, was recently published. The author has brought to his task the experience of a twenty years' residence, by which he has been enabled to sketch familiarly and with general truthfulness the broad features of its climate in its hygienic rela-

tions; and in addition, strong feelings, we may almost add of animosity, towards the writers whose opinions he sets himself to combat. The result is a readable book, containing much valuable information to those who intend visiting Rome, though occasionally marred by the introduction of hasty writing and hasty feeling. In comparing (p. 151) the mortality from typhoid in London in 1870 with that of Rome in 1876, the deaths in London are stated to have been 2,008, or 10 per cent. higher than the deaths in Rome; whereas the deaths from typhoid in London in 1870 were only 976, giving a mortality from this disease of little more than half that of Rome. Technical knowledge also on occasions fails the author; thus it is strongly asserted (p. 120) that the diurnal fall of temperature takes place almost exclusively between 3 P.M. and sunset, and between 9 or 10 P.M. and sunrise, but the two hours after sunset are those when the temperature is most nearly stationary. The mortality statistics, now published weekly by Cocchi, will soon supply information for a satisfactory handling of various questions which have been raised touching the health of Rome.

THE Missouri (U.S.) Weather Service Report for January last is just received (February 24), from which we learn that at St. Louis the temperature did not rise to freezing from December 11 to January 15; the mean temperature of the first ten days of January was only 9°·0, and that of the whole month 26°·9, or 4°·7 below the average; and at Oregon, in the north-west of the State, the sleighing season ended on January 25, after a continuance of fifty days. The lowest observed temperature was − 24°·0 at Phelps City on the 3rd, and at Columbia on the 4th, and temperatures nearly as low were noted on these days at many other places. The rain- and snow-fall was moderate in amount, being about two inches in the extreme south-east and south-west, and along the low country round the mouth of the Missouri, whilst in the north the fall was considerably under an inch of rain and melted snow. The cold of January, 1857, was much more intense than during last month, the mean temperature of that month being only 19°·3, or 12°·3 below the average. It is delightful to note the frank, effective manner in which Director Nipher is bringing about uniformity in his observers' reports; thus, after pointing out that "rainy" or "snowy" days are only those on which the rain or melted snow amounts to at least 0·01 inch, he adds that "this international rule is almost universally disregarded by our observers."

THE meteorological observations made at the Hydrographic Office at Pola during 1878 have been issued, with a full abstract for the year, showing the hourly means of pressure, temperature, and wind-velocity. The most prevalent winds by far are from the quarter of the compass from east-north-east to south-east, these comprising nearly half the winds of the whole year, to which there is to be added a small secondary maximum of west-north-west winds. The wind falls to its daily minimum velocity at 5 to 6 A.M., and rises to the maximum so early as noon, hours all but coincident with the daily maximum and minimum temperature. From the three years' observations now available from Pola, it is seen that in common with sea-side stations of the middle and higher latitudes, the A.M. maximum of pressure occurs later in winter than in summer, in contradiction to inland places where it occurs much earlier. Pola being in latitude 44° 52′ north, and thus within the belt to which Rikatscheff drew attention some time ago, as characterised by the occurrence, or tendency toward the occurrence, of a third maximum of pressure a little after midnight during the cold months of the year, it is interesting to note that four out of the nine individual Decembers, Januarys, and Februarys, show the occurrence of this third maximum, which also appears in the general means of December and January for the three years. The amount of this third maximum is very small, and the evidence yet adduced is not sufficient to determine whether it is a real increase of atmospheric pressure, or merely an apparent increase due to undetected instrumental errors.

OUR ASTRONOMICAL COLUMN

BRORSEN'S COMET.—Notwithstanding the track of this comet at the present appearance is a very favourable one for observation in these latitudes during April and May, the theoretical intensity of light at maximum is much less than that attaching to the first appearance in 1846; indeed, in the middle of April, when it is greatest, it is only half that of the middle of March 1846. The comet in that year was never a conspicuous object in ordinary telescopes; it approached pretty near to the earth, and on March 25 its apparent diameter was about 9′, corresponding to a true diameter of 126,000 miles.

The following positions for part of the present month are reduced to 7h. Greenwich time from Dr. Schulze's ephemeris, which has been calculated for Berlin noon:—

	R.A. h. m. s.	N.P.D. ° ′		R.A. h. m. s.	N.P.D. ° ′
March 10	1 29 4	90 15·4	March 18	1 55 56	82 59·8
,, 12	1 35 39	88 33·0	,, 20	2 2 51	81 0·0
,, 14	1 42 20	86 46·3	,, 22	2 9 50	78 55·8
,, 16	1 49 6	84 55·2	,, 24	2 16 52	76 47·3

The comet will be nearest to the earth (distance = 0·683) on the night of May 3, its position at the time being between 49 and 55 Camelopardi. Between April 14 and June 11 it will not descend below the horizon of Greenwich, attaining its greatest north declination (65° 30′) on May 11, in the head of Ursa Major. The comet was found by Dr. Tempel, as already stated, on January 14, more than a month before the ephemeris by Dr. Schulze commences, and as we remarked in a former note, was thus observed with a much less intensity of light than at any previous opposition. The error of the ephemeris has not yet been published, but it appears not to be large. We shall continue the ephemeris in due course when better advised on this point.

In his report upon the work of the Observatory of Leipsic in 1877, Prof. Bruhns mentions that Herr Harzer a student in that university had, at his request, redetermined the effect of the attraction of Jupiter upon the elements of the comet at the near approach of the two bodies in May, 1842, and with satisfactory results. In 1857 the late Prof. D'Arrest made a first approximation, by the method of the *Mécanique Céleste*, to the orbit which the comet described prior to the great perturbation or on entering the sphere of activity of Jupiter about April 19·5 Berlin time in 1842; the elements at that epoch were found to be as follows (we annex the elements in 1846 at the time of the comet's first discovery for the sake of comparison):

	1842, April 19·5.	1846, Feb. 25·4.
Long. of perihelion	133° 26′·7	116° 28′·2
,, ascending node ...	107° 44′·0	102° 41′·0
Inclination	40° 51′·0	30° 55′·9
Excentricity	0·59275	0·79338
Perihelion distance	1·50130	0·65013
Log. semi-axis major	0·56661	0·49783
Period	7·078 years.	5·581 years.

It will be seen that the perihelion distance before the encounter with Jupiter was much greater than it now is, a sufficient reason, as was pointed out by D'Arrest, for this comet to have been missed, if it had moved in the orbit which was so much changed in 1842.

MINOR PLANETS.—M. Palisa notifies his discovery of No. 192 at Pola on February 17. At 13h. 47m. m.t. its R.A. was 11h. 10m. 20s., and N.P.D., 84° 6′, eleventh magnitude.

Hilda, the most distant of the minor planets, which is

probably in the same region of the sky, has not yet been recovered. The planet which was named *Scylla*, and of which only four observations could be obtained at Pola and Berlin in November, 1875, will probably be difficult to detect again, since the observations, though inadequate to furnish elements with any pretensions to accuracy, sufficiently prove that the inclination of the orbit to the ecliptic must be pretty large. In case any one of our readers should be disposed to examine this point further, we subjoin the four observed positions reduced to longitude and latitude :—

	Greenwich mean time.		Longitude App. Eq.		Latitude North.
			° ′ ″		° ′ ″
1875, November	8·61578	...	48 5 2	...	1 58 41
,, ,,	9·42473	...	47 54 13	...	2 6 28
,, ,,	22·56605	...	44 54 44	...	3 53 18
,, ,,	23·44691	...	44 43 41	...	4 0 7

VARIABLE STARS.—Dr. Weiss, Director of the Imperial Observatory at Vienna, announces several new variable stars. One is Lalande 28607, which varies from 7·0 to 8·8 in a period not differing much from four months; this star is further to be noted for its large proper motion, $\Delta\alpha = -0^s{\cdot}080$s., $\Delta\delta = -0''{\cdot}35$. He also confirms variation in the neighbouring double star Lalande 28590, which had been suspected by Struve. Further, the stars in the *Durchmusterung*, $+17°$, Nos. 2510 and 2511, are found to be variable, the former from 8·8 to 10·0 in rather over eleven months, and the latter, also to the extent of about one magnitude, in a somewhat shorter period, about $9\frac{1}{2}$ months.

M. Ceraski, of the Moscow Observatory, also finds variation in the star, which appears thus in the *Durchmusterung*: mag. 9·2, R.A. 21h. 9m. 25s., Decl. $+67°$ 49′·5.

GEOGRAPHICAL NOTES

THE Council of the Royal Geographical Society have presented a remarkable memorial "to H.M. Commissioners of the University of Oxford, to those of Cambridge, and to the Governing Bodies of either University." The burden of this memorial is that steps ought to be taken for the establishment of professorships of geography in the two universities. The memorial points out forcibly and justly the ignorance of geography in its highest sense, in this country, where it is commonly confounded with mere topography. The Council of the Society, we are pleased to see, show that they possess an adequate conception of the position which geography ought to occupy, and which, indeed, it does occupy in the Universities of Germany, Switzerland, and France. We have often repeated that geography is really the meeting-place of all the sciences, and this is the idea which the Council endeavour to enforce upon the Commissioners and governing bodies of the universities. They show, how, to have an adequate knowledge of geography it is necessary to know something of both the biological and physical sciences, and be able to trace the mutual influence of man and his surroundings. The duties of such a professor as the Council desire to see appointed, the memorial states, would be first, to promote the study of scientific geography, and secondly, to apply geographical knowledge in illustrating and completing such of the recognised university studies as require aid. It is suggested, also, that he might deliver at least one annual discourse on some subject of geographical research. The memorial rightly states that there is no country that can less afford to dispense with geographical knowledge, but we doubt if the number of members of the Geographical Society is any evidence that we have a greater natural interest in the subject than other people. Certainly we ought to have, for our interests are as wide as the world; and as the memorial states, it would not be difficult to cite instances in which these interests have been seriously compromised by a want of geographical knowledge. Thus, that as a nation, we are far behind, both in our conception and in our knowledge of geography in its highest sense there can be no doubt, but whether this state of things is to be remedied by the founding of professorships of geography at Oxford and Cambridge is another question, which at present we cannot discuss. It appears to us at first sight as if it were beginning at the wrong end. Moreover, is not geography in its highest sense really only a branch of physiography, and would not the want in our university education be most effectually met by a professorship, or perhaps a lectureship, on that subject? At all events we are grateful to the Geographical Society for drawing attention to the importance and comprehensiveness which geography has assumed on the Continent, and to the lamentable want of interest in the subject which exists in this country.

ON the suggestion of the Bishop of Salford a committee has been formed in Manchester for establishing a Society of Commercial Geography. Mr. Armitage, the Bishop of Manchester, Mr. Arthur Arnold, Mr. Hugh Mason, Mr. Slagg, Mr. J. E. Taylor, and others, have joined the committee. We suggested some time ago the utility of forming such societies in our chief commercial centres, and we hope the example of Manchester will soon be followed by our principal seaports. That Manchester stands in need of some education in geographical matters was evidenced by the ignorance of African geography shown at the recent meetings to promote the formation of a railway from Zanzibar to the Lake Region. Similar societies have been found of great service in France. Might it not be well, however, if other towns form similar societies, that some common organisation be formed, and perhaps a common journal be published?

FROM the new Yellow Book of the Chinese Maritime Customs we gather some notes respecting the island of Hainan, the port of which, Kiungchow, has been recently opened to foreign trade. So far it has certainly not proved a commercial Eldorado, but what the real capabilities of the island are it is difficult to judge so long as the greater part remains a *terra incognita* to foreigners. This much, however, may be said in its favour, that it possesses an advantage over many islands of its size, viz., a large navigable river by which access may be gained to the interior, and which partially obviates the necessity for good roads. From the *Kiungchow Record* it appears that gold, silver, copper, tin, and loadstone are found in different parts of the island, but no mention is made of coal. The author of the report we allude to knows that peat exists, and samples of carbonate of copper have been shown him by natives. The number of different kinds of grain and other produce enumerated in the Chinese work referred to as growing in Hainan is surprising, and includes many varieties of rice, millet, Barbadoes millet, wheat, barley, beans, peas, sugar-cane, sesamum, ground-nut, taro, and yam. Of medicines (according to the Chinese pharmacopœia) exported the following are the chief items:—*Ai-fên*, a kind of camphor, obtained from the aborigines and said to be distilled from the leaves of the *Artemisia moxa*, *ho-hsiang*, stalks and leaves of *Betonica officinalis*, bitter cardamoms, cardamoms, the berries of *Abrus precatorius*, the stalks of *Dendrobium ceraia*, and tortoise-shell rind.

THE March number of the organ of the Geographical Society opens with the paper "On the Road to Merv," read at a recent meeting by Sir H. Rawlinson, which now appears, enriched with valuable notes, and illustrated by a map of the Turkoman Steppe and Northern Khorassan. Mr. C. R. Markham's paper "On the Basin of the Helmund, Western Afghanistan," is also published, accompanied by a well-executed map of the region. The Zulu-

land bibliography and cartography, which have been compiled with much care, will be found very useful at the present time, but it is to be regretted, perhaps, that a map of the country was not added. The geographical notes include accounts of M. Oshanin's further explorations in the Pamir, and of the Loochoo Islands. There is also an obituary notice of M. Nicholas de Khanikoff.

THE Archbishop of Algiers has received a detailed journal of the experiences of the French missionary expedition on its way to Albert and Victoria Nyanza, and Lake Tanganyika, which he has promised to communicate shortly to *Les Missions Catholiques.* When published in that periodical, it will be accompanied by a map of Equatorial Africa, prepared from original sources of information by Père Charmetant, under whose auspices the expedition started from the east coast.

AT the last meeting of the Society of Commercial Geography at Paris, M. Reclus communicated his report on the exploration of the Isthmus of Darien, conducted under the orders of Lieut. Wyse.

IN the *Bulletin* of the Lyons Geographical Society, which has just been issued, M. Luciano Cordeiro, the learned Secretary of the Lisbon Geographical Society, contributes a second instalment of his papers on the first explorations of Central Africa, and the Portuguese doctrine of African hydrography in the sixteenth century.

NEWS has lately been received by the German African Society from Dr. Buchner, a traveller recently sent out to West Africa. He proposed to leave Loanda towards the end of December for Dondo, on the Quanza, where Major Mechow is delayed by illness.

THE just received *Boletin* of the Madrid Geographical Society for October last contains a lecture by D. Francisco de Paula Arrelaga, on the physical geography of the sea. Also papers on Afghanistan, on Bulgaria, and other eastern countries by Sr. D. Saturnino Giménez, and an account of a journey to Morocco in 1800 by a Spanish Commission.

THE enterprise of Mr. James Gordon Bennett in preparing two vessels for arctic exploration, the one to proceed by way of Spitzbergen and the other by Behring Straits, is already well known to our readers. The steamer *Jeannette* has been assigned to the Behring Straits' service, and is, we understand, already in San Francisco. A bill has been introduced into Congress by Mr. Wood authorising the Secretary of the Navy to accept this vessel and take charge of her. The bill provides that it is to be fitted up with any material on hand, and authority is given to enlist the necessary crew and to provide the naval officers; and the expense, at least the pay of the men, will be subsequently refunded by Mr. Bennett. It is not improbable that this vessel will be made useful in the search for and relief of the *Vega*, Prof. Nordenskjöld's steamer.

NOTES

WE announce with the greatest regret the sad news, just received by telegraph, of the death of Prof. W. K. Clifford at Madeira. We can do no more this week than barely announce this national loss.

THE Emperor of Austria has bestowed upon Dr. Meyer, the director of the Royal Zoological Museum of Dresden, the well-known New Guinea traveller, the order of the Iron Crown.

THE death is announced at Berlin of the well-known chemist, Prof. Sonnenschein. He had reached the age of sixty-two.

THE Council of the Society of Arts have appointed Mr. H. Trueman Wood, Secretary, in the place of the late Mr. P. Le Neve Foster.

ACCORDING to the *Kreuz Zeitung*, Prof. Virchow intends, on the close of the current semester, to accept an invitation of Dr. Schliemann to join him in some excavations at Troy.

THE Italian Ministry of Agriculture, Industry, and Commerce offers a reward of 3,000 lire to the author of the most complete and best monographic essay on the structure, the vital functions, and the diseases of the acid fruits, or species and varieties of the genus *Citrus* and kindred genera, provided that the said work, by a sufficient collection of original observations and experiments, should succeed in furnishing an important addition to the present knowledge concerning such subjects, and thereby supply a scientific criterion for the improvement of the cultivation of these acid fruits and for the cure of their diseases. The date for sending in the works competing for the said prize is fixed for the end of May, 1881. Essays by Italians, or by foreigners written in Italian, are admissible to the competition; but if written in another language they must be accompanied by an Italian translation. The essays sent in for competition are to be sent to the Ministry of Agriculture, Industry, and Commerce, with the superscription, "Competition for the Prizes for the best Essay on the genus *Citrus*," and they must be distinguished by a motto, to be given also in a sealed cover containing the name and address of the author.

IT is intended to make a special effort to issue the Report of the Sheffield Meeting of the British Association at an early date after the meeting. To enable this to be done the Council request that all Reports and Abstracts of all Papers intended to be read in the Sections, may be sent to the Assistant-Secretary not later than July 15, in order that, if approved of by the Organising Committees, they may be put in type before the Meeting. Authors who comply with this request, and whose Papers are accepted, will be furnished *before* the Meeting with printed copies of their Reports or Abstracts. No Report, Paper, or Abstract can be inserted in the volume unless it is in the Assistant Secretary's hands *before the conclusion of the Meeting.*

DR. BOTTOMLEY has called the attention of the Manchester Literary and Philosophical Society to an interesting copy of the "Principia" of Newton. In addition to being an impression of the first edition, it contains the autograph of Edmund Halley. It was a present from Halley to the Abbot Nazari. Nazari was the editor of a scientific journal at Rome from 1668 to 1681. The following is the entry in Halley's hand-writing:—

Illustrissimo Dno
Dro Abbati Nazario
Romæ humillime offert
Edm. Halley.

Subsequently the book was in the possession of Dr. Dalton, and its value is enhanced by his autograph.

M. STEPHAN has been elected a Corresponding Member in the Astronomical Section of the Paris Academy, in place of the late Dr. Hansen, of Gotha.

WE have received one or two letters on the subject of migration of birds, referred to in Col. Donnelly's letter in NATURE, vol. xix. p. 289. Mr. H. Cecil thinks that the most hopeful way of carrying out Col. Donnelly's proposal would be through our consuls. "If a tabular sheet, noting in separate columns the points to observe—drawn up, say, by Mr. A. R. Wallace—were printed on thin paper and transmitted to our consuls abroad, with a request that they would fill them up and remit them to NATURE, my impression is that few would decline. In cases where the consul himself had not the inclination or the time accurately to fill in the paper, he could generally command the services of some one who could. This need in no way interfere with the independent notes of which your correspondent speaks." Mr. Cecil thinks that any funds required could easily be got by subscription. Mr. Allen Harker, of Gloucester, thinks that a student of migration has rather an *embarras de richesse* to contend with than a want of data. "The researches of Middendorf," he writes, "or the admirable work of Dr. Palmen, 'Om foglarnes flyttningsväger,' reviewed in NATURE, vol. xv. p. 465, would furnish your correspondent with much of the

information he desires, not to mention the many published observations of our own ornithologists, which are as reliable as they are voluminous." What is mainly wanted is, he thinks, not so much new records as a tabulation and systematic arrangement of those we already have. Mr. Harker refers to a comprehensive article on "The Migration of Birds," by Lieut.-Col. Drummond Hay, in the *Scottish Naturalist* of last year, which meets in some measure Col. Donnelly's suggestions.

GENERAL MYER has presented M. W. de Fonvielle with an improved weather-indicator in acknowledgment of the services rendered by him during the exhibition in popularising the principles adopted by the U.S. Signal Office. This weather indicator will be exposed in the shop of M. Secretan, the optician of Pont Neuf, and forecasts daily published according to the method adopted by the Signal Office in the several American farmers' post offices.

THE services rendered to meteorology by the observatories of Puy de Dôme and Pic du Midi are so great that it is proposed to establish two others, as we mentioned in our last impression, one on the top of Mont Ventoux, in the south of France, and the other on the top of Ballon de Servance (altitude 1,189 metres) in the department of Vosges. A fort and an electric telegraph having been established recently on the top of that mountain, the expenses will be very small. Two other mountains in the vicinity reach a somewhat higher altitude, but they are on the new frontier, and only a part of them belongs to France. M. Jules Ferry, the new Minister of Public Works, having been born in the Vosges, and being a representative of that department, it is pretty certain he will exhibit the same zeal for this enterprise as M. Bardoux, his predecessor, did for the Puy de Dôme Observatory.

TWO companies are in competition for exhibiting the monster Giffard's captive balloon. One directed by M. Tissandier contemplates continuing the ascents on the site of Cour des Tuileries, but there is some uncertainty whether the old palace will not be restored next summer. A German company offers to establish it at Berlin, on the occasion of the forthcoming International Exhibition.

MDME. SARAH BERNHARD, the celebrated actress, has published a volume on her captive balloon ascents.

IN his last report on the trade and commerce of New Caledonia, Mr. Consul Layard states that he has observed there a great variety of apparently valuable fibres, woods, and oils, which have yet to be developed. He also notes the discovery of a large deposit of good guano on some islands in the prolongation of the reef at the northern end of the island. He considers this somewhat remarkable, as it might have been imagined that the rain which falls in these latitudes would deprive the deposits of much of their valuable constituents. The guano, however, is said to have been tested in Melbourne and Sydney, from which places large orders for its supply have been received.

IN his just-published trade-report H.M.'s Consul at Islay, Peru, mentions that some very rich lodes have been discovered at Caylloma, a district about thirty leagues to the north of where the railway passes at Pampa de Arriero, on the road from Arequipa to Puno. Several parties have surveyed them, and they are supposed to be equal in riches to the famous Caracoles mines in Chile, which created so much excitement a few years back. It has been found, however, that there will be great difficulty in extracting the metal from some of the lodes, which are apparently very rich in silver ore, owing to the damp nature of the ground and the consequent necessity for powerful machinery to draw the water from the mines.

AREQUIPA, Peru, was visited on the night of January 9 by the most severe shock of earthquake that has been felt there since that which destroyed the city on August 13, 1868. The present shock occurred shortly before midnight and caused general consternation. The people quickly left their houses, and rushed frantically through the streets, fearing a repetition of the shock. No other, however, followed at that time, but three days later a long and violent single shock of earthquake occurred also at midnight.

WE are glad to notice that the Ancient Monuments Bill has passed through Committee of the House of Commons, with some slight modifications. We trust that the further stages necessary before the Bill can become law will be got through successfully during the present session.

THE German papers, the *Times* Paris correspondent states, give the following account of an occurrence at Rappelsdorf, in the Erfurt district, which, though dated the 21st of last month, is not uninteresting if true:—"Yesterday, at 5.45 P.M., the water of the Todten Lake suddenly rose with a violent bubbling, flooding the surrounding land for nearly 500 metres, and as suddenly returning to its natural bed. One Rappelsdorf inhabitant will have it that he saw a bubbling pillar of water rise fifty feet out of the lake, and that it burst asunder and spread on every side. During the rise of the water subterranean noises were heard. All that is now to be seen is a deep, gaping rent in the earth, from which from time to time vapour rises. The whole land over which the water spread is covered with innumerable small shells and dead fishes."

FURTHER experiments were made last Thursday in lighting the British Museum reading-room with the electric light. The result showed that by proper arrangement and at a comparatively moderate cost, there is good reason to believe that the end desired can be obtained. The Paris Société Générale d'Électricité have made the experiments at their own cost.

WE learn from the *Colonies and India* that experiments are still being carried on at the Peradeniya Botanic Gardens, Ceylon, with the view of discovering a cure for the leaf-disease in the coffee-tree. Mr. George Wall has devised an ingenious method of applying sulphur fumes to the trees for this purpose. A paper umbrella with a curtain hanging from it, is dropped over the tree, and fastened by the handle, a lighted sulphur fuse is then placed underneath, and it is said that the fumes are retained long enough to attack the spores of the fungus.

AN interesting account, *The Colonies and India* states, has been published in the papers of Barker's Cave, Rosella Plains, North Kennedy district, Queensland, to which place Sub-Inspector Armit had followed the track of a white woman and four black fellows. The tracks were followed for nearly three-quarters of a mile in the cave and then out again. The opening is about 25 feet high and 40 broad, and the average height 40 feet, with a breadth of 60 or 70. For about 180 yards from the mouth some degree of daylight is visible, but after that there is impenetrable darkness. The floor was almost perfectly level for hundreds of yards. A root of ficus was found growing 800 yards from the mouth of the cavern. Some hundreds of yards further on they came to water, and found that no further progress could be made without a canoe. An expedition, provided with a canoe and tools and other implements, is to be sent to make a thorough examination of the cave.

THE competition of Japan teas with those of China and Assam have quite recently received a new impetus. In a recent report on the tea trade of Hiôgo we are told that efforts are being made to stimulate this important native industry by the manufacture of black tea; this it is stated is of the greatest importance to Japan in view of the strong competition that exists between teas produced in the country and those known in trade as Formosa Oolongs, the only great market for both of these kinds being

America, the effect of which has been to reduce prices and consequently to impose a limit upon production. Several hundred piculs of imitation Congou were shipped to London from Hiôgo in the course of last year, and are said to have been favourably received in the market, both quality and flavour being of a high order; the only question remaining to be solved as to the success of these teas is whether they "can be produced at prices low enough to enable them to compete favourably in foreign markets with China and Assam teas."

In the December part of the *Transunti* of the Royal Academy *dei Lincei* of Rome, Prof. Cossa gives an interesting account of his researches on the occurrence of the three metals cerium, didymium, and lanthanum. It appears that although these metals occur always in but minute quantities, yet their occurrence is far more frequent than is generally supposed, Prof. Cossa having been able to trace them even in bones and in the ashes of plants, not to speak of a number of minerals, such as certain apatites, Carrara marble, scheelite, &c. In Carrara marble Prof. Cossa found about two centigrammes of the mixed oxalates of cerium, lanthanum, and didymium in every kilogramme of marble; there were also traces of yttrium.

We have on our table the following works:—"The Elements of Dynamics," second edition, James Blackie (Thin, Edinburgh); "Simple Lessons in Domestic Economy," Wm. Wyley Murly; "Education as a Science," A. Bain (Kegan Paul and Co.); "The Land of Midian," 2 vols., Capt. Burton (Kegan Paul and Co.); "Reise aus den Stillen Ozean," Max Buchner (J. N. Kerns); "The Study of Rocks," Text-Books of Science, Frank Rutley (Longmans); "Dictionary of Chemistry," vol. viii. part 1, Henry Watts (Longmans); "Report of the Recorder of the Botanical Locality Record Club," West (Newman and Co.); "British Burma and its People," Capt. Forbes (Murray); "Life in Asiatic Turkey," E. J. Davis (Stanford); "Geological Survey of Victoria, Report of Progress of the Secretary of Mines" (Trübner); "The Two Voyages of the *Pandora* in 1875 and 1876," Sir Allen Young (Stanford); "Practical Geology," W. J. Harrison (W. Stewart and Co.); "Animal Physiology," Dr. A. Wilson (W. and R. Chambers); "Manual of Practical Chemistry," A. W. Blyth (Chas. Griffin and Co.); "A Ministry of Health," B. W. Richardson (Chatto and Windus); "Morphology of Vertebrate Animals," A. Macalister (Longmans and Co.); "The Colour Sense," Grant Allen (Trübner); "Fuel, its Combustion and Economy," T. Symes Prideaux (Lockwood); "The Evolution of Man," 2 vols., Ernst Haeckel (Kegan Paul and Co.); "Experimental Culture of the Opium Poppy," John Scott (Calcutta Press); "Manual of Opium Husbandry," John Scott (Calcutta Press); "Sewage Poisoning," Edward T. Blake (Hardwicke and Bogue).

The additions to the Zoological Society's Gardens during the past week include a Common Hare (*Lepus europæus*), British Isles, presented by Mrs. F. Buckland; an Impeyan Pheasant (*Lophophorus impeyanus*) from the Himalayas, two Cheer Pheasants (*Phasianus wallichii*) from North India, received in exchange; a Nuthatch (*Sitta cæsia*), British Isles, purchased; a Sambur Deer (*Cervus aristotelis*), born in the Gardens.

THE PHYSICAL NATURE OF THE SUN[1]

The question whether all points of the sun are alike, in reference to the emission of light and heat, is not yet decided. As to the distribution of heat on the sun, many investigations have already been made with a view to answering this important question. Nervander seems to have been the first to discover (from temperature observations at Paris and Innsbruck) a temperature inequality of about ½° R, which has moreover the period of the sun's rotation (27·25 days). Simultaneously, Dr. Buys Ballot made a similar inquiry in Utrecht. Proceeding on the supposition that a kind of heat pole exists in the sun, and that accordingly the rotation of the sun must appear from long series of temperature determinations, he got from observations of temperature at Harlem, Zwanenburg, and Danzig, a period of 27·682 days. Since this result differs so much from that of Nervander, Buys Ballot subjected the calculations of Nervander to a thorough scrutiny, from which he concluded that that observer had "not only taken the moon for the sun, but had also mistaken the former." In his memoir Buys Ballot further showed, that to the colder side of the sun, which was presented to us on 1st January, 1846, a temperature corresponded that was, on an average, about 0·7° lower than that of the warmer side, which was presented to us on 15th January of that year. Carlini and D'Arrest got nearly the same result as Nervander. Airy, on the other hand, was unable to decide from the Greenwich observations. Since by the distinguished researches of Hornstein, Director of the observatory at Prague, and of Broun, it has been proved that the time of the sun's rotation may be deduced from variations of magnetic and barometric phenomena more accurately and from a short series (one year) of observations, and since both the period of Nervander and that of Ballot differ so much from Spoerer's and Carrington's rotation period, I submitted the Prague temperature-observations for 1876 to a closer examination, expecting a much shorter period from these than Hornstein got from magnetic and barometric obserations, as I supposed that it would correspond to the rotation, deduced from spot observations, of the thermal equator of the sun, which, it is known, does not coincide with the true equator. I worked the observations therefore by the method given by Hornstein in the *Sitzungsberichte* of the Vienna Academy (Bd. 67), as it is peculiarly suited for such researches. I here communicate the final result. The most probable value obtained for T was 25·56 days. According to Carrington's observations, the position of the thermal equator of the sun on the foregoing supposition would have the latitude 10° to 20°, according to Spoerer's observations, the latitude 13° to 40°. As recent researches seem to show that the influence of variation of the forces of the sun is reflected in the variations of meteorological phenomena, I further investigated the wind components of the year 1870, in their relation to the rotation-time of the sun. For the east-west-components I found a period of 26·71 days. Whether from this result may be concluded a correspondence between prevalent winds in the sun, such as Spoerer has deduced from his spot observations, will have to be decided by closer investigation.

[1] By Dr. Gruss, in the *Astronomische Nachrichten*.

THE STRUCTURE AND ORIGIN OF LIMESTONES[1]

After the obituary notices of eminent Fellows lost during the past year, who were more than usually numerous, the president confined his own special address to the consideration of the structure and origin of limestones, relying mainly on his own observations, but incorporating general facts derived from other sources. Since, in order to properly understand the nature of the various constituent fragments of which many limestones are composed, it is necessary to know the organic and mineral constitution of the various different living calcareous organisms, this question was first considered from a somewhat novel point of view, and they were regarded, not merely as living tissues, but also as mineralised organisms, much attention being paid to their special optical characters. Much attention had been also paid to their true mineral constitution, so as to ascertain in which groups the carbonate of lime exists in the form of calcite, and in which as aragonite. The results are in some cases remarkable, even in relation to biology, and are of great interest and importance in the study of limestone rocks and their included fossils, since subsequent changes depend mainly on whether the original material was calcite or aragonite. This is due to the fact that calcite is in a state of stable equilibrium, and cannot be changed to aragonite, whereas aragonite is relatively in a state of unstable equilibrium, can be changed to calcite, and usually has so changed in limestone rocks. This circumstance has given rise to a complete difference in the state of preservation of many fossils. When they were originally calcite, they may have been further consolidated, but retain their original structure and optical properties, whereas when they

[1] Abstract of Anniversary Address to the Geological Society by Mr. H. C. Sorby, F.R.S., President, communicated by the author.

were aragonite they have sometimes been completely removed by solution, and in other cases are usually changed into a mass of crystals of calcite, and have lost their original microscopical and optical characters. The general structure of various recent and fossil organisms was then considered, and it was shown how and to what extent they could be distinguished, when occurring as minute fragments in thin sections of limestones.

The various facts connected with the disintegration of shells, corals, and other organisms, are of great importance in studying limestones, since without an adequate knowledge of the manner in which they decay and fall to pieces, very inaccurate conclusions might be formed respecting the origin of calcareous deposits. The results mainly depend on original structure, and on whether they are composed of calcite or aragonite. The next questions considered were the manner in which the external form of minute fragments is preserved in limestone, and the various chemical changes occurring after deposition or consolidation; and, having thus established the general principles necessary for their accurate study, the President entered on a description of our various English limestones, in descending order.

The main object was to ascertain, as far as possible, the exact nature of the material from which each particular rock was derived. Some beds are mainly composed of definite fragments, so as to be analogous to sands, and then the true nature of the various organisms from which the fragments are derived can be ascertained, provided they were originally calcite, whereas, if they were originally aragonite, and their structure lost, very often all that can be said is that they were portions of aragonite shells or corals. Many associated beds are or were composed of fine granules, and analogous to clays. In many cases these have in all probability been derived to a great extent from aragonite organisms decayed down into small granules of calcite, and it is quite impossible to further identify the material.

The structure and origin of oolitic grains was dwelt upon at some length. Usually they are evidence of true chemical deposition. They occur in three distinct types, viz., those composed of aragonite, having a concentric structure without any radii, giving rise with polarised light to a black cross optically positive; those which are composed of calcite, having a radiate structure and giving rise to a negative black cross; and those which have recrystallised since their original formation. After describing the chief points of interest connected with the leading limestone rocks of our country, the president collected together the results into two tables, the more condensed of which may here be given.

Name of rocks.	Chief constituent fragments, &c., in descending order.
Cretaceous	Shell prisms, Foraminifera, Coccoliths.
Wealden	Freshwater aragonite mollusca, Entomostraca.
Jurassic	Chemical deposits, Aragonite mollusca and corals, Brachiopoda, Echinoderms, Shell prisms.
Permian	Original structure lost by dolomitisation.
Carboniferous ...	Encrinites, Brachiopoda, Foraminifera, Corals, and Polyozoa.
Devonian	Encrinites, Corals, and allied organisms.
Silurian	Encrinites, Corals and Polyzoa, Brachiopoda, Trilobites.
Metamorphic ...	Original structure lost, Quartz and Silicates formed *in situ*.

He concluded as follows:—

"On examining these tables, especially the more detailed ones, it will be seen how remarkably and characteristically our limestones differ from one another. There would usually be little difficulty in deciding the general age of any characteristic, somewhat coarse-grained, specimen. Though this difference must to a great extent have depended on the nature of the organisms living at each period, yet it must also have depended on the accompanying mechanical and chemical conditions of the water in which the deposits were formed. The structure of each rock was therefore dependent on two most important circumstances, and we need not be surprised to find the results so varied and characteristic. Passing upwards from the earlier rocks, we may often trace a gradual change, broken here and there by a complete contrast, which is in perfect agreement with results arrived at from a totally different class of facts. On the whole, this is perhaps the most important conclusion that we can at present draw from the subject before us. Possibly further research may teach us much more, since I am quite sure that much remains to be learned. In fact, long as I have studied these questions, and long as this address has been, I know quite enough of the facts to be convinced that it is only a sort of first attempt and rough sketch of a very wide and complex subject."

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

MR. MILMAN, who for some years has acted as Assistant-Registrar, has been appointed to succeed Dr. Carpenter as Registrar of London University. It is stated that Mr. H. N. Moseley is a candidate for the Assistant-Registrarship.

MR. A. CRAIG-CHRISTIE, F.L.S., lecturer on botany, Edinburgh, is a candidate for the Chair of Botany in the University of Edinburgh.

IN a recent report by the British Consul at Hakodate, some account is given of the public buildings and other institutions of Sappora and Ishcari. Referring to the Agricultural College buildings, we are told that they consist of four distinct houses, as follows:—A two-storeyed house, comprising lecture and recitation-rooms, cabinets, and offices. A one-storeyed house, used for dormitories to accommodate from fifty to sixty students, attached to which is a similar building providing a large dining-hall, kitchen, bath-rooms, offices, and servants' quarters. In connection with this, again, is a two-storeyed building, which serves as a lecture-room and a general sitting-room and study. A two-storeyed house, which is the chemical laboratory; the ground-floor of this house is used as a general laboratory for the students, and on the second floor are the lecture and apparatus-rooms, and the rooms for collections in mineralogy, geology, and chemistry. Besides these there are several other buildings in European style, used for various scientific and industrial purposes. It is further intended to erect, at an early date, an Agricultural College, likewise two-storeyed, which will be another imposing building. Here will be zoological, mineralogical, geological, botanical, and agricultural museums, with separate halls for lectures and experiments in the above-mentioned branches. The Sapporo Agricultural College was founded by the Kaitakushi for the education and practical training of young men from all parts of the Empire, who are expected to remain in the Government service in Yesso, after graduation for a term of five years. The number of students is limited to sixty, and all their expenses while in college are defrayed by the government. Candidates for admission must be at least sixteen years of age, of sound constitution and good character. They will be examined orally and in writing in the Japanese and English languages (which they are expected to read, write, and speak correctly and fluently), arithmetic, geography, and universal history. If they succeed in this preliminary examination they will have to sign a prescribed contract with the government and furnish a satisfactory surety or guarantee. The course of instruction will occupy four years and embrace all the branches of a general education, with the study of the Japanese and English languages. Moreover, they will be thoroughly instructed in agriculture and horticulture, civil engineering, and chemistry, astronomy, botany, geology, zoology, military science and tactics, and before they leave college, in the fourth year, they will have to devote some time to political economy. As the students are destined to become practical agriculturists, including the use of hand implements and machinery, and the care and management of domestic animals, they have to work in the fields with their foreign instructor two afternoons of each week. There are at present three foreign professors or instructors, viz., one for mathematics and engineering, one for botany and chemistry, and one for agriculture, besides the native teachers, and it is expected that later will be added an instructor for military drill, and one specially for the English language, and a foreign doctor. The number of students at the time the report was written amounted to thirty, fifteen being added annually up to sixty in the fourth year of the foundation of the college, when the first batch of fifteen (the original number started with) will retire and graduate if they have completed their course of studies in a satisfactory manner, whereupon they will enter government employ. In another part of the report, speaking of the progress made by the students, the reporter says, "they are most assiduous at their studies, and it is indeed astonishing the progress they have already made. All their studies are conducted in English, and they speak and discuss in English without the slightest hesitation, making use of very good language. They also appear to enter fully into the different branches of study."

SCIENTIFIC SERIALS

Annalen der Physik und Chemie, No. 1, 1879.—This begins with a portion of an extended inquiry by Herr F. Kohlrausch into the electric conductivity of aqueous solutions of hydrates and salts of the light metals, as also of sulphate of copper, sulphate of zinc, and nitrate of silver. The paper is in three parts—an experimental, a practical, and a theoretical (the first two in this number). The practical part gives tables for use, and formulæ of conductivity, especially of dilute solutions; specifies bodies which show a maximum of conducting power at a degree of concentration of solution below saturation, indicates liquids which commend themselves as a standard for electric conductivity, &c.—Herr W. Kohlrausch furnishes an experimental determination of the velocities of light in crystals. He employed the new instrument called a total reflectometer, and he comes to the conclusion that Fresnel's theory of double refraction in optically uni- and biaxial crystals gives a form of light wave-surfaces, which, within very small errors of measurement, is in general experimentally confirmed for uniaxial crystals, and for the principal sections of biaxial crystals.—Herr Groshaus contributes some interesting observations on the densities of substances in the gaseous and liquid states, in relation to their chemical composition.—Herr Ritter calculates that the quantity of heat radiated annually from the sun 75,000 years ago must have been about 1 per cent. less than at present (700,000 years ago about 10 per cent. less), a result which is supposed to explain the "glacial period," while the previous tropical climate is accounted for by a less thickness of the solid crust of the earth. He also estimates that each kilogramme of the sun's mass contains on an average about 43,000,000 units of heat.—Herr Wiedemann declines to regard the oxide containing copper separated electrolytically from solutions of acetate of cupric oxide, as a peculiar allotropic modification of copper.—There are also papers on the thermo-electric properties of apatite, brucite, &c. (Hankel), the theory and application of electro-magnetic rotation (Margules), the influence of temperature on galvanic conductivity of liquids (Exner and Goldschmiedt), and two new fluorescent substances (Lommel).

SOCIETIES AND ACADEMIES

London

Royal Society, February 27.—"Studies in Acoustics. I. On the Synthetic Examination of Vowel Sounds." By William Henry Preece and Augustus Stroh.

The authors had studied the formation of vowel-sounds on Helmholtz's theory, and had succeeded in constructing an instrument which reproduced the principal vowels with greater distinctness and accuracy than the phonograph, and which fully confirmed that theory. In the pursuit of this study they constructed a new phonautograph, a machine for drawing harmonic curves either on paper or on smoked glass, compounded of one or many partials varying in phase and amplitude, called a "synthetic curve machine," a new syren, a new musical instrument dependent on the vibration of a diaphragm and several instruments for reproducing vowel-sounds. They had also studied the intensity of sound, and showed experimentally how loudness was dependent on the quantity of air thrown into vibration, and independent of the amplitude of vibration of the sonorous body which remained constant. They also introduced a new stereoscopic slide, which rendered very complicated curves perfectly perspective.

Linnean Society, February 20.—Prof. Allman, F.R.S., president, in the chair.—The Rev. G. Henslow exhibited portions of an elm bough having a pulley centrally imbedded; exteriorly all trace of its presence was obliterated, and the wood-growth indicated thirteen years subsequent to the entrance of the foreign body.—Mr. R. Bowdler Sharpe showed and commented on a series of rare birds. Among those from New Guinea were skins of *Paradisea raggiana*, collected by the Rev. Mr. Lawes; of others obtained in the Fijis by Baron von Hugel were species of the genus *Pinarolestes*, which also inhabit Tutuela, one of the Samoan Islands.—Mr. W. H. Fitch passed round a coloured drawing of a remarkable large crimson-coloured pitcher (twelve inches long by nine in circumference) of *Nepenthes sanguinea*, grown at Bury, by Mr. O. Wrigley.—A paper was read by Dr. H. Trimen, on the genus *Oudneya*, Brown. This is a small cruciferous shrub discovered by Dr. Oudney in the desert between Tripoli and Mourzuk. The genus has been obscure in consequence of Brown's short insufficient diagnosis. This latter Cosson has shown to be a *Moricandia*, hence Brown's genus has been doubtfully referred to the same. Dr. Trimen shows from an examination of Oudney's herbarium in the British Museum, that *Oudneya* is identical with *Henophyton*, Coss., which name will supersede, having the priority of thirty-one years.—The abstract of a communication on some South American genera of plants of uncertain position, by Mr. John Miers, was read by the Secretary. The author refers the *Pleoaginea* of Arruda da Camara, who mentions three species belonging to the Chryobalanaceæ, but of which two only should be retained in that genus, the third belonging to the true *Conepia*, Aublet. Among *Parinarium* the two species described and figured by Aublet alone ought to be retained. Those to be excluded are the two British Guiana species of Bentham, and seven others of Brazilian origin described by Dr. Hooker, and which from their floral structure and development of fruit do not differ from *Licania*. The Malayan species of Blume are now shown to belong to the *Petrocarya*, Jack., while the African species enumerated by De Candolle, together with five others yet undescribed, must be referred to *Griffonia*, Benth. and Hook., a genus notable for the conferrumination of the cotyledon of the embryo. The genus *Minquartia*, Aubl., belongs to the Crescentiaceæ, as does *Senapea*. Bentham's and De Candolle's *Kigelia* are widely different, the *K. africana*, Benth., properly belonging to *Tripinnaria*. The genus *Managa*, Aubl., Mr. Miers avers belongs to the Aurantiaceæ; *Racceria*, Aubl., does not come under Sapindaceæ, as De Candolle supposed, but to the Meliaceæ, and is allied to *Melia* and *Azenderachta*, Juss.—Dr. Maxwell Masters next gave the chief points of a paper on the inflorescence of Crassulaceæ. Though devoted chiefly to this group he discussed the schemes of classification proposed by Roeper, Bravais, and others, as also the emendations of Hofmeister, Sachs, and the modern German school of botanists. He proposed a re-arrangement under the heads of Monopodial, or indefinite; Choripodial, or dichotomous; and Pleiopodal, or definite; the latter comprising the Sympodial varieties. The modifications brought about by suppressions, adhesions, congenital or otherwise, real or apparent, and by displacement of varying kind and degree were alluded to, the general conclusion being that while suppressions and adhesions do occasionally occur, yet that in most instances the phenomena witnessed might easily be explained by displacement of parts, and especially by that process of elongation known as up-lifting. The history of development, as well as the internal structure, he believes are consistent with this latter view, but not, as a rule, with the theory of adhesion.—Messrs. Ed. A. Fitch, Laurence Scott, and Wm. Stone were elected Fellows of the Society.

Chemical Society, February 20.—Dr. Gladstone, president, in the chair.—The following papers were read:—On colouring-matters derived from diazo compounds, by Dr. O. N. Witt. For some time after the introduction of anilin dyes, though magentas, violets, and blues were obtained in profusion, no choice of yellow or green anilin dyes was to be had. A few years back, however, a beautiful yellow dye, chrysoïdin, was described by Hofmann, and since that time numerous patents have been taken out for the manufacture of similar substances. In the present paper the author gives an account of these various substances, which are oxy or amido derivatives of azobenzene, including the different tropæolins.—Investigations into the action of substances in the nascent and occluded conditions; hydrogen, continued by Dr. Gladstone and Mr. Tribe. The authors have investigated the actions of nascent hydrogen obtained by electrolysis and hydrogen occluded in palladium or platinum on nitric and sulphuric acids; they establish a close similarity of character, and therefore of condition between the so-called nascent hydrogen and the hydrogen occluded by metals.—On some methods of vapour density determinations, by Mr. J. T. Brown. The author criticises the methods and formulæ of previous experimenters, and suggests the determination of the vapour tensions of mercury by estimating the vapour tension of a substance over Wood's metal and over mercury at different temperatures.—On the decomposition products of quinine and the allied alkaloids, by Mr. J. J. Dobbie and Dr. W. Ramsay. The authors have oxidised the four principal alkaloids derived from cinchona bark, and find that they all yield, on oxidation, the same acid, tricarbopyridenic acid. They also point out that there is a close relation between the cinchona bark alkaloids and the bases of the pyridin series.

Geological Society, February 5.—Henry Clifton Sorby, F.R.S., president, in the chair.—Arthur Ernest Baldwin, James

Farie, Benjamin Neeve Peach, were elected Fellows of the Society.—The President announced the receipt of a legacy of 1,000*l*. bequeathed to the Society by the late Sydney Ellis, Esq., of The Park, Nottingham.—The following communications were read:—On the occurrence of pebbles with Upper-Ludlow fossils in the lower carboniferous conglomerates of North Wales, by Aubrey Strahan, F.G.S., and Alfred O. Walker, F.L.S. The authors described the mode of occurrence near Abergele of certain lower carboniferous conglomerates, best exposed in Ffernant Dingle, and especially of one containing numerous red and green sandstone pebbles, which inclose fossils of Upper-Ludlow forms, and lying above the so-called "bastard limestone." From the arrangement of the beds the authors believe that they may have been deposited against a bank or sloping surface of Wenlock shale; and they state that the great majority of the pebbles in the conglomerate are quite unlike any rock known in the district, but closely resemble the Upper-Ludlow beds of Kendal and Central Wales. The authors discuss the origin of the pebbles, and suggest "the probable extension of the Ludlow beds under Lancashire as the most likely source from which they can have been derived."—On a new group of pre-Cambrian rocks (the Arvonian) in Pembrokeshire, by Henry Hicks, F.G.S.; with an appendix on their microscopic structure by T. Davies, F.G.S. In some new areas of pre-Cambrian rocks, discovered by the author last summer in Pembrokeshire, some rocks of a character hitherto unrecognised in this country were made out. As they were found to hold there, and subsequently also in other areas, a very definite stratigraphical position, with a vertical thickness of several thousand feet, they have been separated by the author from the other pre-Cambrian groups under the distinctive name of Arvonian. They were also found to occupy an intermediate position between the Dimetian and Pebidian formations, and at all points, so far as could be made out, appeared to be separated from each of those formations by stratigraphical breaks. The new areas where they are chiefly exposed are situated some few miles to the north of Haverfordwest, where they form ridges running in a direction from north-east to south-west. They occupy an average width of about a mile, attain at some points to a height of nearly 600 feet, and together have a length of over nine miles. The rocks are flanked by Pebidian and Cambrian beds along their north-west borders, and on the south-east Silurian rocks have been brought against them by faults. In general appearance, as well as in their more minute lithological characters, they are easily distinguished from any of the rocks hitherto described by the author as characteristic of the Dimetian and Pebidian groups in Pembrokeshire. They are, however, so closely allied to some of the true "hälleflinta" rocks of Sweden, that it seems to the author and Mr. Davies that this is the name that should be applied to them in a petrological sense. The author and Mr. Davies believe the origin of the rock to have been a sedimentary one.—On the pre-Cambrian (Dimetian, Arvonian, and Pebidian) rocks of Caernarvonshire and Anglesey, by Henry Hicks, F.G.S.; with an appendix on their microscopic structure by the Rev. Prof. T. G. Bonney, F.R.S. In this paper the author gave the results of some further researches made in Caernarvonshire and Anglesey since his previous communication to the Society on December 5, 1877. A brief statement of some of the results was read at the last meeting of the British Association in Dublin; but much additional evidence was now brought forward, besides many important facts obtained since by microscopical examination of the rocks.—On the quartz-felsite and associated rocks at the base of the Cambrian series in north-western Caernarvonshire, by the Rev. Prof. T. G. Bonney, F.R.S. The great masses of quartz-felsite (or quartz-porphyry) which occur in the vicinity of Bangor, Caernarvon, and Llyn Padarn, are coloured in the Survey map as intrusive, and in the memoir regarded as most probably the result of an extreme metamorphosis of the lower beds of the Cambrian series. The author showed that these quartz-felsites exhibited, in places, all the characteristics of true igneous rocks.—On the metamorphic series between Twt Hill, Caernarvon, and Port Dinorwic, by the Rev. Prof. T. G. Bonney, F.R.S., and F. T. S. Houghton, B.A. In the Geological Survey map this district is coloured as "intrusive felsite," together with those spoken of in the last paper. It was asserted to be probably metamorphic rock by Prof. Hughes and Dr. Hicks in a communication made to the Society last year, and the first author confirmed that view by microscopic examination of a specimen collected by them. The authors had during the past autumn more minutely examined the district, and found: 1. That the general character of the series was that of a metamorphic one; 2. That the rocks of granitoid aspect were associated with well-marked beds of conglomerate; 3. That this series extended up to a little beyond Port Dinorwic, where the quartz-felsite set in. The paper described the microscopic structure of some of the rocks, and the author expressed the opinion that the more granitoid specimens were probably the results of alterations of felspathic grits.

Physical Society, February 22.—Prof. W. G. Adams, in the chair.—New Members: Rev. Coutts Trotter, Prof. G. D. Living, J. C. Adams, F. W. Paterson.—Dr. C. W. Siemens described his new electric current regulator. A necessary condition of the transmission of power to a distance by electricity along a single conductor and re-distributing it by means of branch circuits to separate electric lamps or motors, is that the current strength in each lamp shall be practically uniform. Otherwise the current flowing in the whole branch varies. Hence the necessity of a regulator to regulate the flow of current so as to keep it uniform, however the resistance of the circuit or the electromotive force of the source may vary. The author believes that by properly arranging a number of dynamo-electric machines, either in series or parallel (for intensity or quantity), at each end of the wire, a vast amount of power may be sent along a small copper conductor successfully, provided the distribution is properly regulated. He has designed a regulator based on the heating of a wire by the passage of a current through it. A fine strip of mild steel $\frac{1}{20}$mm. thick is stretched horizontally between two terminals. An upright spindle is supported by means of an insulating foot, upon the middle of this strip, in such a manner that, as the strip bends or sags by its expansion, the spindle sinks with it. Now this spindle carries at its top a table or plate of metal (or, as the case may be, a set of radial springs), and as the spindle rises or sinks to different heights, this plate or these springs make contact with other springs set radially round; and these contacts take out from or throw in resistance coils into the circuit of the current. The sensitive strip is so thin that it may be regarded as a radiating *surface* merely, and it may be assumed that its temperature, due to heating by the current, balances itself with the radiation instantaneously. After passing through the steel strip, the current flows through the coils thrown into circuit, and, by the arrangement we have described, if the current increase so as to over-heat the strip, the latter sags a little more, the spindle sinks, and the consequence is that one or more of the spring contacts is broken, and one or more coils inserted in circuit. A rise of 1° F. in the temperature of the strip is sufficient to liberate two or three of these coils. The fact that the temperature of the strip varies as the square of the current, favours the sensibility of the apparatus. An older form of this apparatus, having pendulous contacts, was also shown; also a regulator in which the expansion by heating of a sensitive wire caused the resistance of several carbon buttons in contact to vary through the pressure exerted on them by means of a bell-crank lever. Dr. Siemens had not been able to prepare carbons which gave the wide variations of resistance obtained by Mr. Edison. Siemens' regulator can also be used as a current meter by causing the sensitive strip to actuate a lever carrying at its end a pencil writing on a moving paper. Dr. Coffin said that he had thought of a regulator in which the heating of a wire spiral in a gaseous chamber would cause the gas to expand and drive up a mercury column past a series of contacts which would throw resistances in circuit. Dr. Guthrie suspected, from some experiments of his, that the conductivity of conductors was not strictly proportional to their sectional area.—Dr. Schuster then gave the results of some observations of his on the spectrum of lightning. These were made by a spectroscope with two prisms, one for the red and the other for the blue end of the spectrum, which were shifted into the line of sight by a chamber arrangement. Three observations were made: one at Las Animas, one at Manitou, and one at Salt Lake City last year. These showed the three nitrogen lines with three well-defined bands and one doubtful band. The nitrogen lines correspond to the spectrum of air, and the bands appear to Dr. Schuster to agree with the spectrum of the light round the negative pole of the spark in a tube containing oxygen with adulteration of carbonic oxide.—Prof. Ayrton then exhibited an exisothermal model of a cooling globe, the globe in question being a trachyte earth 8,000 miles in diameter. The model gives graphically the temperature of every single part of the earth from the moment when it was at the temperature of

molten trachyte down to 800,000,000,000 years afterwards, that is, long after the present era.

Royal Microscopical Society, February 12.—Annual meeting.—H. J. Slack, president, in the chair.—The report of the council was presented and read by the Secretary.—The president read his annual address, in which the oil immersion objectives and the recent discussion on fermentation were referred to.—Dr. L. S. Beale, F.R.S., was elected President.—Herr Petzold's slides of insects, kindly lent by the editor of NATURE, were exhibited, also catoptric immersion illuminator, by Mr. Stephenson, and microscopes by Mr. Crisp.

BOSTON, U.S.A.

American Academy of Arts and Sciences, February 12.—Hon. Charles Francis Adams in the chair.—Prof. Pickering announced the completion of the observations of the zone assigned to the Harvard College Observatory in the revision of the *Durchmusterung* of Argelander. The observer, Prof. W. A. Rogers, has devoted in this work a large portion of his time for the past eight years. The stars are all included between 49° 50′ and 55° 10′ N., and number over 8,000. The accuracy required has made the work very laborious, the total number of observing hours being greater than was required in the Catalogue of Argelander, containing the approximate places of over 300,000 stars. The deductions are still to be made, and will require some years.—Prof. N. S. Shaler read a paper on the explosion of coal-dust in mines, and suggested that a solution of calcium chloride, which is obtained at no other expense than the cost of preparation from the water of salt works, be driven in the form of spray against the walls of the mine in order to fix the dust in a deliquescent substance upon the walls.—Prof. Asa Gray read a paper on the characters of some new genera and species of plants, chiefly of California and Oregon.—Mr. Thomas P. James made some remarks upon American bryology and some new species of mosses described by himself and Leo Lesquereux.—Mr. N. D. C. Hodges presented a paper on a new absolute galvanometer. The current is measured by its effect in changing the time of vibration of a magnet with its axis parallel to that of the coil. Mr. Hodges also presented a method of determining the reduction-factors of a tangent galvanometer for all deflections when the value for any one is known. By measuring a current by the deflection and then with the same coil and magnet, by the change in time of vibration, the ratio between the reduction-factor of the instrument when the magnet makes any angle with the plane of the coil to its value when the magnet is perpendicular to the coil may be found.

PARIS

Academy of Sciences, February 24.—M. Daubrée in the chair.—The following papers were read:—On the induced currents resulting from movement of a bobbin across an electromagnetic system, by M. Du Moncel. *Inter alia*, the direction of induced currents caused by a given movement of a bobbin before a magnetic pole may be diametrically opposite, according as the movement is tangential or normal to the pole, and the magnetic core on which the bobbin glides is in contact with the inducing pole, or distant from it.—Observations on M. Planté's recent work, "Researches on Electricity," by M. Becquerel. These researches relate to secondary currents.—On the hemihedric forms of alums, by M. Lecoq de Boisbaudran.—Resistance to change of state of crystalline faces in presence of their mother-water, by the same. The passage from a state of very slow dissolution to one of very slow growth does not take place suddenly; each face rests intact, while the mother-water varies within certain limits. There is no mobile equilibrium or exchange of molecules between a crystalline face and its mother-water, but merely erosion or continuous deposit, and, between the limits of resistance to change of state, neither erosion nor deposit. The resistance to change of state is modified independently for each system of faces.—Experiments on a modification which has been made in the sluice of Aubois, permitting the suppression of the alternate motion of vessels in the lock, by M. de Caligny.—Reflections on M. de Lesseps' communication regarding contagion of the plague, by M. Bouillaud. Considering the plague contagious, he says the important problem now is to ascertain the nature of the *principle* or *agent* by which it is communicated.—M. de Lesseps presented the reports he had drawn up for the Alexandrian authorities during the plague in Egypt in 1834–35.—M. Stephan was elected Correspondent in the Section of Astronomy, in place of the late M. Hansen, of Gotha.—On latex during the germinative evolution of *Tragopogon porrifolius*, &c. (continued), by M. Faivre.—Observations of eclipses of Jupiter's satellites, made at the observatory of Toulouse in 1878, by M. Baillaud.—Direct photography of solar protuberances without use of the spectroscope, by M. Zenger. He puts on the sensitive plate, before a very short exposure, a solution of pyrogallic acid and citrate of silver, and uses a layer which absorbs all the rays composing the light of the corona and the solar protuberances.—Geometrical laws of deformations produced by a force applied at a point of an indefinite solid, and calculation of the error fallen into, when, according to the principles of classical mechanics, one conceives this point of application displaced by a certain quantity in direction of the force, by M. Boussinesq.—Projection of molecular shadows, by Mr. Crookes.—Action of different coloured lights on a layer of bromide of silver impregnated with different organic colouring matters, by M. Cros.—On plates sensitised with tincture of mallow or black-currant, the direct spectrum of the Drummond lamp is inactive in all the middle green, while the red and violet extremities are very active. With carthamine, again, the middle part is most active. With chlorophyll the action continues throughout the visible spectrum and a little beyond it, presenting several minima and maxima. M. Becquerel pointed out that these researches had been to some extent anticipated.—On the production of crystallised chromate of baryta, by M. Bourgeois. This gives some new results by the method of calcining an alkaline chromate with the chloride of the metal which is desired to enter into the saline combination.—On the composition of beer yeast, by MM. Schutzenberger and Destrem. Yeast contains complex compounds both hydrocarbonised and proteic, formed like glucosides, and easily decomposed by acids and alkalies.—On pyrogenic carburets of American petroleum, by M. Prunier. He has obtained carburets with considerably more carbon than any compounds hitherto known (97 per cent., the highest previously 95 per cent.).—On glycide, by M. Hanriot.—On the generation of aniline-black by chromates in presence of chlorates, by M. Grawitz. He disproves M. Witz's recent assertion against this.—On varions selenides of lead and copper from the Cordilleras of the Andes, by M. Pisani.—On the presence of a segmentary organ in endoproct Bryozoa, by M. Joliet.—On the segmentary organs and the genital glands of sedentary polychætous Annelides, by M. Cosmorie.—On the scales of osseous fish, by M. Carlet. He describes the effects of colouring with picro-carminate of ammonia, and of subjecting to polarised light.—On the mode of employment of telephones at the Artillery School of Clermont, by M. de Champvallier. The success realised is attributed to the method of regulating the position of the magnet. The milled button for turning the screw has at its base a pointer (at right angles to the axis) which moves over a circle of copper. The positions of this pointer for distinct transmission one way or the other are noted.

THE UNITED STATES FISHERIES

United States Commission of Fish and Fisheries—Report of the Commissioner for 1875–76. (Washington: Government Printing Office, 1878.)

THE series of volumes now being issued by Mr. Spencer Baird, Fishery Commissioner of the United States, of which the fourth has just reached us, is in every way remarkable. As a much required contribution to our scanty knowledge of fishery economy and the natural history of American food fishes, it presents a mass of very valuable information; the details incidental to the propagation of carp and salmon are particularly interesting, not only because they show the gigantic scale on which these things are done on the other side of the Atlantic, but also because of what they teach as to the mode of doing them. The historic and economic sketches of the fish and fisheries of various other nations are likewise full of interest, Mr. Baird having allowed nothing to escape which he thinks will illustrate his subject or render testimony to the value of the work in which he is engaged.

The contents of the present volume, if not so varied as those of some of its predecessors—over 750 of its pages being devoted to a historical account of the American whale fishery—are certainly not less interesting. There is a report on the fisheries of Chicago and vicinity, which, we are told, yield annually about 12,000,000 lbs. weight of fish; there is also an article on the condition of the salmon fisheries of the Columbia River, from which we have recently been receiving enormous consignments of canned salmon; the present volume likewise contains notes on the fishes of the Delaware, together with an abundant supply of information regarding the propagation of various of the minor food fishes of America.

We are not in the least surprised to learn that a diminution of the supplies of Columbia River salmon (*Salmo quinnat*) has taken place. These fish, consequent on being free to all who choose to capture them, have given constant employment to about fifteen "canneries" during ten or twelve years, each of which, if we strike an average, will turn out a million pounds weight of fish per annum. There are various kinds of salmon in the Columbia River, but there seems to be some confusion regarding their proper identification; that we have mentioned is the one which is captured for the canneries. It will probably be found on further investigation that one or two of the so-called varieties are simply the same fish in different stages, as in the case of *Salmo salar* and the "grilse;" fish of all sizes being, we are told, found together in the Columbia and its tributaries. It is rather singular that no very large salmon are found in that great stream. Mr. Livingstone Stone who reports to the Commission on the subject, says that the largest salmon he ever saw had a girth of 31 inches, and was 35 inches in length and weighed 65½ lbs. One which was *said* to have weighed 83 lbs. was reported to Mr. Stone by a fisherman who saw it. The average weight of the Columbia salmon (*Salmo quinnat*) is from 22 to 23lbs. whole, but when dressed for market only about 17lbs. The ratio of salmon growth has never been accurately determined. Some large salmon (*Salmo salar*) are captured in the salmon streams of Scotland, but the age of such fish cannot be set down with any certainty. In a report made by Mr. Stone given in a previous volume of Mr. Spencer Baird's reports (1872-73) regarding the Sacramento salmon, it is mentioned as a "theory" that salmon are full-grown at the age of about three years. We commend this question of salmon growth to the farther notice of Mr. Commissioner Baird. In the United Kingdom the evidence obtained on this point has hitherto been of the most contradictory nature. Our own opinion is that salmon are never "full grown," or rather that as long as they are alive they continue, under proper conditions of food and living room, to increase in weight and size. After much weighing of evidence we recently came to the conclusion that a fish which we handled in August last (1878), and which weighed 54 lbs., was at least nine or perhaps ten years old. From some inquiries which we are making, we hope to be provided with sufficient data for a settlement of the question during next fishing season. Returning for a moment to *Salmo quinnat*, the following notice of the periods and strength of its migration may be useful for comparison with the habits of *Salmo salar*:—"The salmon make their first appearance in February, though in very small numbers; the main body arrives in May, June, and especially in July, when the run is enormous. The May salmon are largest. Perhaps the most correct view to take of the running of the salmon is to consider all the salmon as included in one run, beginning in February, increasing in May and June, and culminating in July, though they might also be legitimately divided into three runs, the first or meagre run coming in February, March, and April, the second or full run in May and June, and the third or maximum run in July. After July they diminish very rapidly, and soon almost entirely disappear from the river."

It is at present being considered, we believe, whether or not it will be necessary to resort to "pisciculture" on the Columbia river. Would it not be better to limit for a time the spoliation of the water? At present no check whatever is placed on the fishery, and each "cannery" captures and tins all the salmon that it can find, and with each establishment working up a million pounds' weight per annum, the complete exhaustion of the supply is only a work of time, as has been demonstrated in our own rivers.

The artificial hatching of salmon is conducted in the United States on quite a gigantic scale. A table is given in the report of "operations on the McCloud river in 1876," from which we learn that on one day, Sept. 4, over a million salmon eggs were obtained by a process of artificial spawning. During the years 1874-75 and 1876, the number of ova taken for despatch to different rivers was 21,877,300. In 1875, 8,629,300 eggs were secured, which, at the British rate of a thousand eggs for each pound of salmon weight, represents the handling of a large number of fish. The cost of collecting the spawn is about four shillings per thousand. The eggs taken in the McCloud river are widely distributed, some being sent to Canada and a portion to New Zealand.

Much valuable information is given in the present series of reports on the best modes of salmon hatching, and the

careful observations of temperature made during the manipulation are tabulated for future use. With reference to *Salmo quinnat* of the Sacramento, it may be confidently affirmed that there is almost no difference between it and *Salmo salar*, which, in form and habits, it closely resembles; it has, however, if we mistake not, more rays in the anal fin, and is of course able to endure a higher temperature: the eggs mature in summer and hatch in the autumn. In ascending to their spawning grounds the *gravid* fish must frequently pass through river water having a temperature of over 76°. We were not prepared for the following remarkable statement from New Zealand, made in the present volume (p. 989):—"*So far as yet observed, the adult fish all die after spawning, and never return to the sea.*" This fact is stated in a "memorandum respecting the American salmon and white fish recently introduced in New Zealand by Dr. James Hector, of the Colonial Museum, Wellington." We shall be glad to have some authoritative statement with regard to the above fact, as without some explanation it seems too extraordinary for belief.

An interesting account of the distribution and habits of the "Shoodic salmon" is given in the present volume. These fish, *Salmo sebago*, are known as "land-locked salmon," at one time probably in communication with the sea, but now shut out from it altogether, and thus forced to pass their lives in fresh water for ever. There is, however, no evidence that "the supposed change of habits—the abandonment of the seaward migrations—came about in such a way as the term, *land-locked*, implies." Mr. Atkins, in his report to the commissioner, makes a statement which we should like to have explained. In collecting the spawn of the "Shoodic salmon," there was taken, he says, a single female specimen of *Salmo salar*; "she yielded 10,000 eggs, which were impregnated with the melt of the 'Shoodic salmon;' they developed well, and hatched into vigorous fish." But how did a female specimen of *Salmo salar* come to be among the "land-locked" fish? and what became of her?

The operations of the United States Fish Commission commenced eight years ago, and are still being prosecuted. The work has been varied, as we have indicated, and, so far, it has been well done, and the information accumulated will form a quarry which will yield a lasting supply of fishery knowledge to all inquirers.

THE PACIFIC ISLANDS

Reise durch den Stillen Ocean. Von Max Buchner. (Breslau: J. U. Kern, 1878.)

THE author of this pleasantly written and very interesting book of travel became, as he tells us, a ship's medical officer, in order to gratify his desire to see the world. He sailed in an emigrant ship from Hamburg to New Zealand and returned home by Fiji, the Sandwich Islands, San Francisco, and the Pacific railroads. He made a considerable stay at New Zealand, Fiji, and the Sandwich Islands, and the chief interest of his book lies in the accounts of what he saw at these places. Though there is little new information in the work the descriptions are extremely good.

On board the emigrant ship there devolved on him not only the usual medical work but also the entire charge and government of the 397 emigrants and the division of rations amongst them. He draws a very unpleasant picture of the dangers and sufferings incurred by passengers in such a vessel. The captain seems to have known little of his business. After a narrow escape of collision the ship appears to have incurred a still narrower risk of running on the Goodwin Sands, and on the open ocean there seems to have been constant doubt as to longitude. A terrible picture is drawn of the sufferings of the emigrants—a mixture of Poles, Scandinavians, Germans, and Dutch—in a storm. The captain, who in such voyages receives a small percentage on the profits of the voyage from the owners of the ship, made constant attempts to cut short the allowance of food to the passengers. The author, who acted in the interests of the New Zealand Government and their emigrants, had great difficulty in making the captain, who cursed and swore and hammered the table with his fist when appealed to, act up to the details of the contract in the matter of rations. Even then the food seems to have been insufficient, and the salt beef was constantly being stolen, the beef tub being forcibly broken open for the purpose. The barbarous old custom of shaving on crossing the line was carried out, but we are glad to find that only volunteers amongst the emigrants were operated on. An outbreak of typhoid fever occurred on board before New Zealand was reached and caused nine deaths.

The author gives a most interesting and lively account of the present condition of the Maoris. At Lake Taupo there is now a very good clean hotel kept by a German and an Italian; and a Maori, who goes by the name of Mr. Jack, has established himself as guide of Taupo. He has constructed a bathing-place at the hot springs with a room over the bath and dressing-room, and charges a shilling for each bath. Close by, but hidden in the vegetation, our author discovered an equally good or better natural hot bathing-place, but the crafty Maori had filled it with dirt for fear it should compete with his own. At Ohinemotu on the south shore of Lake Rotorua, where are the principal hot springs, there are two good hotels for tourists and a population of about 300 Maoris. Every evening the greater part of the population turn out and bathe together in a small bay of the lake which is kept constantly warm by the hot springs, and whites and browns of both sexes swim about and sit in the warm mud together, conversing for hours at a time. Close by the bathing-place are a group of huts, the owners of which are dead, and which are tabu, and are described as full of ancient native implements, spears, adzes, wood-carvings, and other desiderata for ethnological museums, but which no one dares to touch. A performance of the "haka," the old New Zealand dance, was got up for the author and his friends, on their paying a sovereign a-piece, but the young Maoris seem not to care for the dance any longer, and to perform it only for the benefit of tourists for money, and the performance lacked spirit, and soon came to an end. The hula, hula, in the Sandwich Islands, seems to be dying out in the same manner, and in Tahiti, when the old lascivious dances are performed, they are usually got up for the benefit of European visitors, through the agency of the native washermen, who combine such offices with their legitimate business. The young Polynesians in New Zealand, as elsewhere, prefer the waltz

and other European dances. The author enjoyed himself so much in Ohinemotu that he spent all his money and had to travel to Tauranga on foot. Here he saw the ceremony of nose-rubbing performed with great solemnity; it is, however, now kept up almost only by the old; the young Maoris have taken to kissing as a substitute. There is still a wide tract of the northern island of New Zealand 1,000,000 acres in extent, known as King Country, inhabited by about 10,000 Maoris under King Tawhiao, who keep themselves free from British rule, and do not permit whites to enter their country. King Country seems to be a thorn in the side of the Government, and the city of refuge of murderers and thieves, who are there out of harm's way.

At the Fiji group, the author visited only one island, that of Kandavu, at which the mail steamers call. He, however, explored a great deal of this island, in company with the natural history collector employed by Goddefroy Brothers, Herr Kleinschmidt, who is laboriously exhausting the fauna of the Fiji group, collecting carefully for several months in each island. The author's account of Kandavu, and especially of the natives, is full of interest. One of his observations may be cited here. A Fijian youth, employed as an assistant in collecting, whose body was already beautified by many cicatrisations, was devoting his attention to two groups of small suppurating wounds on the outer side of each upper arm. When visitors from neighbouring villages were present, he used to open these wounds anew and inflame them with a burning stick, or sand, or by scratching them with glass, in order to show his fortitude, never moving a muscle of his face in public, but making very wry faces afterwards in private. Many other youths had similar wounds on their upper arms, and it turned out that vaccination was being carried out by the Government in Kandavu, village by village, and that pustules on the upper arm were hence the fashion. The dandies would not wait till the turn of their village arrived, or perhaps the natives wished to avoid the actual operation by giving their arms the appearance of having been already vaccinated.

The author very rightly denounces the absurd method of spelling the Fijian language introduced by the missionaries. Because, in Fijian words, before the sounds *d g k* and *m*, an *n* nearly always is sounded, and before *b*, an *m*, the missionaries in first writing the language chose to omit the *m* and *n* in all cases in spelling before these letters, which complicates matters unnecessarily, and must eventually give great trouble to Fijians when they come to read English. Thus Thakombau, the name of the former king of Fiji, is spelt Thakobau. Kandavu is spelt Kadavu. Some writers have carried useless confusion still further, and have rendered *th* by *c*, so that Thakombau becomes Cacobau, and so it was most often spelt in newspapers at the time of the annexation of Fiji, so that English readers derived very little impression of the real sound of the name.

The author proceeded to Honolulu by Pacific mail steamer. Amongst the passengers was a San Francisco concert company and a reverend Yankee travelling lecturer. The concert company hoped to give a performance on the day on which the steamer stopped at Honolulu on its way to San Francisco, but the lecturer had been too sharp for them, and had engaged the only available hall long beforehand, and they found the town posted all over with advertisements of his lecture on the Tower of London. The author visited Hilo, in Hawaii, and the volcano of Kilauea. He returned from Hawaii to Honolulu in an open whale-boat, touching at the island of Maui on the way, an exploit which seems to have astonished the people of Honolulu extremely, since they have come to rely upon schooners and steamboats entirely for such long passages, and no longer make the voyage, as of yore, in war canoes. The author's account of San Francisco and its Chinese quarter is hardly so interesting as the earlier part of the book, as this quarter has been done to death in so many books of travel, and after all Chinese life at San Francisco is in all essentials identical with Chinese life at home. Perhaps before many years we shall have a Chinese quarter in London.

The official account of the Pacific railroads, sold on the line, "Williams' Pacific Tourist," which is got up in the interests of the railroad companies, is very properly denounced by the author. It is, indeed a shameless puff of the supposed beauties of the scenery on the line of the railroad, which exist for the most part only on paper and in the fervent imagination of the writer. An account of Salt Lake City and Niagara close Dr. Max Buchner's very pleasant volume. Some passages in the book are rather free in their tone; a case of midwifery on board ship is described with needless detail; many of the doings of Polynesians are also described with little reserve.

OUR BOOK SHELF

Index Medicus. A Monthly Classified Record of the Medical Literature of the World. Compiled under the Supervision of Dr. John S. Billings, Surgeon U.S. Army, and Dr. Robert Fletcher, M.R.C.S. Eng. (New York, F. Leypoldt; London, Trübner and Co.)

FOR some time back Dr. Billings, of the United States Army, has been engaged in the preparation of an Index-Catalogue of the library of the surgeon-general's office at Washington. To those who do not understand what this work is, this may not seem to be at all extraordinary, but those who know that the work is really an universal catalogue of medical literature, giving not only the names of the authors, but the subjects of the papers which have appeared in all medical periodicals throughout the world from the time of their first issue until the present, will be astonished that any man has had the courage to undertake such a task, and still more to learn that the MS. of this catalogue is now nearly ready for press, and is only awaiting the authority of Congress to print it. For the sake of medicine throughout the world we trust that this authority will be granted without delay, for to every man who has the interests of medicine at heart this work will be an invaluable boon. It has been suggested that such a catalogue should be supplemented by some current publication, which should show all recent works, together with articles and periodicals arranged by subjects, and the present publication has been issued to supply this want.

"In its pages the practitioner will find tables of parallels for his anomalous cases, accounts of new remedies, and the latest methods in therapeutics. The teacher will observe what is being written or taught by the masters of his art in all countries. The author will be enabled to add the latest views and cases to his forthcoming work, or to discover where he has been anticipated by other writers; and the publishers of medical books and periodicals must necessarily profit by the publicity given to their productions."

Dr. Billings very sensibly suggests that all medical men who approve of the objects of this Index, will put their approval into practical shape by subscribing promptly for the Index and taking care that a copy of every book, pamphlet, &c., of which they are the authors, is forwarded to the editors. This recommendation we heartily endorse, and trust that so useful a publication may receive the support it deserves.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

The Tides at Chepstow and Fundy

In NATURE, vol. xix. p. 363, Mr. Moseley, of Exeter College, Oxford, quotes a passage from Lyell's Principles, to the effect that the tides at Chepstow have a range of 72 feet.

This statement is continued in the last edition (1875), in Chap. XX., on Tides and Currents, p. 492; and the tidal range in the Bay of Fundy is set down at 70 feet (p. 564). I do not believe either of the statements.

The Admiralty Tide Tables give the following:—

	Spring Range. Feet.	Neap Range. Feet.
1. Chepstow	38	28·5
2. Bay of Fundy (Noel Bay) ...	50·5	43·5

I may add that Lyell's whole treatment of the subject of the tides is loose and inaccurate. Thus, for example, he says (p. 491): "In any given line of coast the tides are greatest in narrow channels, bays, and estuaries, and least in the intervening tracts where the land is prominent."

He then proceeds to illustrate this proposition by giving the ranges of tide from the mouth of the Thames to Flamborough Head (including, of course, the well-known *tidal node of minimum range* off Yarmouth); but he is utterly unconscious that these ranges depend altogether on the tidal motion of the water, and have no relation whatever to the form of the coast.

Trinity College, Dublin, March 3 SAML. HAUGHTON

Magnetic Storms

It is surprising that an accomplished telegraphist like Mr. Mance (NATURE, vol. xix. p. 409) should not see the necessity and advantage of expressing earth-currents in webers. It is precisely because every one can, if he likes, appreciate the magnitude of an earth-current so expressed, and no one but himself can do so if Mr. Mance's plan were adopted, that I advocate the weber, or rather, its more convenient sub-multiple, the *milliweber*. A milliweber is the current produced by one Daniell's cell (strictly one volt), through 1,000 ohms. Currents can be reduced to this unit from any galvanometer. The tangent galvanometer is, perhaps, the simplest to use—it is that which we employ in England. Supposing for simplicity that your constant, viz., one Daniell cell through 1,000 ohms (including cell and galvanometer) gives 45°, then the tangent of any other reading will give you the current in milliwebers. Then, knowing the resistance of your circuit and its geographical position, you have all the data necessary to determine the elements of earth-currents.

I will act on Mr. Mance's suggestion, and bring the matter before the Society of Telegraph Engineers with a view of organising a systematic mode of observation in different parts of the world. W. H. PREECE

Wimbledon, March 8

Atmospheric Pressure and Solar Heat

May I be permitted to supplement the table given by Mr. Allan Broun in NATURE, vol. xix. p. 7, by the following figures for Calcutta. The pressure anomaly at Bombay for each year, as given by Mr. Broun, is here compared with Calcutta, and the table is extended down to 1877:—

Table Showing Difference of Mean Pressures at Calcutta as Compared with Bombay for the whole Year and the Summer Months, the Sign + Indicating an Excess at Calcutta, and − a Defect; and Character of the Rainfall in the North-West Provinces and Behar.

Year.	Year.	Summer.	—
1847	−37	+ 5	Excessive.
1848	+ 7	−13	Defective.
1849	+14	+ 5	Excessive.
1850	+21	+ 5	Average.
1851	+ 8	+11	Excessive.
1852	+16	+18	,,
1853	−19	−31	Defective.
1854	+ 1	− 2	Excessive.
1855	−10	−30	Defective.
1856	− 2	− 1	Average.
1857	− 9	−10	Defective.
1858	− 3	− 9	,,
1859	+ 8	+26	Excessive.
1860	−15	−13	Defective.
1861	−12	− 3	Average.
1862	+12	+15	Excessive.
1863	− 7	−16	Defective.
1864	−14	−27	,,
1865	+15	+13	Excessive.
1866	−10	−20	Defective.
1867	+ 5	+ 4	Average.
1868	− 6	−13	Defective.
1869	+ 1	+ 5	Excessive.
1870	+ 3	+ 4	,,
1871	−37	− 3	,,
1872	+13	+18	,,
1873	+ 3 ?	−11	Defective.
1874	+ 5 ?	+24	Excessive.
1875	−15	− 2	Average.
1876	−24	− 5	Defective.
1877	+14 ?	+ 3	,,

Since from 1847 to 1852 there are frequent blanks in the registers, sometimes exceeding ten days in length, the figures are of somewhat doubtful value.

It will be seen on examination that the decennial period is nearly as distinctly marked at Calcutta as at Bombay, though the minor fluctuations are more frequent, and that, as Mr. Chambers supposed, the amplitude of the anomaly, like that of the diurnal and annual variation, is greater at Calcutta than at Bombay.

Mr. Broun considers the discovery of the decennial period of barometric pressure to be one of great importance, as forming a link in the chain of evidence which connects the variations of rainfall with those of the sun's heat. As an illustration of the way in which the variations of pressure influence the distribution of rainfall, I have entered a word descriptive of the character of the rainfall of each year in the North-West Provinces and Behar. In the great majority of cases a relatively low pressure at Calcutta, especially during the summer months, April to September, means defective rainfall over the valley of the Ganges, which is watered by easterly winds from the Bay of Bengal, and a relatively high pressure at Calcutta means excessive rainfall. Had the station with which Calcutta is compared been situated seven or eight degrees to the north of Bombay, the rule would probably have been without exception. The influence of what he calls the "relative barometric anomalies" upon the distribution of rainfall in India has been pointed out by Mr. Blanford on more than one occasion since 1868, and the examples here given will illustrate and enforce this point.

Mr. Broun's remarks regarding the relations between the range of the monthly means of barometric pressure and that of the monthly mean temperature, are interesting as confirming the views put forward by General Strachey, as long ago as 1850, in an unpublished work on the physical geography of the Himalaya and the neighbouring countries. The range of the monthly mean pressure at Calcutta is 0·488 inch, and that of the monthly mean temperature 18°·6 F. The range for one degree is therefore ·026 inch, a figure which differs little from those for Madras, Bombay, and Trevandrum. S. A. HILL

Allahabad, December 7, 1878

Intellect in Brutes

IN answer to the objections raised by W. P. Buchan and Henry Muirhead to the case of rats gnawing water-pipes for the express purpose of obtaining water, as described in my letter to NATURE, vol. xix. p. 365, I propose to give particulars of the situation of the pipes so gnawed in two instances. No. I. At Poplar. Pipe laid on second floor, between flooring-boards above and ceiling below, between joists the usual distance apart; plenty of room all round pipes to obtain access to any part of the floor, also rat-holes in woodwork to facilitate communication. As the pipe lay above the ceiling of the floor below, there was no necessity to attack the pipe in order to get through that ceiling—if that were desired. A hole could easily have been made at any point on either side of the pipe. The upper floor was a corn loft, and it is inferred from the circumstances, that the rats, feeding upon this very dry food, had tapped the water-pipe to obtain a supply of water close at hand. No. II. On Haverstock Hill. Cistern in scullery about six feet from the floor, pipe (lead), comes thence down wall, passes under floor of scullery to kitchen to supply kitchen boiler. Pipe laid on the *earth*, between joists, raised, of course, on bricks. Pipe gnawed on upper side. Plenty of room all round for rats to pass freely under all parts of the floor, as any practical builder will readily understand. They could have tunnelled *under* this $\frac{3}{4}$-inch pipe from either side through the soft earth. Of the two holes in the pipe one will admit a small pin, the other is about $\frac{1}{20}$th of an inch in greatest diameter, and about an inch from the first. These are transverse perforations, the ineffectual attempts are in a longitudinal direction. It is of course quite possible, as in Mr. Buchan's cases, that rats occasionally find gas-pipes in their way and are *compelled* to attack them, but I do not think any of your readers will imagine that his question, "Now, are they cut to get at the gas?' needs a moment's consideration. Possibly some of your correspondents may be able to corroborate the following—A ship's carpenter told me that, in the old days before the use of iron tanks on board ship became general, the rats used to attack the water casks, cutting the stave so thin that they could suck the water through the wood, without actually making a hole in it. If any one could substantiate this it would have an important bearing on the question under consideration.

ARTHUR NICOLS

I AM glad my remarks have elicited others, for I want to have my difficulty solved, which I will put thus:—Why is it that no dog ever (to my knowledge, of course) observed a person ring a bell, noticed that the bell brought the servant, and then went through the process of reasoning—"Because such was the result I will ring the bell too"? This I call abstract reasoning. On the other hand, why is it at all necessary to teach the dog to ring the bell? for it is not necessary to teach a boy. Boys do acquire sooner or later abstract reasoning, but it is with them practically a feeble power, as I have shown, and with rustics it seems, sometimes, to be totally in abeyance, as the following illustration will show. An entertainment was given to some hundred labourers and their wives, and a Mr. Cross told them to spend the afternoon in a field, but hoped none of them would be *his name*. Not one understood him, or could go through the simple process of reasoning—"We are not to be his name, his name is Cross, therefore we are not to be cross." It is this *mental reflection* which seems to me to be wanting in animals; thus, monkeys will warm themselves by a fire of burning sticks, but do not seem capable of thinking—"Because sticks burn, therefore, if I put more sticks on the fire I shall get more warmth." I should be extremely glad to hear of any cases of such purely *abstract mental reflection* in animals, for at present, there seems to me to be a hiatus here.

GEORGE HENSLOW

On the Freezing of Lakes

WE wish to draw your attention to a statement contained in an article under the above heading which appeared in NATURE last week, p. 412.

The author, Mr. J. Y. Buchanan, says:—

"Most of the observations were made with one of Negretti and Zambra's 'half turn' deep-sea thermometers, which proved a useful instrument for this species of inquiry. It was necessary, however, to fit it with a suitable inverting contrivance, as the apparatus supplied for this purpose by the makers is quite useless."

Fortunately this thermometer and apparatus has now been in use for some time, and its performance fully tested by persons whose opinion is of the highest value. We can only say that had Mr. Buchanan used the apparatus according to our printed direction, viz., lowered the instrument to the required depth, let it remain a few seconds, and then pulled it up as fast as practicable and without stopping, he would not have failed to have obtained correct results. We cannot possibly imagine how he could have failed; had we not ourselves tried the inverting apparatus in every possible way, and had we not received the highest testimony as to its efficiency, we would have remained silent, but as it is, and knowing we have invented as good an instrument as has ever been contrived for the purpose, we cannot allow the statement to pass unchallenged that we have supplied a useless apparatus. If Mr. Buchanan could not obtain satisfactory results with our apparatus it must only have been because he did not use it as we directed.

HY. NEGRETTI AND ZAMBRA

THE MIGRATION OF BIRDS

MORE than four years ago an article, headed as above, appeared in this journal (vol. x. p. 415) giving rise to some comments of more or less importance (*tom. cit.*, pp. 459, 520, and xi. p. 5). Since that time two very remarkable treatises on the subject have come forth, the one by Dr. Palmén, on the routes taken by birds in their migrations, and the other by Dr. August Weissmann, dealing generally with the whole question.[1] The first, originally published in Swedish,[2] was translated into German soon after, and in due time was reviewed in these columns (vol. xv. p. 465). An excellent English version of the second has recently appeared in the "Contemporary Review" (February, 1879, p. 531), and therefore my readers may be presumed to be acquainted with the views of both authors. It cannot be denied that each of them has to some extent enlarged the boundaries of our knowledge of the subject, and still more widely those of our speculations upon it.

As regards Dr. Palmén's work, the opinion held by his reviewer in these columns as to the assignment of routes to the migratory birds of North-Western Europe being "purely conjectural" is one that I wholly accept. I should even be inclined to go further, and say that it might be called rash, as it is evident that no such observations as would justify its adoption exist. Still I concur with the reviewer in that I would not at present term it entirely erroneous, though I venture to express my entire disbelief in the route "X." This is supposed by Dr. Palmén to start from Greenland and Iceland, and to pass by the Færoes to the Hebrides, when, after coalescing for a short distance with one or more lines from the north-east, it either loses itself on the West Coast of Ireland, or, running down St. George's Channel, skirts Scilly and crosses to the shores of the Bay of Biscay. Space forbids my entering into details which would show, I think, that this route is altogether imaginary. I will only say that what we know of the movements of two very characteristic summer visitants to Iceland, *Motacilla alba* and *Limosa ægocephala*, points to that conclusion, and I would leave it for Irish ornithological observers to prove whether Dr. Palmén is right or not.

Dr. Weissmann, happily for him, has no such compunction. He fully accepts Dr. Palmén's conjectures as absolute truths. Suppose, however, we assume them to be established—and there seems no reason why further observation should not establish most of them—they would show in Dr. Weissmann's opinion that the migrating birds of to-day in crossing the sea follow what once were "land-bridges" (*Landbrücken*), that is, isthmuses of dry land separating seas or oceans under which they are now submerged. The existence of such former terrestrial communications between continent and con-

[2] Om Foglarnes flyttningsvägar. Helsingfors, 1874.

tinent, at the present time revealed to us by shallow soundings and some mountain-peaks changed into islands, may be indubitable. I, at least, in regard to Europe and Africa do not question it, and it may be true all the world over. But this same hypothesis has been more or less hinted, if not absolutely promulgated, by Prof. Baird (*American Journal of Science and Arts*, May, 1866) and Capt Hutton (*Trans.* N. Zealand Inst., v. p. 235). So far, then, there is nothing novel in the Doctor's views.

In like manner Dr. Weissmann seems to me to have been anticipated by Capt. Hutton (*ut suprà*) and by Mr. Wallace (NATURE, vol. x. p. 459) in his explanation of why birds migrate at all. The only material difference between the last of these authors and the Doctor is that, while Mr. Wallace most rightly (as it seems to me) regards migration as originating with the bird at its breeding-quarters, Dr. Weissmann considers it to begin with the bird in its winter retreat. Perhaps this does not much matter, but it is as well not to put the cart before the horse if you want to prosper in your journey, and so long as lack of food be admittedly the strongest incentive to migration, it seems preferable to look on migration as beginning where that incentive is strongest. This, it scarcely needs to be said, is when, towards the close of summer, the supply of food grows scarce.

However, the most important part of the whole business is the question how the birds find their way to the places whither they repair, whether for the purpose of breeding or for that of procuring sufficient sustenance. Dr. Palmén regards it simply as a matter of "experience," and Dr. Weissmann hardly differs from him. It is "practice" (*Uebung*), says the latter—not indeed the practice acquired by the single bird, but the practice acquired by the whole species. "This faculty (*Virtuosität*) of finding the way has not arisen suddenly, but most gradually, in the course of many thousands of generations." Now with all my faith in the marvellous results which are doubtless produced by the hereditary transmission of certain qualities, I think some caution is needed before we accept "practice" as the true explanation of the puzzle. Dr. Weissmann says that he does not see what more is needed than a fine power of observation and a keen eye to take in every thing of importance for a knowledge of the way, and then a very remarkable memory for places by means of which all details of the long route shall be retained. The knowledge of direction (*Orientirung*) will then follow of course. Subsequently he takes the instance of a woodpecker being able to find the tree containing its nest, though surrounded by hundreds of similar trees, and declares that this knowledge or sense of direction must, in the case of birds when migrating, be wholly analogous. He suggests also that the height at which birds sometimes fly, referring apparently to a remark by Mr. Tennant (NATURE, xiii. p. 447), would enable them to cross the Mediterranean, and seldom or never lose sight of land.

This may be; but migration goes on in other parts of the world, and a good explanation ought to apply elsewhere. Will Dr. Weissmann's hold good for our Antipodes? In regard to New Zealand Capt. Hutton has remarked (*Trans.* N.Z. Inst., v. p. 235):—"That we should have two cuckoos which migrate regularly to other countries, each more than a thousand miles distant, is a fact that deserves special attention, for I know of no parallel case in any other part of the world, the distance across the Mediterranean being less than half that travelled over by our summer visitors." These two cuckoos are *Chrysococcyx lucidus* and *Eudynamis taitensis*, the former, it is supposed, making its annual journeys to and from Australia,[1] and the latter to and from the Friendly Islands or the Fijis, it being found in both groups, to say nothing of other places further off. Let us consider the case of the *Eudynamis*. Due north of New Zealand there appears to be no land until Fiji is reached, but a little to the westward of the direct line lies Norfolk Island and its companions, and about as far to the eastward are the Kermadecs. Of these, the most southerly is 450 miles from New Zealand, and the most northerly about the same distance from Pylstaart, an outlier of the Friendly Islands. The *Eudynamis* starting from New Zealand for the northward would have nothing to supplement its inherited "sense of direction" save the landmarks offered to the right and left by the Kermadecs and Norfolk Island respectively. To see the former it would have to mount to the height of some twenty miles,[1] and to again mount about as high on leaving the Kermadecs on its way to Pylstaart. It might be urged that the bird having by "practice" a sense of the direction in which it ought to go, might fly half the distance, keeping the land of departure in sight—though, considering the position of birds' eyes, this would not be easy—and then, without exceeding the level of six or seven miles, it might behold the Kermadecs, but even this is an elevation far beyond Dr. Weissman's 20,000 feet. The route by Norfolk Island being longer, need not here be discussed.

[1] I should rather suspect to and from New Caledonia.

It is much to be desired that something positive were known as to the height at which it may be possible for birds to perform their passages, but on this point we have (so far as I am aware) little information. The experiments made by Mr. Glaisher on the six pigeons taken up in his celebrated balloon ascent, September 5, 1862 ("Rep. Brit. Ass.," 1862, p. 385), unfortunately admit of no definite deductions. One pigeon thrown out at the height of three miles "extended its wings and dropped as a piece of paper." A second at four miles "flew vigorously round and round, apparently taking a dip each time." A third between four and five miles "fell downwards as a stone." A fourth at four miles, in the descent, "flew in a circle," and then alighted on the balloon. The two remaining pigeons were brought down, and one was found to be dead! Perhaps a little more "practice" or "experience" was wanted, but at any rate the results do not seem to favour the notion that birds can fly comfortably at those heights. Nor is this surprising, considering the well-known effects of the rarification of the air at great heights. I of course pretend to no special knowledge of this subject, but Mr. J. W. L. Glaisher, F.R.S., kindly informs me that at an elevation of five miles the density of the air is about $\frac{1}{2\cdot7}$ of what it is on the earth's surface, at an elevation of seven miles about $\frac{1}{4\cdot1}$, and of ten miles about $\frac{1}{7\cdot5}$. I know not whether experiments have been made to test the endurance of a bird's life under such a condition as the last, but it could of course be easily produced under an air-pump. It would not be so easy to test the power of flight under the same condition. It is only obvious that the power would be very greatly diminished, and I should be glad to learn the results of any investigation of this kind. Physicists and physiologists might here give ornithologists great help.

But to return to the question of distance and sight. How comes it that the American Golden Plover (*Charadrius virginicus*) passes regularly every year in large flocks over the Bermudas, 600 miles from the nearest point of land, and that a point whence these flocks certainly do not take their departure. If the islands are "still vext" by stormy weather, the flocks alight and afford the inhabitants a good deal of sport. If the weather be fine, the flocks seem to continue their southward course. Nor is this plover the only *regular* visitant. The American Night-Hawk (*Chordiles popetue*) is as constant in its appearance at spring and fall, and so are

[1] Of course the exact height would depend on the elevation of the land, concerning which I have no information.

more species of *Limicolæ*, and perhaps of other groups, than I can here name. Is it to be supposed that all these birds, some of them flying by night, make Bermuda by the means which Dr. Weissmann considers sufficient? If his explanation is good it must be good for New Zealand and Bermuda, as well as for the Mediterranean. But there is yet a stronger case to be cited. The Sandwich Islands, as I have learned on authority I cannot doubt (though I know not any mention of the fact in print), are yearly visited like Bermuda, but with even greater punctuality, by large flocks of Golden Plovers—whether *C. virginicus* or *C. fulvus*, is undetermined, but that does not much matter. If the birds belong to the first of these forms they must come from the west coast of America, if to the second from the east coast of Asia. Now there is no land between the Sandwich Islands and the Californian or the British-Columbian coast, but between them and the Aleutians, as I learn from Mr. Rye, there is one islet, Roca de Plata or Crespo. This, however, does not lie in a straight line, and is some 720 miles north-west of the Sandwich Islands, and 1,200 south-west of the Aleutians. Running generally westward of the Sandwich Islands is a series of islets, at distances, perhaps, not exceeding 150 miles, which no doubt might serve as guide-posts for the plovers did they but make for them, but the series comes to an end in about long. 178° W., and though by turning suddenly to the north-east from Morell Island towards Mellish Bank (300 miles), the Aleutians again appear as the nearest land in a northerly direction, the distance of 1,020 miles has to be covered! On the supposition that the birds are of Asiatic birth, and therefore come by another course, we find that due west of Morell Island is Ganges Island, but that is 930 miles off, and thence to reach the easternmost of the Japanese group is 690 miles further! Thus, whichever form of golden plover it be that visits the Sandwich Islands, its regular advent there needs, I think, some fuller explanation than that afforded by Dr. Weissmann's theory.

Then again, there is another set of facts which seem to me irreconcilable with the theory of mere "practice" or "experience." It must be remembered that though Dr. Weissmann relies most on the inherited practice of the *species*, still he does not neglect the *individual*, and both he and Dr. Palmén make considerable use of the observation that adults, and male adults in particular, lead the migratory flocks. This fact, so far as I am aware, has only been noticed in the northward movement in spring, and elsewhere I have endeavoured to account for it ("Encycl. Brit.," ed. 9, iii. p. 767). In autumn it may be doubted whether there is anything of the kind, and we have in many species, the young of the year—birds that are but three months old, or even less, migrating southward with the greatest regularity unaccompanied by adults. This seems to happen with nearly all the *Accipitres*, nearly all the *Limicolæ*, and perhaps, some others, that are bred in arctic or sub-arctic districts. It happens also with our own Cuckoo (*Cuculus canorus*), and this case is still more wonderful, for the young Cuckoo has had no communication whatever with its progenitors (who have already taken their departure from our shores some weeks earlier), and its foster-parents with us are generally species which do not migrate to any great extent—the Hedge-Sparrow (*Accentor modularis*), Titlark (*Anthus pratensis*), and Pied Wagtail (*Motacilla lugubris*). Yet our young Cuckoos, starting alone and travelling over utterly unknown country, must, on the whole, successfully reach their destination, or the breed would become extinct here.[1] Dr. Weissmann may indeed well say of migrating birds, that the young, when it cracks the shell, possesses "great geographical talent"!

I might easily prolong this article, for there is much more to be said on the subject, and in some details, by no means unimportant, Dr. Weissmann seems to have fallen into errors that I have not here noticed, but my chief object in making these remarks has been to hinder persons who have not previously thought on the matter from taking his easy explanation of the mystery of ornithological mysteries to be sufficient. Believing, as I once before said, that its solution is probably simple in the extreme, and having a strong faith in the hereditary transmission and accumulation of faculties so as to become a wonder-working power, I yet cannot think that he has succeeded in making known the secret and in satisfactorily explaining how birds cross "the sacred spaces of the sea."

ALFRED NEWTON

[1] Since I wrote this I have heard from Mr. Gätke, so well known for his observations on migratory birds, that young Starlings pass over Heligoland during July by hundreds of thousands, "without a single old bird accompanying them," while the old birds begin to migrate at the end of September and continue for the next two months.

THE DIMENSIONAL PROPERTIES OF MATTER IN THE GASEOUS STATE

BY assuming a sufficient number of sufficiently insignificant individuals to constitute a group, it is possible to imagine a state of things in which as far as it can be observed from a certain distance, all evidence of individual action is entirely lost. In this way has been framed the molecular hypothesis or kinetic theory of gas. But it must be obvious to every one who has considered this molecular hypothesis, that the apparent uniformity in the actions we perceive must be the result of the distance (so to speak) from which these actions are observed, and that could we sufficiently localise (as regards time and space) our observation, we must perceive in all their varieties the individual actions of the molecules. And even failing this, between the actions of the individuals and the absolute mean action there must be local or parochial actions which would be distinguishable at greater distances than the purely individual actions.

In order that the properties of a gas may appear perfectly uniform in all directions and quite independent of the shape and volume of the space which the gas is constrained to occupy, the number of molecules must be countless, and the temporary action of each individual must be confined to an imperceptibly small portion of the space observed. If these conditions are not fulfilled then the properties of the gas will not be uniform, and we must have dimensional properties depending on the dimensions of the constraining surfaces.

The idea of our being able actually to perceive such properties does not appear to have been entertained hitherto. Until fifty years ago, all the mechanical properties of gases were regarded as quite uniform, the only mechanical distinction between one kind of gas and another being that of weight. Since that time in the phenomena of diffusion, and the phenomena attending the passage of gases through minute channels, properties of gases have been recognised which readily distinguish between one kind of gas and another, and even more than this, for Graham found that there was a difference in the relative behaviour of different gases in differing through porous plates of different coarseness. Still, neither Graham nor any one else appears to have recognised evidence of dimensional properties.

Neither did the development of the mathematical theory lead to the revelation of dimensional properties. Since 1864 it has been known that this theory included the explanation of all the uniform properties of gas. But in developing this theory attention appears to have been paid exclusively to the mean of the motions. And although Prof. Maxwell points out that there must ultimately be dimensional properties, he has not pursued the investigation, so as to reveal their character.

In 1874 a very remarkable phenomenon was brought to light by the experiments of Mr. Crookes—that in ex-

tremely rare media light bodies are apparently repelled by hot and attracted by cold bodies. At first this was not recognised as a gaseous phenomena—in fact the non-presence of gas was supposed to be essential to the occurrence of the highest form of the action.

That such motions might result from the inequalities in the pressure of the residual gas caused by the communication of heat between the objects and the gas, was first shown by the author in May, 1874 (*Proc.* Roy. Soc. 1874, p. 402).

It was shown that when heat is passing from a surface to a gas whether by direct communication or by evaporation the reaction from the receding molecules causes an excess of pressure proportional to the heat communicated.

The reasoning was definite so far as it went and, although manifestly incomplete, the conclusion arrived at, viz., that the phenomena resulted from the heat communicated to the residual gas appears very soon to have been generally accepted as it was found to be verified in various ways. Several papers appeared in which attempts were made to render the explanation more complete, but these attempts were for the most part based on a misconception of the phenomena to be explained and were altogether wide of the mark.

In November of 1878 the clue to the step that was wanting to complete the explanation occurred to the author. It was then seen that although the surfaces with which the phenomena occurred were of limited extent, no account had been taken of this fact in the attempts to explain the actions. Having once hit on this point the deduction of a complete theory of the phenomena was only a matter of labour. It was found that although the excess of pressure is proportional to the quantity of heat communicated, it also contains a factor which is proportional to the divergence of the lines of heat flow; and hence the reciprocal of the density of the gas at which the phenomenon would occur should vary inversely as the size of the vanes. So that by using vanes of comparatively small size the phenomena should be obtained at proportionally greater densities of the gas.

On considering how this conclusion might be experimentally tested it appeared that in order to obtain any results at measurable pressures the vanes would have to be very small indeed, too small almost to admit of experiment. It was while searching for some means to overcome this difficulty that it became apparent that if the vanes were fixed, then, instead of the movement of the vanes, we should have the gas moving past the vanes —a sort of inverse phenomenon—and then instead of small vanes small spaces might be allowed for the gas to pass. Thus the probable existence of phenomena of *Thermal Transpiration* was suggested, and it was obvious that the porous plug would furnish the means of verifying the conclusions. This probable connection between the phenomena of the radiometer, which may be called *Impulsion*, and the phenomena of transpiration through porous plugs raised the question whether the same extension of the dynamical theory of gas which explained the radiometer would not include the results obtained by Graham not then explained. This idea was followed up, and a method was devised of extending the dynamical theory of gases so as to take into account the forces tangential, and normal, arising from a varying condition of molecular gas.

This theory appeared to explain fully all the results established by Graham as well as the then known phenomena of impulsion (the radiometer), besides definitely indicating the phenomena of thermal transpiration to be expected, as well as the effect of employing small vanes in the radiometer. That this step had been accomplished was intimated by the author in the following passage in a letter published in NATURE, vol. xix. p. 220.

"Now, however, I have arrived at a result, which, although somewhat unexpected and striking, will, I hope, be found to reconcile what has hitherto appeared to be anomalous in the phenomena already known, and to have suggested certain hitherto unexpected phenomena which now only await experimental verification."

This experimental investigation which was at once commenced, proved to be a much more serious undertaking than had been anticipated, and was not completed until the end of August, this was not so much on account of difficulties, although these were considerable, but because it was found possible to do so much more than had been expected.

One of the results of the investigation was to show that a difference of pressure is maintained whenever two chambers of the same gas are separated by a porous plate, one face of which is hotter than the other.

With a plate of meerschaum ·44 inch thick, one side of which was something less than 212°, while the other side was about 50°, the difference of pressure was ·25 inch of mercury with air at the atmospheric pressure, and ·88 of an inch with hydrogen at the same pressure.

The existence of this thermal transpiration, although a new phenomenon, is not considered to be the most important result of this part of the investigation, for it appeared on comparing the results obtained with different plates, and different densities of gas, that there was a constant relation between the pressures for different plates at which proportional results were obtained. Thus comparing a plate of stucco with a plate of meerschaum, it was found that the ratios of the difference of pressure to the mean pressure, was the same for both plates so long as the mean pressure with the meerschaum was six times greater than with the stucco, and that this law held although the mean pressures with the meerschaum ranged from 30 to 1·25 inches of mercury. This ratio of the pressures at which corresponding results were obtained, was the same whether the gas used were hydrogen or air; and for plates of different thickness, and hence it was clearly shown to depend only on the coarseness of the plates.

Thus in thermal transpiration we have a phenomenon of gaseous motion depending on a relation between the density of the gas and the dimensions of the space which it is constrained to occupy. The discovery of this relation between the density of the gases and the coarseness of the plates at which corresponding results of thermal transpiration were obtained, suggested the possibility of obtaining a like relation for corresponding results when the gases were forced through the plates by a difference of pressure. Graham had found that the relative rates at which different gases transpired through plates differed very considerably with the coarseness of the plates and no explanation had been given of the phenomena. On trying the experiments not only was it found that with plates of different coarseness corresponding results were obtained whenever the pressures of the gas have a constant ratio but it was also found that with the same plates the ratio was the same as in the case of thermal transpiration.

A successful attempt was then made to verify the conclusion that the phenomena of the radiometer might be obtained at higher densities by using smaller vanes. By suspending fibres of silk and spider lines the repulsive action of heat was rendered apparent at pressures ranging up to the pressure of the atmosphere.

These results, as well as the theory from which they were deduced, have been fully described in a paper, an abstract of which was read before the Royal Society on the 6th inst.

As regards transpiration and impulsion, the investigation appears to be complete; most, if not all, of the phenomena previously known have been shown to be such as must result from the tangential and normal stresses consequent on a varying condition of a molecularly constituted gas; while the previously unsuspected

phenomena to which it was found that a variation in the condition of gas must give rise, have been found to exist.

The results of the investigation lead to certain general conclusions which lie outside the immediate object for which it was undertaken; the most important of these is that gas is not a continuous plenum.

The experimental results considered by themselves bring to light the dependence of a class of phenomena on the relations between the density of the gas and the dimensions of the objects, owing to the presence of which the phenomena occur. As long as the density of the gas is inversely proportional to the coarseness of the plates, the transpiration results correspond; and in the same way, although not so fully investigated, corresponding phenomena of impulsion are obtained as long as the density of the gas is inversely proportional to the linear size of the objects exposed to its action; in fact, the same correspondence is found with all the phenomena investigated.

We may examine this result in various ways, but in whichever way we look at it, it can have but one meaning. If in a gas we had to do with a continuous plenum, such that any portion must possess the same properties as the whole, we should only find the same properties, however small might be the quantity of gas operated upon. Hence, in the fact that we find properties of a gas depending on the size of the space in which it is inclosed, and on the quantity of gas inclosed in this space, we have proof that gas is not continuous, or, in other words, that gas possesses a dimensional structure.

In virtue of their depending on this dimensional structure, and having afforded a proof thereof, it is proposed to call the general properties of a gas on which the phenomena of transpiration and impulsion depend, the *Dimensional Properties of Gas*.

Although the results of the dimensional properties of gas are so minute that it has required our utmost powers to detect them, it does not follow that the actions which they reveal are of philosophical importance only; the actions only become considerable within extremely small spaces, but then the work of construction in the animal and vegetable worlds, and the work of destruction in the mineral world, are carried on within such spaces. The varying action of the sun must be to cause alternate inspiration and expiration, promoting continual change of air within the interstices of the soil as well as within the tissue of plants. What may be the effect of such changes we do not know, but the changes go on; and we may fairly assume that, in the processes of nature, the dimensional properties of gases play no unimportant part.

OSBORNE REYNOLDS

OUR ASTRONOMICAL COLUMN

THE BINARY STAR α CENTAURI.—Dr. Doberck, with the aid of measures made during the last few years has calculated elements of α Centauri, which, though given as only provisional, will doubtless approach nearer to the true ones than any previously published. They are as follows:—

Passage of the peri-astre	1875·12
Node	25° 32′
Angle between node and peri-astre	45° 58′
Inclination	79° 24′
Excentricity	0·5332
Semi-axis major	18″·45
Period of revolution	88·536 years.

Comparing this orbit with weighted means derived from Mr. Gill's measures at Ascension in 1877, the following differences are shown:—

1877·614	Position	+ 2°·32	Distance	− 0″·23
1877·858	,,	− 0·39	,,	+ 0·05

For 1879·5 the elements give position, 173°·4; distance, 3″·47; and for 1880·5, position, 185°·2; distance, 5″·30; the smaller star will be due south of the larger one at the beginning of 1880, distant 4″·37. The above value for the semi-axis major, taking the annual parallax of α Centauri, a mean between the values of Maclear and Moesta, indicates that the mean distance between the component stars is rather greater that the mean distance of Uranus from the sun. Frequent measures of α Centauri during the next few years are much to be desired.

A NEW VARIABLE STAR IN SAGITTARIUS.—The following case appears a singular one, if the star is not variable to a considerable extent:—On April 28, 1783, D'Agelet observed a star which he estimated of 4·5m., and which is No. 4,627 in Gould's Catalogue. It does not occur in Piazzi or Lalande, nor in Bode, but it is found on Harding's Atlas as 6m. It is wanting in the Uranometries of Argelander and Heis, but the former observed it three times in his Zones. In Z. 218, July 2, 1849, it is rated 5m.; in Z. 225, on July 13, only 7m.; and in Z. 391, June 30, 1851, it is 5·6m. The mean position for 1850 from Argelander's observations is in R.A. 17h. 59m. 6·57s., N.P.D. 107° 10′ 9″·9, or reducing to 1880 in R.A. 18h. om. 51·1s., N.P.D. 107° 10′ 10″. It is difficult to account for such an object having escaped the notice of other observers, except upon the supposition of variability; perhaps, like some other variables, it is only conspicuous for a short time. The star follows 6 Sagittarii 6m. 26s., in 1′·4 greater N.P.D. It is proper to state here that Mr. J. E. Gore, in his "Southern Stellar Objects," p. 104, has a reference to this star amongst stars possibly variable, but the observations of D'Agelet and Argelander do not appear to have been known to him.

NEW MINOR PLANET.—No. 193 was discovered by M. Coggia at Marseilles on March 1, not far from the place of No. 192, detected at Pola by Herr Palisa, in the previous month.

INTRA-MERCURIAL BODIES.—In a letter addressed to M. Mouchez, communicated to the Academy of Sciences at Paris on March 3, Padre Ferrari, Director of the observatory of the Collegio Romano, mentions that, having had occasion to institute researches respecting the observation of a rapidly-moving spot upon the sun's disk by De Cuppis on October 2, 1839, at the instance of Prof. Oppölzer, he had met with particulars of a similar observation by De Vico in 1837. Reference is made to this observation in "Memoria intorno ad alcune osservazioni fatte alla Specola del Collegio Romano, 1838," p. 15, but the year only is there mentioned. De Cuppis, a friend and frequently co-operator of De Vico's has, however, preserved the date in the journal *L'Album* for 1838, July 7, where the observation is thus described: "In una osservazione del 12 luglio, 1837 parve al sullodato astronomo (De Vico) del Collegio romano veder rinnovato il fenomeno, in una piccolissima macchia perfettamenta rotonda e senza traccia della cosi detta penombra, la quale nel breve spazio di 6 ore trascorse buona parte del disco solare."

This observation does not occur in Haase's Collection, nor is there here more than a reference to the observation of Decuppis, which is thus given in a note by Arago at the sitting of the French Academy on December 16, 1839:—"M. Decuppis annonce que le 2 Octobre, en continuant des observations qu'il faisait sur les taches du soleil, il a vu une tache noire, parfaitement ronde et à contours nettement terminés, qui s'avançait sur le disque de l'astre d'un mouvement propre rapide, de manière à ce qu'elle a dû en traverser le diamètre dans environ six heures. M. Decuppis pense que les apparences qu'il a observées ne peuvent s'expliquer qu'en admettant l'existence d'une nouvelle planète."

There are other observations upon record in January

and July which might apply to the object seen by De Vico, assuming it to have been an intra-Mercurial planet. Leverrier did not attempt to discuss these observations, confining his attention to those made about the equinoxes, clearly belonging to a different body.

GEOGRAPHICAL NOTES

SOME of our contemporaries have been a little premature in appointing the Earl of Northbrook to the presidency of the Royal Geographical Society, for at the time when the announcement was first made his lordship was not even a fellow of the Society. The fact, we believe, is that Lord Northbrook has expressed his willingness to accept his nomination by the Council, but there is no likelihood of any election taking place till the anniversary meeting on May 26th.

AT the meeting of the Geographical Society on Monday evening Dr. James Stewart, of the Livingstonia Mission, East Africa, read a paper on the "Second Circumnavigation of Lake Nyassa." The voyage was undertaken in the little steamer *Ilala* in the latter part of 1877. It was found that Lake Nyassa has hitherto been laid down on our maps too far to the east, and that its position ought to be shifted at the north end as much as thirty miles to the westward. Dr. James Stewart was also fortunate in discovering two harbours such as were needed for the safe navigation of the lake; the one Rombashi inlet or river on the northern coast, and the other the Kambwe lagoon a little to the south of it on the west coast. Mr. James Stevenson afterwards gave a few particulars respecting the explorations now being carried on by Dr. Laws and Mr. James Stewart, of the Bengal Civil Service, in the country on the western side of Lake Nyassa.

THE Abbé Debaize, the leader of the French expedition to Central Africa, sends to M. Richard Cortambert a letter, rejoicing at the success of his expedition so far. He writes from Taboro, in Unyamwezi, and states that hitherto he has been completely successful; there have been no desertions, little expenditure, and no misfortunes of any kind. This good fortune he ascribes to his own excellent health, to his firm discipline, and his personal superintendence of all arrangements. He has a very poor opinion of Miramboa, and thinks the English are striving hard to become masters in Central Africa; indeed he hints that "annexation" is not far off. At Mpwapwa, where the sole white population are an English "reverend, a mason, and a carpenter," there are already four stone houses, while there are English stations in Ukerewe, Uganda, and at Ujiji.

THE *Daily News* Lisbon correspondent states that the Portuguese Minister of Marine has informed the Cortes that he has received a telegram stating that the Portuguese African explorer Pinto, who was separated from his companions at Bihe, has succeeded in traversing Africa from west to east, having reached the Transvaal.

FRANCE and the United States will soon establish a comparison of the longitude of Paris and Washington by cable. As is known, these operations lead to a determination of the velocity of propagation of electric waves. Commander Perrier and M. Lœwy have recently published a volume giving the details of the comparison between Paris, Marseilles, and Algiers.

MR. STANFORD has just published a very fine stereographical map of Zululand, with portions of the adjoining territories. On the bases of what observations there are as to the physical conformation of the country, together with the pretty fair notions we have of the courses of the rivers, a good general notion is conveyed of the character of the surface and its various levels. The map conveys, moreover, a great amount of information in a clear and striking manner, that will be extremely useful to those who wish to understand the history and bearings of the Zulu difficulty.

UNDER the title of "Le Maroc" the current number of the *Tour du Monde* contains the commencement of a translation of M. Edmondo de Amicis' account of his experiences in Morocco in 1875. The present instalment deals with Tangier, and is accompanied by several illustrations.

WE understand that Prof. Geikie, of Edinburgh, will probably deliver a lecture on Geographical Evolution before the Royal Geographical Society on Monday, March 24.

THE Emperor of Austria has presented Captain von Oestreicher with the medal for letters and arts (*literis et artibus*) in recognition of his recent highly interesting geographical work, "Aus fernem Osten und Westen."

DURING last year the following journeys were made by Russian explorers in Central Asia:—Generals Stolyetoff and Razgonoff were accompanied during their mission to Kaboul by several topographers and explorers; M. Oshanin has made explorations in Karategin and Hissar; M. Matséeff in Badakshan and Eastern Afghanistan; M. Grodékoff in Western Afghanistan and Herat; M. Bykoff has explored the Amu darya River from Kobadian to Khiva; M. Yavarsky has traversed for the fourth time the region between Tashkend and Kaboul; M. Mayeff has visited for the second time the hilly track between Karshi, Keliff (on Amu darya), Kobadian, and Hissar; and, finally, the steamer *Samarkand* has navigated the Amu, from Petro-Alexandrovsk to Khodja-Sale.

UNDER the title of Société de Géographie de l'Est, there has been founded at Nancy a new geographical society.

A STUDY IN LOCOMOTION[1]

IF the interest of a scientific expositor ought to be measured by the importance of the subject, I shall be applauded for my choice. In fact, there are few questions which touch more closely the very existence of man than that of animated motors—those docile helps whose power or speed he uses at his pleasure, which enjoy to some extent his intimacy, and accompany him in his labours and his pleasures. The species of animal whose co-operation we borrow are numerous, and vary according to latitude and climate. But whether we employ the horse, the ass, the camel, or the reindeer, the same problem is always presented: to get from the animal as much work as possible, sparing him, as far as we can, fatigue and suffering. This identity of standpoint will much simplify my task, as it will enable me to confine the study of animated motors to a single species; I have chosen the horse as the most interesting type. Even with this restriction the subject is still very vast, as all know who are occupied with the different questions connected therewith. In studying the *force of traction* of the horse, and the best methods of utilising it, we encounter all the problems connected with teams and the construction of vehicles. But on a subject which has engaged the attention of humanity for thousands of years, it seems difficult to find anything new to say.

If in the employment of the horse we consider *its speed* and the means of increasing it, the subject does not appear less exhausted. Since the chariot races, of which Greek and Roman antiquity were passionately fond, to our modern horse-races, men have never ceased to pursue with a lively interest the problem of rapid locomotion. What tests and comparisons have not been made to discover what race has most speed, what other most bottom,

[1] "Moteurs animés; Expériences de Physiologie graphique." [Lecture by Prof. Marey at the Paris meeting of the French Association, August 29 1878.

what crossings, what training give reason to expect still more speed?

Lastly, as to what is called the exterior of the horse, and his varied paces, specialists have for long devoted themselves to this department. The horseman is trained to distinguish between these different paces, to correct by the education of the horse those which seem to him defective, to fix by habit those which give to his mount more pleasant reactions or a much greater stability. The artist, in attempting to represent the horse, seeks to transfer his attitudes more and more faithfully, to express better and better the force, the suppleness, and the grace of his motions.

These questions, so complicated, I wish to bring before you by a new method, and I hope to show you that the *graphic method* makes light of difficulties which seem insurmountable, discerns what escapes the most attentive observation; finally, it expresses clearly to the eyes, and engraves upon the memory the most complicated notions. The graphic method was almost unknown twenty-five years ago; to-day it is wide-spread. Thus, in almost all countries, recourse is had to the employment of graphic curves as the best mode of expression to represent clearly the movement of administrative, industrial and commercial statistics. In all observatories apparatus known as *registering* or *recording*, trace on paper the curves of variation of the thermometer, the barometer, rain, wind, and even atmospheric electricity. Physiology utilises still more largely recording apparatus; but I shall only require to show you a very small number of these instruments, those which serve to record forces, rates of speed, or to note the rhythms and the relations of succession of very complicated movements.

1. *Of the Force of Traction of the Horse, and the best Means of Utilising it.*—When a carriage is badly constructed and badly yoked the traveller is jolted, the road is injured, the horse is fatigued more than is necessary, and is often wounded by parts of the harness. Science and industry have long sought to discover these inconveniences, to find out their causes in order to get rid of them. But it is only in our own time that great progress has been made in this respect. When we complain of being jolted in a humble cab, we ought to go back in thought to the time when people knew nothing of the hanging of carriages. No roughness of the road then escaped the traveller. A Roman emperor mounted on his triumphant chariot was, in the midst of his glory, as ill at ease as the peasant in his cart. Except some improvements, such as the use of softer cushions, things went on thus till the invention of steel springs such as are now employed, for the leather braces of old-fashioned carriages still left much to desire.

Does this mean that the present mode of suspending carriages by four and even eight springs is the final step of progress? Certainly not. Our present springs diminish the force of jolts, transform a sudden shock into a long vibration; but the perfect spring ought always to maintain a constant elastic force, to allow wheels and axles all the vibrations which the ground demands of them, without allowing any of these shocks to reach the carriage itself. The search for this ideal spring has engaged the attention of one of our most eminent engineers. M. Marcel Deprez has found happy solutions to the problem of perfect suspension; he will, doubtless soon apply these in practice.

A good suspension also saves the carriage by suppressing the shocks which put it out of order and destroy it in a short time. Finally, suspension saves the wheel itself. On this subject let me recall a remarkable experiment of General Morin. On a high road, in good condition, he drove a diligence with four horses at the trot, and laden with ballast instead of passengers. The springs of the vehicle were raised so that the body rested on the axles. After the diligence had passed and repassed a certain number of times, it was found that the road on which it was running was notably deteriorated. The springs of the carriage were replaced and the same movements were repeated on another part of the road; the marked deterioration was no longer produced. It is thus clearly proved that a good suspension is favourable to a good condition of the roads.

But with non-suspended vehicles, in order thus to shock the passengers, disjoint the carriage, and abuse the road, force is necessary. It is the horse which must supply this; so that, independently of the useful work which we demand of them, the animal supplies still other work which gives rise to a multitude of shocks, and has only injurious effects. The employment of suspending springs has rendered the double service of suppressing injurious vibrations and of collecting into a useful form all the work which they represent.

Is this all? Do there not remain, even with the best carriages, other vibrations and other shocks which must be pursued and destroyed in order to render more perfect the conditions of traction? You have all experienced, at the moment of the sudden start of a carriage, and even at each stroke of the whip on a living horse, horizontal shocks which sometimes throw you to the bottom of the carriage. In a less degree, shocks of the same kind are produced at each instant of traction, for the speed of the horse is far from being uniform, and the traces are subjected to alternate tension and slackness. Here are veritable shocks which use up part of the work of the horse in giving only hurtful effects which bruise and contuse the breast of the animal, injuring his muscles, and, in spite of the padding of the collar, sometimes wounding him. To prove the disadvantages of this kind of shocks, some experiments are necessary. I have borrowed one from Poncelet; it is easily made, and any one may repeat it. I attach a weight of 5 kilos to the extremity of a small string; taking hold of the free extremity of this, if I gently raise the weight, you see that the cord resists the weight of 5 kilos and holds it suspended. But if I attempt to raise the same weight more rapidly, I bruise my fingers, the cord breaks, and the weight has not budged. The effort which I have made has been greater than the preceding, since it has exceeded the resistance of the cord; but the duration of this effort has been too short, and the inertia of the weight not being overcome, all my exertion has been expended in injurious work. If, instead of an inextensible cord, I had attached to the weight a cord a little extensible, the sudden effort of elevation which I made would have been transformed into an action more prolonged, and the weight would have been raised without breaking the cord and bruising my fingers. To render the phenomenon more easy of comprehension, I shall make a new experiment under conditions a little different.

You see on a vertical support (Fig. 1) a sort of balance-beam, which bears on one of its arms a weight of 100 grammes, on the other a weight of 10 grammes suspended at the end of a cord one metre long. Between these two unequal weights the beam is maintained by a spring-catch, which prevents it from falling to the side of the heavier weight, but which, on the other hand, permits the beam to incline in the opposite direction, if we bring to bear on the end of the cord an effort greater than the weight of 100 grammes. But, by letting the smaller weight fall from a sufficient height, at the moment when this reaches the end of its course, it will stretch the cord which holds it, and will develop what is called a *vis viva*, capable of raising the weight of 100 grammes to a certain height; but this elevation will only take place on condition that the application of this force does not give rise to a shock. If the cord which sustains the weight of 100 grammes is inextensible, and if that which bears the weight of 10 grammes is the same, at the moment of the fall of the latter, you will hear a snap; a shock agitates

the whole apparatus, but the weight of 100 grammes is not raised.

Now suspend this weight of 100 grammes to an india-rubber cord or an elastic spring, and repeat the experiment. You see each time that the weight falls that the 100-gramme weight is raised to a certain extent. But this elevation is effected under peculiar conditions. At the moment when the weight falls and the cord is stretched, the balance inclines, stretching the elastic spring, but the mass of 100 grammes does not yet move; it is only when this spring is stretched that the mass, obedient to the prolonged action of this elastic spring,

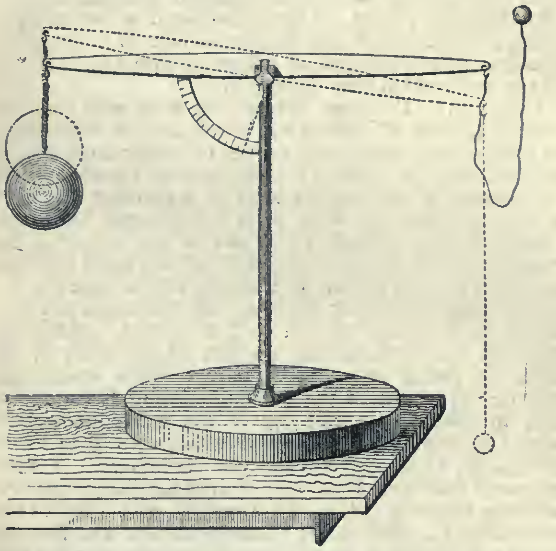

FIG. 1.—Apparatus to show that a *vis viva* directly applied to the displacement of a mass is lost in a shock, while the same force transmitted by an elastic medium may perform work.

begins to move and rises, representing a certain amount of work accomplished.

Thus, the suppression of shock in traction, economises a certain part of the moving labour; it is *then* advantageous to give to the traces of a carriage a certain elasticity. One of the most simple methods consists in interposing between the trace and the carriage an elastic medium. Here are some of these elastic pieces, which I call *tractors*. One of the patterns has been made by M. Tatin; it is composed of a spring which is compressed by traction and deadens the shock. The other is formed of a similar spring placed in the very inside of the carriage-trace.

If you wish to be convinced of the advantage of this mode of traction, yoke yourself to a hand-barrow by

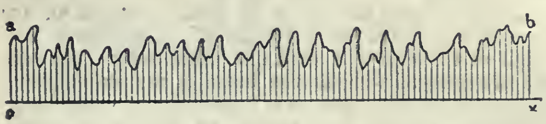

FIG. 2.—Tracing of the dynamograph for a vehicle drawn by a horse.

means of a rigid leather strap, such as you see used in the streets of Paris or London, where too often man is employed to drag burdens. When you have well noted the painful shocks which this mode of traction transmits to the shoulders, place between the strap and the barrow the elastic tractor and repeat the experiment. After that no doubt is possible; the shoulders are no longer bruised by the shaking of the pavement, and a comfort is experienced which will evidently be experienced in the same degree by a horse placed in conditions of elastic traction.

To obviate suffering to men and animals is unfortunately not a motive sufficient to induce everybody to modify the old system of harnessing. To certain minds known as *positive*, it is necessary to prove that elastic traction has economical advantages, and that a horse thus harnessed is able to draw heavier loads. This fact, which results from the experiments which you have seen, requires, to be rigorously proved, the aid of the graphic method. It is to the genius of Poncelet that we owe the record of work expended by different motors.

Everybody knows what a dynamometer is, viz., a spring which, yielding to tractions exerted upon it, is deformed in proportion to the efforts developed. Let us adapt to a spring of this kind a pencil which touches a strip of paper, and let us so arrange things that the movements of the wheel of a carriage shall impress upon the paper a motion of translation. While the effort of traction of the horse will communicate to the spring movements more or less extended, the progress of the carriage will

FIG. 3.—Tracing of the dynamograph for a vehicle drawn with an elastic intermediary.

draw out the paper, and from these combined movements will result a curve (Fig. 2), which can be resolved into a series of ordinates or vertical lines in juxtaposition, expressing by their unequal heights the series of efforts resulting from each element of the road traversed. The sum of these elementary efforts, otherwise the surface of paper limited in height by the flexures of the curve, will be the measure of the work expended. If we record in a comparative manner the work done by the same vehicle harnessed with rigid traces or supplied with elastic tractors, we see (Figs. 3 and 4) that the *area* of the curve is greater, that is, that there has been more work expended, while rigid traces have been used. In the most favourable cases that I have met with, the economy of work by elastic traction has been 26 per cent.

But, it may be objected, the recording dynamometer itself constitutes an elastic intermediary which suppresses

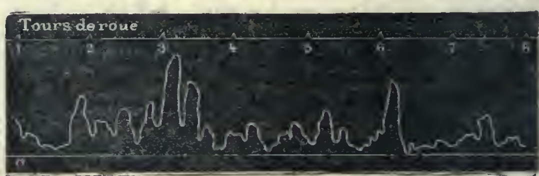

FIG. 4.—Tracing of the dynamograph for a hand-barrow drawn by a rigid trace.

the shocks. But it is not the ordinary dynamometer which I have used in my experiments, but a special dynamometer which undergoes under the strongest tractions only an almost insignificant elongation. This elongation, amplified by certain organs and transmitted to a distance by a lever fitted with a pen, is recorded in the form of a wavy curve in conditions referred to above. To sum up, in the employment of animated motors for the drawing of burdens, to find out wherever they produce shocks and vibrations, and to absorb them in elastic springs which restores to useful work a force that seemed only to destroy vehicles, tear up the roads, cause the animals to suffer—such is the direction in which much progress has been realised, and much more may still be realised.

2. *Of the Speed of Animated Motors.*—I shall per-

haps astonish many of you by saying that the speed of a vehicle is one of the things most imperfectly known. It is generally believed to be sufficiently expressed by stating how much way has been made and how much time has been occupied for that. I have come, you may say, from the Pont de Sèvres to the Madeleine in $41\frac{1}{4}$ minutes; the road is well mile-stoned, I possess a good watch; what greater precision do you require? Assuredly you have measured accurately the space traversed and the time employed, but that constitutes only the expression of a mean speed resulting from a series of variable speeds, of accelerations, of retardations, and sometimes of stoppages

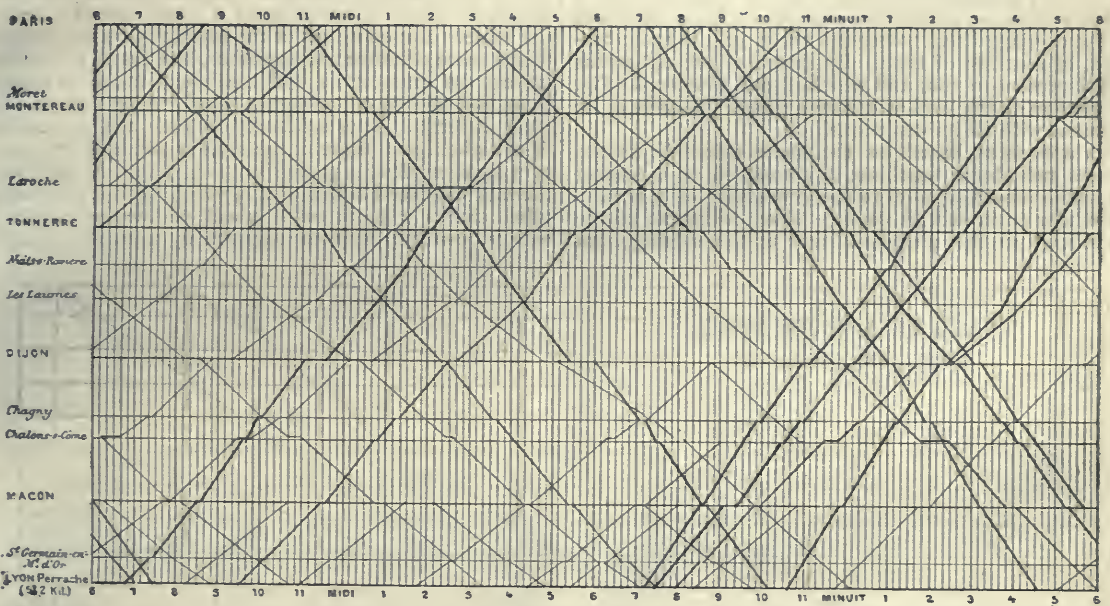

FIG. 5.—Graphic of the progress of trains upon a railway, after Ibry's method.—When we place the figure before us we read from the left, on the axis of the ordinates, the series of stations, that is, the divisions to be run over; the distance between the stations on the paper is proportional to the kilometric distances which separate them. In the horizontal direction, that is, on the axis of the abscissæ, are counted the divisions of time in hours, themselves subdivided into spaces of ten minutes each. The breadth of the table is such that the twenty-four hours of the day are represented on it, commencing at 6 A.M., and ending next day at the same hour. If we wish to express that a train is on a certain point of the line at a certain hour, we shall point out its position on the table, opposite the station or any point of the line which it occupies and on the properly chosen division of time. A single point of the table satisfies these conditions. At successive instants the train will occupy points on the table always different; the series of these points will give rise to a line which will be descending and oblique from left to right for trains coming from Paris, while it will be ascending and oblique in the same direction for trains going to Paris. The line which corresponds to each of the trains expresses the hours of departure and arrival, the relative and absolute rates of the trains, the instant of passing each of the stations, and the duration of stoppages. In fact, if we consider any particular train, we see that a train starts from the station at Paris at 11 A.M.; if we follow this train in its progress, we find that it has seven stoppages (during which it is not displaced in space, but only in time). These stoppages are translated by the horizontal direction of the line, opposite the station where they take place; the length of this horizontal line measures the duration of the stoppages. The line of the train, followed to the end, shows that the arrival takes place at 6 P.M.; but, if we reckon the distance on the axis of the ordinates, we see that 512 kilometres have been traversed in eleven hours ten minutes, stoppages included, which gives a mean rate of about 46 kilometres per hour.

where time is quite unknown. A rigorous measurement of rates supposes the road traversed by the vehicle at each instant; in other words, the position which it occupies upon the road. It is thus that physicists have determined the accelerated motion of the fall of bodies—Galileo and Atwood, by means of successive measurements, Poncelet and Morin by means of that admirable apparatus which traces by a single stroke the curve of a movement.

This machine is now too well known to need description; however, I shall make it work before you in order to interpret its language and to show how a graphic curve translates all the phases of a movement. The parabolic curve traced expresses for each of its points the position in which the body is found at each of the instants of its fall; it thus supplies the most complete information on the nature of the movement. But if, knowing only the space run over and the time employed, we join the two extreme points of departure and arrival by a straight line, that line, which will express the mean rate of the fall, will not correspond to any of the rates which the body has successively possessed.

The expression of movement by a curve has been put into practice. An engineer named Ibry has devised a method of representing graphically the progress of trains upon a railway. This mode of representation, incomparably more explicit than the tables of figures of our railway *indicators*, has not yet got into the hands of the public; and this is to be regretted, for it gives a genuine interest to a journey, as you may see by inspection of one of these graphics.

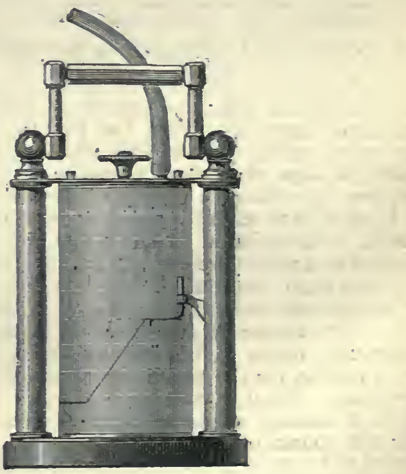

FIG. 6.—Odograph, reduced to one-third of its diameter.

The table which you see (Fig. 5) is prepared by engineers according to the regulation progress of trains

a progress supposed uniform; we see, in fact, that the lines of progress are all straight, joining to each other the two points which express the place and time of departure, the place and time of arrival. It does not then take into account the real movement of the train, which is accelerated or retarded under a great number of influences. The problem which we seek to solve, that of a graphic expression of the real rate of a vehicle, supposes that the carriage itself traces the curve of the roads traversed, in function of time. By means of the apparatus which I present to you, and which I call *Odograph* (Fig. 6), a waggon or any kind of carriage traces the curve of its movement with all its variations.

This apparatus, based on the same principle as the Poncelet and Morin machine, is composed of a tracing style which moves parallel to the generatrix of a revolving cylinder covered with paper. The movement of the style follows all the phases of that of the carriage, but on a very reduced scale, in order that the tracing of a distance of several myriametres may be contained in the dimensions of a sheet of paper. As to the movement of the cylinder, it is uniform, and commanded by clockwork placed in the interior. In order that the movement of the style may be proportional to that of the vehicle, things have been so arranged that each turn of the wheel causes the style to advance by a small quantity, always the same. But as a turn of the wheel always corresponds to the same distance accomplished, the faster the vehicle travels the more turns will the wheel make in a given time, and the more movements of progression will the style undergo. This solidarity between the movements of the wheel and those of the style is obtained by means of a small excentric placed on the vane. At each turn there is produced a puff of air, which, by a transmitting tube, causes a tooth of a wheel of the apparatus to escape, and the style to advance by a small quantity.

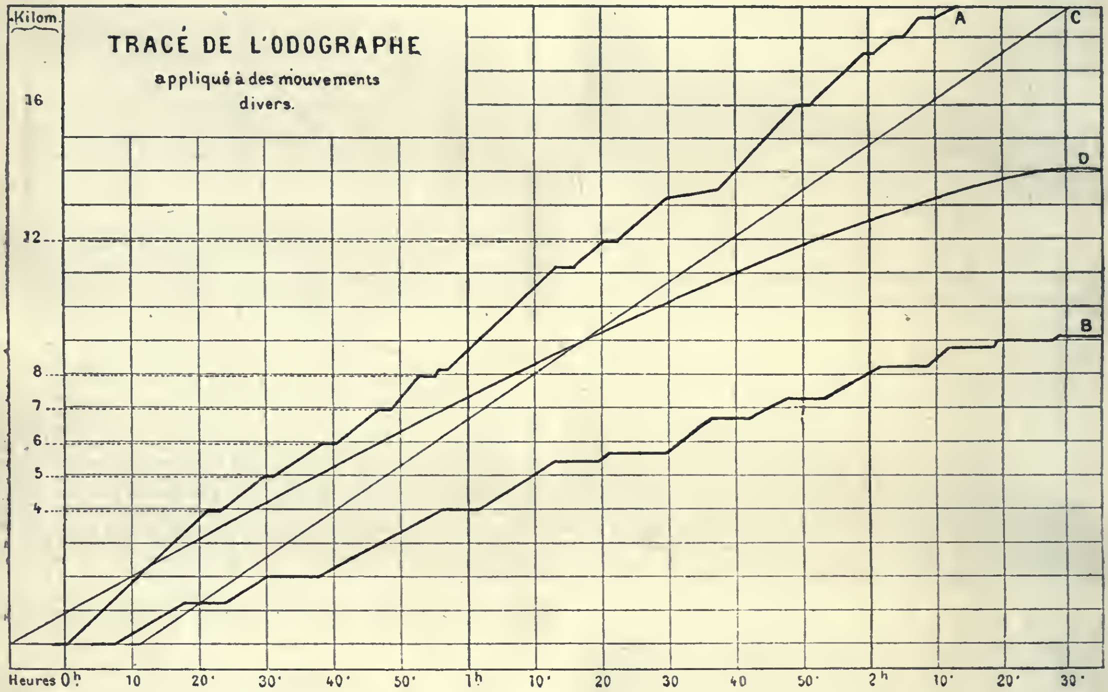

FIG. 7.—Tracings of the Odograph. A, rapid coach with stoppage; B, slow coach; C, gas meter, frequency of turns of the wheel; D, curve of the turns of a clock wheel-work with fly.

Similar effects may be obtained by means of electromagnetic apparatus. Thus the swifter the vehicle goes the more rapidly will the line traced ascend; the comparative slope of various elements of the tracing will express the variations of rate, as seen in Fig. 7.

If we wish to learn the absolute value of time and distance, it is sufficient to know that each minute corresponds to a millimetre counted horizontally on the paper, and that each kilometre corresponds to a certain number of millimetres traversed by the style in the vertical direction. The course of the style, which corresponds to a kilometre, ought to be experimentally determined for each vehicle, for the perimeter of wheels is not always the same. But it is clear that, if from each kilometrestone to another we obtain five millimetres, for example, for the course of the style, this length will always be found to be traversed each kilometre by the same vehicle. Our apparatus is then a measurer of distances, and dispenses with the necessity of attending to the existence of kilometre-stones; it enables the distance traversed on any road whatever to be estimated, and even when there is no beaten track. Thus in a journey of discovery we may measure the distance traversed by a cart. To remain in the conditions of ordinary life, have we not sometimes, in the country, a choice of two or three roads to go from one place to another? To know which is the shortest, we appeal to the watch, as if the least duration of a walk corresponded to the least distance. The odograph will give in this respect very precise information.

There is again a great number of questions which we ask daily without being able to solve them. Does such a draught horse go quicker than such another? Does this trot better to-day than yesterday? By increasing the ration of oats do we increase speed? Compare the slope of two curves of rates, and you will have the reply to all these questions without being obliged to make special experiments on a measured road, watch in hand.

It is not only to the speed of vehicles that the registering apparatus applies; it traces, though with less precision, the rate of progress of men and animals. We

slip into our boots a bellows sole, which is connected by a tube with a portable odograph. Each pace impresses on the style a small movement, as does each turn of the wheel of a carriage; and if the paces be absolutely equal, we may measure with certainty the distances travelled. In walking on level ground we take steps of astonishing regularity; but if the ground rises, the step gains in length; in descents, on the contrary, the steps are shortened. There may result from this slight errors in the distances traversed. Notwithstanding this, the employment of this apparatus will effect a great progress; it may be substituted with many advantages for the pedometer, which gives, at the end of a certain time, only the paces accomplished, without taking count of the stoppages or the changes of rate.

In short, when we make an experiment on a measured road, if there are produced variations in the length of the tracing represented by a kilometre, we conclude therefrom variations in the length of the pace. Such variations are observed under the influence of the slope of the country, the nature of the soil, the boots we wear, the rate of walking, or the weight carried. These studies in applied physiology have, I believe, a great practical importance, and numerous applications to the march of troops in a campaign.

(*To be continued.*)

WILLIAM KINGDON CLIFFORD

IT was with feelings of the deepest regret that we last week recorded the sad loss the scientific world and the country at large had sustained by the death, at the early age of thirty-three, of one of the deepest thinkers and most brilliant writers this century has seen. W. K. Clifford was the eldest son of the late Mr. William Clifford, J.P., of Exeter, and was born on May 4, 1845. Receiving his earlier education at the school of Mr. Templeton of that city, he proceeded to King's College, London. Here he at once gave evidence of his great powers by obtaining in his first year, 1861, the Junior Mathematical and Junior Classical Scholarships, as well as the Divinity prize. In the two succeeding years he gained the Classical and Mathematical Scholarships of the year, and in addition to the Inglis Scholarship for English language an extra prize for the English essay. Even at this time, whilst pursuing with such success so many branches of study, he sought a more genial occupation for his active mind in constantly reading in the college library the higher mathematical works to which he could obtain access, and towards the end of his school life, as also during his time as an undergraduate at Cambridge, he took great delight in solving and propounding problems in the *Educational Times*. While still in his eighteenth year the "Analogues of Pascal's Theorem" was written, and constitutes the first of his papers recorded in the Royal Society Catalogue. Passing from his school life, we find him entered at Trinity College, Cambridge, securing a Foundation Scholarship, college prizes in each academic year, and the English Declamation prize. Early in his career at the University he read such portions of the Tripos subjects as possessed any interest for him, and soon turned his attention to the study of the original writings of Sylvester, Cayley, Salmon, and some of the great Continental masters. In vain did his private tutor, the Rev. Percival Frost, who always had the highest admiration for him, and was anxious that he should attain his proper place in the Mathematical Tripos, urge him to devote a little more attention to examination subjects; his mind could tolerate no such restraint; nothing but the fresh and original thoughts of the greatest mathematical writers could satisfy his wants.

His neglect of the examination subjects was such that it is said he only once wrote out a paper of bookwork questions, and that under the impression that he was solving problems; many also, well qualified to judge, were agreeably surprised when he obtained the position of second Wrangler in the Mathematical Tripos of 1867, while his success in obtaining the second Smith's prize was doubtless anticipated from the wider scope for his talents afforded by that examination. During this period the course of his future work is clearly seen; divinity and classics, at one time so ardently studied, are laid aside, and the writings of the great philosophers divide his attention with the study of higher geometry. One of his longest and most fully worked out papers, "Analytical Metrics," published subsequently in the *Quarterly Journal of Mathematics*, was written at this time, 1864.

Of the circle of intimate friends Clifford formed at this time, nothing need here be said; two or three have gone before him, the remainder have watched with the deepest interest and pleasure his widening reputation and growing influence, and are now left with a blank no one can fill, and all bear in affectionate remembrance his ready sympathy, delicate sense of humour, and sweetness of disposition. His success in the Trinity Declamation prize, and his popularity in the debates at the Cambridge Union Society, showed him to be a speaker of no common order, but it was not until he delivered his first Friday evening lecture at the Royal Institution of London, the year after he took his degree, and subsequently at the Sunday Lecture Society, that crowded audiences bore testimony to his extraordinary power of lucid exposition. The Royal Institution lecture, "On some of the Conditions of Mental Development," delivered March 6, 1867, was the first time he addressed a large public audience, which included many of the leading thinkers of the time, and from that day he took a recognised position amongst them. A short extract from this lecture reflects the habit of his mind on leaving the University, and indicates plainly that the course of study pursued while an undergraduate, probably by many thought misguided, was, in reality, the expression of a deep inward conviction. Speaking of the mind, he says, "still less must it tremble before the conventionalism of one age, when its mission may be to form the whole life of the age succeeding. No amount of erudition, or technical skill, or critical power, can absolve the mind from the necessity of creating, if it would grow. . . . . The first condition of mental development, then, is that the attitude of the mind should be creative, rather than acquisitive;" and again, "It is quite possible for conventional rules of action, and conventional habits of thought to get such power that progress is impossible." Two other Friday evening lectures were given later by Clifford, on "Theories of the Physical Forces," Feb. 18, 1870; and on "Babbage's Calculating Machines," May 24, 1872; in the latter case no pains were spared by him to thoroughly master all the mechanical details of those intricate machines, and for years afterwards he would occasionally discuss schemes for the completion of the analytical engine. In public lecturing his greatest success was probably the evening lecture at the meeting of the British Association at Brighton, August, 1872, "On the Aims and Instruments of Scientific Thought." Throughout this lecture the key-note of so much of Clifford's most powerful writing can readily be detected, as may be shown by a short extract:—"If you will allow me to define a reasonable question as one which is asked in terms of ideas justified by previous experience, without itself contradicting that experience, then we may say as the result of our investigation, that to every reasonable question there is an intelligible answer, which either we or posterity may know. . . . By scientific thought we mean the application of past experience to new circumstances, by means of an observed order of events. . . . Remember then that it (scientific thought) is the guide of action; that the truth which it arrives at is not that which

we can ideally contemplate without error, but that which we may act upon without fear; and you cannot fail to see that scientific thought is not an accompaniment or condition of human progress, but human progress itself."

Several lectures delivered at St. George's Hall for the Sunday Lecture Society, such as those on "Ether," "Atoms," the "Sun's Place in the Universe," were all characterised by his extraordinary power of explaining some of the most difficult physical conceptions to a popular audience, and were invariably listened to with the greatest attention and pleasure. In his numerous contributions to the *Fortnightly*, *Contemporary*, and *Nineteenth Century Reviews*, his outspoken earnestness of purpose plainly showed the conscientious conviction of the writer, and riveted the attention of his readers even where they failed to convince. As many years secretary and afterwards a vice-president of the Mathematical and Physical Section of the British Association, he read many short original papers on mathematical subjects at the meetings, but it is to be regretted that no record of most of these remains. In the last few months of his active work, Clifford published the first part of a text-book he had long contemplated, entitled the "Elements of Dynamic." Bursting the bonds of the old method of treatment of the subject by the cumbrous rectangular coordinates, which had been so uncongenial to him in his college days, he draws the student lightly and softly into the toils of quaternions, thus almost imperceptibly introducing this simple and powerful method of analysis; sad it is indeed that his failing health did not allow him to complete this work which would have long remained as a valuable record of his method of teaching. Soon after taking his degree he was elected to a fellowship at Trinity College, and filled the post of assistant-tutor until his election to the chair of Applied Mathematics and Mechanics at University College, London, in August, 1871, which he held until his death. He was elected a Fellow of the Royal Society, June, 1874.

A critical examination of the value of his mathematical labours cannot be attempted; few, indeed, could do justice to them; but it is to be hoped that it may not long remain undone. All that can be said in concluding this brief sketch of his short and brilliant life is to give expression to the regret so widely felt that it was so prematurely cut off. He was—some of his friends may think unfortunately—most generally known for his philosophical and polemical writings. That his fame will rest on no such narrow basis, the following list of papers from the Royal Society Catalogue abundantly testifies:—

1. "Analogues of Pascal's Theorem" (January, 1863), *Quart. Journ. Math.*, vi. 1863, p. 216.
2. "Jacobians and Polar Opposites," *Messenger Math.*, ii. 1864, p. 229.
3. "Analytical Metrics," August 30, 1864, *Quart. Journ. Math.*, vii. 1866, p. 54; viii. 1867, pp. 16, 119.
4. "On the Principal Axes of a Rigid Body," *Messenger Math.*, iv. 1868, p. 78.
5. "On the Theory of Distance," Brit. Assoc. Report, 1869, p. 9.
6. "On the General Theory of Anharmonics," Lond. Math. Soc., ii. 1869, p. 3.
7. "On a Generalisation of the Theory of Polars" (1868), Lond. Math. Soc., ii. 1869, p. 116.
8. "On some of the Conditions of Mental Development" (1868), Roy. Inst., v. 1869, p. 311.
9. "On Syzygetic Relations among the Powers of Linear Quantics" (1869), Lond. Math. Soc., iii. 1869-71, p. 9.
10. "On a Case of Evaporation in the Order of a Resultant" (1870), Lond. Math. Soc., iii. p. 80.
11. "On a Cononical Form of Spherical Harmonics," Brit. Assoc. Report, 1871, p. 10.
12. "Synthetic Proof of Miquel's Theorem," *Messenger Math.*, v. 1871, p. 124.
13. "On a Theorem Relating to Polyhedra Analogous to Mr. Cotterill's Theorem on Plane Polygons" (1872), Lond. Math. Soc., iv. 1871, p. 178.
14. "Geometry on an Ellipsoid" (1872), Lond. Math. Soc., iv. 1871, p. 215.
15. "Preliminary Sketch of Biquaternions," Lond. Math. Soc., iv. 1873, p. 381.
16. "On Mr. Spottiswoode's Contact Problems," Roy. Soc. *Proc.*, xxi. 1873, p. 425.
17. "Graphic Representation of the Harmonic Components of a Periodic Motion" (1873), *Messenger Math.*, iii. 1874, p. 153.

DAVID PAGE

FEW names have been more familiar to general readers in geology than that of this practised writer. Born in Fife, his early years were spent in literary work of an unambitious kind. Among other occupations he edited for a time a newspaper in his native county. There used to be a story told of his having temporarily edited also the opposition paper during its editor's absence, and having carried on a most lively warfare in the rival pages. Whether well-founded or not, the story shows the estimation in which he was held as a facile writer. He afterwards entered into the employment of Messrs. W. and R. Chambers, and for some years took an active part in the preparation of their comprehensive series of educational publications. It was while in this capacity that he wrote his first introductory text-book of geology—a little volume which had a large sale and proved singularly useful in diffusing an elementary knowledge of the science. It was also during Page's connection with the Messrs. Chambers that the celebrated "Vestiges of the Natural History of the Creation" appeared anonymously. Looking back upon this now half-forgotten and superseded volume, it is hardly credible that it should have excited such keen feeling and passionate controversy. Having been the production of more pens than one, it was never formally owned by any one of its several authors. Robert Chambers was always credited with the lion's share of it, but there can be little doubt that he had powerful assistance from Page.

Quitting the service of Messrs. Chambers, Mr. Page embarked on a career of successful authorship. He re-wrote his "Introductory Text-Book of Geology," and prepared an Advanced Text-Book on the same science. He likewise published manuals on Physical Geography, and from time to time issued various popular works on geological subjects. These were always well written. He had little original power as an observer, though some of his work, particularly among the crustaceans and fishes of the Upper Silurian and Lower Old Red Sandstones, shows considerable acumen, and raises a surprise that he should not have done more in that department. His great merit—and it is one which professed students in science, immersed in their own original inquiries, are apt to overlook and undervalue—was that he had the power of seizing on the leading features of scientific progress and discovery, and presenting them clearly and vividly before non-scientific readers. He has done good service in widening the circle of sympathy with research, and for this chiefly he deserves to be gratefully remembered by geologists. On the establishment of the Newcastle College of Physical Science, in connection with Durham University, he was chosen to lecture on geology. He had already, however, had premonitions of the paralytic affection which has at last proved fatal. He was eventually relieved of the duties of practically instructing his students in the field, this part of the work of the college being undertaken by Mr. Lebour. His failing health has for several years prevented him from appearing at the meetings of the British Association and elsewhere, as was his wont. He has at last been removed from among us in his sixty-fifth year.

NOTES

FIFTY-THREE candidates for the Fellowship are "up" at the Royal Society.

THE sum proposed in the Civil Service Estimates to be spent on the main fabric of the new Natural History Museum at South Kensington during the next financial year is 47,476*l.*, being the balance of a sum of 409,466*l.*, the "revise estimate" of the total cost of the erection of the building. It is also proposed to spend 20,000*l.* on "internal fittings." From the reply lately given in the House of Commons to Lord Arthur Russell, it seems that the Botanical and Mineralogical Departments will be transferred into the new building before the close of the year.

AT a meeting on March 7 at Cambridge of the general committee of the Darwin Memorial Fund, to decide whether the memorial should assume the form of a bust or a picture, and to select either the sculptor or painter willing to execute such memorial, it was stated that the funds promised amounted to over 400*l.*, which sum would be sufficient to procure either a bust or a picture. After some discussion it was resolved by a large majority that the memorial should take the form of a picture, and Mr. W. M. Richmond was selected as the artist to execute the same.

WE are informed that the committee appointed to receive subscriptions for presenting a bust of Mr. Wm. Spottiswoode, P.R.S., to the Royal Institution, as a testimonial of his valuable services as its treasurer and secretary successively, have engaged Mr. Richard Belt as the sculptor.

SINCE Parliament reassembled the finest example of practical telegraphy that has probably ever been witnessed has been going on between London and Ireland. Two news wires have been worked simultaneously and continuously between London, Dublin, Cork, Belfast, and Londonderry at the unprecedented speed of 130 words per minute. The Post Office authorities have recently been making very great improvements in their fast speed apparatus. The forthcoming International Conference and the success of the American quadruplex system are probably stirring them up to maintain their pre-eminence in this field. England cannot run second to any nation in telegraphy.

WE are greatly disappointed and much surprised to learn that the application of the Scottish Meteorological Society for assistance to establish an observatory on Ben Nevis has been rejected both by the Meteorological Council, with its yearly 15,000*l.*, and the Government Grant Committee, with its 5,000*l.* The former had other matters to attend to, the latter handed the application over to the Council of the Royal Society, labelled "highly commendable." We have recently shown our readers with what heartiness and cosmopolitanism such nationally beneficial undertakings are managed in France; yet in this disgracefully wealthy country, with 15,000*l.* a year expressly devoted to meteorology, a plan of promoting meteorological research that would lead to results of the highest consequence must collapse for want of a paltry 500*l.* to start it. It would be a shame if so really national an enterprise were to depend entirely on private subscription.

MR. MONCURE CONWAY proposes to hold a "Memorial Service" on the late Prof. W. K. Clifford at South Place Chapel, Finsbury, on Sunday morning next. After the service, Mr. Conway will deliver a discourse, taking Prof. Clifford for his subject.

IT is stated that the Botanical Exchange Club will have to be dissolved after the next distribution, in consequence of the difficulty of finding any one with the requisite critical knowledge of British plants and the leisure to enable him to perform the duties of curator. The club has been of great service in furnishing a medium of intercommunication between British botanists; and the annual reports of the curator have frequently been essays of considerable value. It is greatly to be lamented that one result of the increasing attention paid by botanists to the physiological side of the science should be the discontinuance of so useful an institution.

AT the annual meeting of the Geological Society, the Wollaston gold medal was awarded to Prof. Bernard Studer, "the father of Swiss geology;" the Murchison medal to Prof M'Coy, of Melbourne; the Lyell medal to Prof. E. Hébert, of Paris: the Bigsly medal to Prof. E. D. Cope, of Philadelphia; the balance of the Wollaston Donation Fund to Mr. Samuel Allport; the proceeds of the Murchison Geological Fund to Mr. J. W. Kirkby; a moiety of the balance of the proceeds of the Lyell Fund to Prof. Alleyne Nicholson, and the other moiety to Dr. Henry Woodward, F.R.S.

IT is stated that Capt. Sir George Nares, K.C.B., has been appointed to be the chief of the Harbour and Marine Department of the Board of Trade, in succession to Rear-Admiral Bedford. Sir G. Nares is now in command of Her Majesty's ship *Alert*, which is on a scientific cruise in the Straits of Magellan. Capt. J. F. L. P. Maclear has been appointed to the *Alert*.

A COMMITTEE has been organised to obtain subscriptions for erecting a statue to Nicephore Niepce, the inventor of photography. A circular has been published and will be sent to all scientific societies over the world.

THE movement for the propagation of electric lighting in Paris has not abated. A new paper entitled *La Lumière électrique* will be started in a few days under the editorship of M. de Parville. M. Regnier, the inventor of a lamp working by contact will begin experiments at Breguet's workshop. M. Ducretet is busy with his new lamp with a floating positive-carbon in mercury, and the Alliance Company will try Werdermann's on a large scale. The gas company and Jablochkoff are preparing to illuminate the spaces which have been allotted to them. Although the scientific question may be considered settled except under improved electrical conditions the Paris electricians are sanguine that the final verdict will not be given against the electric light.

THE experiments with the electric light recently made in the reading-room of the British Museum have satisfied the trustees of its applicability for the purposes of the room as far as the amount and distribution of light are concerned, although the full number of lamps was not employed. On three occasions the light was turned on at dusk, in order to enable readers to continue their studies without interruption for another hour. As far as could be ascertained they were enabled to work by it without difficulty, even at the tables where the light was weakest. The experiments are discontinued for the present, but a further trial of the light will probably be made some months hence, with the view to utilise it on dark days, and for extending the hours for using the reading-room in the winter.

THE Report by the Regius Keeper of the Edinburgh Botanic Garden for 1878 complains of the want of accommodation in various ways, and of the insufficiency of the present grant. These complaints are not now made for the first time, and we trust they will meet with speedy attention in the proper quarter.

RECENT explorations of the lake-dwellings of the Lake of Geneva prove that they were destroyed by fire during a spring, when the waters of the lake stood at the same level as now. A layer of charcoal from the burnt dwellings is to be found along the whole coast, beneath a layer of sand and gravel.

REMAINS of lake dwellings of the highest scientific interest have been discovered by members of the Donaueschingen Historical Society under the guidance of Dr. B. Spuren. The

dwellings are situated in the so-called Pfohrener Ried, near Donaueschingen. Numerous objects have been brought to light, such as remains of textures, and implements dating from the stone, bronze, and iron ages.

IN the present year the eighteen centuries will be complete, which have elapsed since Pompeii, Herculaneum, and some neighbouring cities were destroyed by a rain of ashes and torrents of lava from Mount Vesuvius. The directors of the excavations at Pompeii intend to commemorate the event in a scientific manner in November next, and have issued invitations to the most eminent Italian archæologists to participate in the celebration.

DURING the night of January 7-8, an earthquake was felt at Alaghir, Caucasus; it consisted of five shocks which had a direction from north to south. An earthquake visited Laibach on February 12. Two severe shocks were felt at 2.42 P.M. within about three or four seconds. The phenomenon was observed in the whole of Carniola and Lower Styria, also in some part of Carinthia and at Trieste. The direction of the undulations was from south to north, and they were preceded by loud subterranean noise; their duration was about five seconds. It is remarkable that this earthquake was observed in Southern Austria on the same day, as one of the Teplitz sources ceased to flow. On February 14, at 2.45 P.M., more shocks were observed at Laibach and Krainburg, but they were extremely weak. Subterranean shocks were also felt at Riva on the Lake of Garda on February 14, as well as at Bischofslaak in Carniola on February 16.

A REMARKABLE phenomenon is reported from Neufchatel. On February 10 the Lake of Neufchatel suddenly assumed a motion like the sea with its tides, only with the difference that the rise and fall of the water succeeded each other in much shorter intervals. The phenomenon began at noon and lasted until 2 P.M. Boys who were playing on the shore were so suddenly surprised by the rising lake that they were up to their knees in water before they had time to escape. In the evening there was a violent thunderstorm, which also visited Berne at the same time.

ROMAN antiquities have been recently discovered in the open space in front of the Votive Church at Vienna. The space is in course of transformation into a public garden. Among the objects found are some rare coins, toga clasps, urns, as well as the remains of tombs and of a bath.

IN the basin of the Teplitz Stadtbad, the recent stoppage of which has caused so much alarm in the charming Austrian watering-place, Roman coins and antiquities have been found. On one of the coins a female bust is represented with the circumscription "Sabina Augusta" (wife of the Emperor Hadrian, A.D. 117-138). The source must therefore have been well known to the Romans, and it is quite possible that even before the year 762, when it is first mentioned in Bohemian history, it may have temporarily ceased to flow. Besides the Roman coins, Bohemian and German coins (up to the year 1740) were discovered.

THE *China Overland Trade Report* mentions that a scheme is about to be carried out for establishing a woollen manufactory at Lanchow-fu, in North-Western China. Though Kansuh, the province of which it is the capital, is not populous, the locality has been chosen on account of raw material being plentiful in the neighbourhood. Machinery is said to have been already shipped from Europe, and two German gentlemen have been engaged to superintend the preliminary operations and to start the enterprise.

AT the last meeting of the St. Petersburg Society of Russian Naturalists, M. Grimm made a very interesting communication on the crustaceans of the Caspian Sea. The crustacean fauna of that sea has some likeness with the faunas of Lakes Baikal and Titikaki, especially as to the richness of both in amphipods, and as to the nearly total want of decapods. But the likeness is closer with the faunas of the European lakes, as well as with the faunas of the Black Sea, and yet more, with the Arctic Ocean and Lake Aral. Altogether, the study of the Caspian crustaceans proves that at a recent epoch the Caspian Sea was in connection with these lakes and seas, and that the connection of the Caspian with the Arctic Ocean and Lake Aral continued until a more recent period than the connection with the Black Sea.

AT the same meeting Prof. Bogdanoff proposed to the Society to undertake the publication of a work comprising all trustworthy data about the ornithology of the northern parts of Russia in Europe. The proposal met with great approval, and a commission consisting of MM. Bogdanoff, Polyakoff, Pleske, and Keppen, was appointed for the preparation of the said work.

AT the last meeting of the Paris Geographical Society, a communication was read by M. Sconzac, a French officer, belonging to the Chinese service on the origin and propagation of the Russian plague. The lecturer contended that this epidemic originated in the province of Yunan, and was carried by travellers *viâ* Mesopotamia. The lecture will be published *in extenso* in the Society's *Bulletin*.

A VERY satisfactory report was presented at the recent annual meeting of the Royal Microscopical Society, which has now been in existence forty years. The members number 437, and the funds are in a flourishing state.

VOL. VII., part 1, of the *Proceedings* of the Yorkshire Geological and Polytechnic Society contains a number of important papers on local geology, and one or two of more general interest.

IN the just issued number of the *Proceedings* of the Geologists' Association is the continuation of Mr. W. H. Huddleston's valuable paper on the Yorkshire oolites, while Prof. Bonney contributes some interesting observations on the igneous rocks of Arthur's Seat.

M. FERRY, the new French Minister of Public Instruction, has visited the Sorbonne, the School of Medicine, and other buildings devoted to science, for the purpose of deciding what repairs must be done immediately.

THE Swiss Palæontological Society has just published the fifth volume of its *Abhandlungen*, which contains several valuable papers. Prof. Rütimeyer gives the conclusion of his most interesting researches into the deer of the tertiary period. Prof. P. de Loriol continues his researches into the Swiss fossil crinoids, and gives the conclusion of a very valuable monograph on the fossils of the Baden formation, a subdivision of the recent Jura formation. Dr. Wiedenheim publishes for the first time a complete description of the *Labyrintodon rütimeyeri*, discovered in 1864 in the sandstone of Rieben, at Basel, and M. J. Bachmann describes the fossil eggs from the neighbourhood of Lucerne. Twenty-five fine coloured plates illustrate the papers. The Society was founded in 1874, with statutes and aims much like those of the British Palæontological Society, especially for the study of Swiss palæontology; and the five volumes already published by the Society contain a great diversity of very valuable papers by Professors Rütimeyer, in Basel, De Loriol, in Geneva, and Renevier, in Lausanne.

THE Swiss meteorological stations have adopted a system of weather warnings. All the territory of Switzerland will be divided for that purpose into eight regions, each of which will have its central station. The information on the state of weather

in Europe, received at these stations, will be graphically represented on maps, and these maps will be exhibited between four and five P.M. at a central point of the town, under glass, for public use. Besides there will be given a prognostic of weather for the following day; and this information will be sent to each commune and person who will pay monthly the sum of 15 francs. This system is already introduced in Zurich and Berne, and the prognostics are correct in eight cases out of ten.

WE have received from Mr. Downing, of Whiskin Street, a neat little cabinet of twenty specimens of rocks, fossils, and minerals to illustrate Geikie's *Geology Primer*. Considering the number and quality of the specimens, and their suitability for the purpose, the cabinet is a wonder of cheapness, and ought to have a wide sale.

IN view of the apparently insurmountable difficulties which attend the completion of the New National Opera House on the Victoria Embankment, the *Globe* understands that all the agents-general for the different colonies have entered into negotiations for the purpose of securing this site for the proposed Colonial Museum.

INTERESTING correspondence has appeared in the British Guiana *Royal Gazette*, we learn from the *Colonies and India*, relative to the qualities assigned to the fruit of the papau-tree. It has been recently asserted, in an article in the *Pharmaceutical Journal*, "that the most interesting property attributed to it is the power of its juice to render bad flesh tender." Mr. Monro, of Georgetown, furnishes certain facts which he says are commonly known to the natives of British Guiana relative to this fruit. A horse tied near one of these trees rapidly loses health, and a stud horse becomes useless. Any pressure on the body of the animal leaves an inelastic indentation. The sap of the tree will soften steel, and before the process of tempering was known in the Colony, the blacksmiths used to drive their brittle chisels and plane vices into the wood, leaving them there for a day or two; and tough meat wrapped in the leaf for only a few minutes becomes tender, and the same thing happens if it be suspended against the tree itself. The seed of the ripe fruit is an excellent vermifuge, and children have a great partiality for it.

IN a recent paper in the *Journal de Physique* complementary of the theory of dew, M. Jamin points out that moist surfaces are subject to two superposed causes of cooling, one radiation (like dry substances), the other evaporation. The difference between the two actions is that the former persists at every temperature, while the latter, at first considerable, decreases and becomes *nil* when saturation is reached (it does not produce dew, but contributes to prepare and accelerate it, for it renders the air both moister and colder). The quantity of heat borrowed from the air by evaporation is very considerable: 1 gramme of evaporated water lowers about one degree the temperature of 2,553 grammes of air (or nearly two square metres' volume). Thus is explained how moist bodies, like plants, especially herbaceous, are cooled much more quickly than dry bodies. The dew forms on them more quickly; once it has commenced it continues by the sole effect of radiation. In driving rapidly down from a plateau into a valley one is often struck with the sudden cold. This cold is probably the effect of more rapid evaporation from the herbs, aquatic plants, and all moist surfaces of the valley. Other facts illustrate the double effect of radiation and evaporation, *e.g.*, the danger of plants in early spring after being moistened by a shower, and the well-known mode of manufacture of ice in Bengal. The *rôle* of dew is that of moderating and sometimes arresting the nocturnal cooling, and preserving plants from the early frost.

AN interesting lecture on certain enigmatical phenomena of astronomy has been recently delivered by M. Houzeau before the Belgian Academy of Sciences, of which he is president. The points he takes up are, the apparent enlargement of heavenly bodies near the horizon (not adequately explained by a weakening of the rays, or interposition of terrestrial objects); the supposed satellite of Venus, observed seven times in 119 years, by eminent astronomers, but quite unobserved during the 114 years since; the phenomena connected with Biela's comet; the effects of the earth encountering a comet (may such a thing occur? has it occurred?); and the zodiacal light. The lecture appears in the Academy's *Bulletin* (No. 12 of 1878).

WE have on our table the following books:—"Text-Book of the Steam Engine," T. M. Goodeve (Crosby, Lockwood, and Co.); "The Aborigines of Victoria," 2 vols., R. Brough Smith (Trübner); "Report of the British Association for the Advancement of Science, 1878," Dublin (Murray); "The Circle and Straight Line," John Harris (Wertheimer, Lea, and Co.); "Moore's Columbarium," reprinted by W. B. Tegetmeier (*Field* Office); "Practical Treatise on the Manufacture of Sulphuric Acid," A. G. and C. G. Lock (Sampson Low and Co.); "Atlas of Histology," Part i., E. Klein and E. N. Smith (Smith, Elder, and Co.); "Geologische Uebersichtskarte des Tyrolisch-Venetianischen Hochlandes zwischen Etsch und Piave," 6 Maps, Dr. Edmund Mojsisovics, (Vienna: A. Holden); "Die Dolomit-Riffe, von Sudtirol und Venetien," Heft i. to vi., E. V. Mojsisovics (Vienna: Alf. Holden); "Meteorological Observations made at the Adelaide Observatory, years 1876 and 1877," Ch. Todd; "Journey through Khorassan," 2 vols, Col. C. M. M'Gregor (Allen and Co.); "Lakes and Mountains of Africa," J. F. Elton (Murray); "On the Annelida Chætopoda of the Virginian Coast," H. E. Webster; "Fécondation des Fleurs," E. and G. Gevaert (G. Mayolez).

THE additions to the Zoological Society's Gardens during the past week inclnde three Japanese Deer (*Cervus sika*) from Japan, presented by the Viscount Powerscourt, F.Z.S.; a Syrian Bear (*Ursus syriacus*) from West Asia, presented by Dr. J. Huntley; a Green Monkey (*Cercopithecus callitrichus*) from West Africa, presented by Miss E. A. B. Payton; a Pig-tailed Monkey (*Macacus nemestrinus*) from Java, presented by Mrs. J. E. Fenton; a Coati (*Nasua nasica*), an Acouchy (*Dasyprocta acouchy*) from British Guiana, two Mountain Finches (*Fringilla montifringilla*), British Isles, purchased.

SCIENCE IN RUSSIA

WE take from the just issued Annual Report of the St. Petersburg Academy of Sciences for 1878, the following information as to the work done by the Academy during the year in the mathematical and physical sciences.

Prof. Chebysheff has continued his researches into the properties of parallelograms which consist of three elements, and are symmetrical with respect to one axis, these researches already having led him to important results; among them we notice his general formula for determining what are the simplest combined systems which, when set in motion, give a straight line.

Prof. Minding has published two papers, one of which is an important addition to his former researches on curves.

The Pulkova Observatory has published the ninth volume of its Memoirs, which contains the micrometrical measurements of double stars by Prof. O. Struve, during forty consecutive years. The value of these very numerous and precise measurements is much increased by the circumstance that they were made during so long a period by the same person, with the same instruments, and on the same methods; the comparison of M. Struve's observations with those of several known astronomers affords a means of reducing all of them to one system.

The transit of Mercury was observed at Pulkova with fourteen telescopes. It is worthy of notice that the observations proved that Mercury does not have such a dense atmosphere as that discovered around Venus.

The interesting researches of the late Prof. Asten into the

motion of the comet of Encke were already well prized by all men of science. The *Memoirs* of the Academy contain this year a new work by Prof. Asten, on all the appearances of that comet from 1819 to 1875. M. Asten has published also new ephemerides of the comet for this year, and their precision was already proved by the numerous observations made in the southern hemisphere. Unhappily he could not see this brilliant confirmation of his researches, death having taken him from the ranks of men of science.

Prof. Bredikhine was engaged in very interesting researches into the tails of comets, and he established that there are three quite different kinds of tails, according to the different relations between the attractive and the dispersive force of the sun, which last is modified by the different properties of the particles of which the tail is formed. Spectral analysis will probably confirm this hypothesis.

As to spectral analysis in its application to heavenly bodies, the report states that it is not based, as yet, on sufficiently positive data, and that to elaborate these data with the accuracy usual to other astronomical observations, is the special aim of the astro-physical department of the Pulkova Observatory. Thus M. Hasselberg has published two works, one of which reduces the observations of Kirchhoff to wave-lengths, and the other deals with a precise description of the spectra of absorption of NO_2, and bromine. The same author has recently proved that the displacement of spectral lines does not depend upon the density of the gas.

Observations on the variations of luminosity of stars were pursued by M. Lindemann, who has added 42 other stars to the 280 variable stars, included in the catalogue of M. Sjölerup. Prof. Savitch has made observations on oppositions of planets and on the transit of Mercury. He has also read at the Academy a paper on corrections on the pendulum of Repsold. Finally, we notice the observations of M. Njuren on earthquakes, as noticed by vibration of the sensitive levels of astronomical instruments.

In physical science the report begins with the work of the Central Physical Observatory at St. Petersburg. The Director of the Observatory, Prof. Wild, has a memoir on the determination of the real temperature of the air by a thermometer, and on the precautions to be taken for avoiding various secondary influences on the instrument, especially those of radiation. Thermometers which allow the determination of the temperature of the air with a precision of one-tenth of degree, have already been introduced into Russian meteorological stations. Besides, Prof. Wild has proposed very satisfactory improvements in the siphon barometer which allow easily the transportation of the barometer dismounted, without changing its error, and thus afford a means for comparing with great accuracy the normal barometers of different stations. After having given, during the preceding years, special attention to terrestrial magnetism, the Central Physical Observatory has occupied itself with atmospheric pressure, and Capt. Rykatcheff has published a paper on the diurnal changes of barometrical pressure, based on the observations of eleven Russian and twenty-four foreign stations. The theory for explaining the diurnal changes of pressure, proposed by M. Rykatcheff, seems to be more probable than that of Dove, usually accepted until now. Among other meteorological papers, published by the Academy, there are worthy of notice those by Prof. Lenz, on the Galvanic Resistance of Solutions of Salts of Kalium, Natrium, and Ammonium; by Capt. Rykatcheff, on Winds on the Baltic; by M. Dorandt, on Anemometers; by M. Hellmann, on the Comparison of the Normal Barometers at St. Petersburg, Helsingfors, Dorpat, Stockholm, and Upsala; and by M. Stelling, on the Intensity of Day-Light at St. Petersburg.

In chemistry Prof. Menshutkin has continued his researches on the Influence of the Isomerism of Alcohols and Acids on the Formation of Compound Ethers; and the Report notices among the chemical papers which have appeared in the publications of the Academy, those by Mrs. Lermantoff, on the Influence of the Tertiary Sodic Butyl on Isobutylene, and by M. Paoloff and Jawein, on Organic Chemistry.

In geology the year 1878 is marked by the appearance of the most important work, by Prof. Frederick Schmidt, on Silurian Trilobites of the Eastern Coasts of the Baltic, being the result of twenty years' researches, and of a thorough comparison of Russian trilobites with those of other countries. The work will contain the description of about 140 species; the first fascicule, actually in the press, contains a general description of the silurian rocks in the governments of St. Petersburg and Esthonia. Prof. Meller has described the collections brought from the Manyeh by M. Danilcosky, and has proved the former extension of the Caspian very near to the Sea of Azov.

In botany the first place is occupied by the work on the Algæ of the White Sea, by M. Gobi. Prof. Famintzin has continued his researches into the embryology of plants, and by means of preparations made on the method of Nestermeyer, he has arrived at important results as to the formation of tissues in the embryons of plants. M. Klinge has made very interesting histological researches on roots of several Monocotyledons.

In zoology Prof. Brandt has published important additions to his former work (appeared in 1877) on the Rhinoceroses, living and extinct. But the most interesting of his works is certainly that on the Elasmotherium. Judging by the few teeth, found until now, of this extinct mammal, which formerly inhabited Europe from the Rhine to the Kirghiz Steppes, Prof. Brandt had described the elasmotherium as a form of the family of rhinoceros, but very near akin to the horse. A complete skull of this animal, which was recently found at Sarepta, on the Volga has quite confirmed the opinions of this zoologist. The elasmotherium is most nearly related to several kinds of rhinoceros, having at the same time several features common with the horse, and forms a separate sub-family of rhinoceros; he lived at the same time as the bison, the rhinoceros, tichorhinus and man. Prof. Kessler gives interesting descriptions of new fishes from Central Asia. M. Mereshkofsky has explored the sponges of the White Sea, and M. Boetger is publishing an important monograph on the *Clausiliæ*. Finally, the Report mentions the works of Prof. Ovsiannikoff on the anatomical structure of the cerebrum of the dolphin and other vertebrata, and the papers by Prof. Gruber, on variations of the muscles and the bones of man.

In the report of the historico-philological section of the Academy we mention the works of Prof. Dorn on inscriptions in the Pelegvian language and on the Semnan language, a now nearly extinct branch of the Iran branch; and memoirs, by Prof. Schiffner, on Buddhism; and by Prof. Wideman, on Finnish languages, namely, of that of Zyryans.

As to the premiums awarded by the Academy, those bearing Lomonosoff's name, for works in chemistry, physics, and mineralogy, and Buniakofsky's, for works in mathematics, were not awarded this year. A new premium, bearing the name of Helmersen, was founded this year for works in geology.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

PROF. JAMES STUART'S efforts to develop a school of Applied Science at Cambridge, have produced further fruit in the shape of a report of the Board of Mathematical Studies, recommending an alteration in the scheme of examination in mechanism and applied science for the ordinary B.A. degree. It is proposed now that papers on mechanics and on heat shall be obligatory on all candidates, while they shall choose one only of three other subjects, viz., (1) Mechanism. (2) Theory of Structure, Strength of Materials, and Principles of Surveying and Levelling. (3) Electricity and Magnetism. The examination is to be made as far as possible a satisfactory basis for a professional career by its practical character. Thus every candidate will be required to show his ability to write an accurate description or specification of an instrument, machine, or model exhibited, and to make a working sketch to scale. Evidence of actual capacity to use the tools or instruments belonging to the subject selected by the candidate will be demanded. The first class in the class list is to consist only of those who have distinguished themselves in one of the three alternative subjects. We do not doubt that it will soon be realized that a student who has to pass an examination in Greek and Latin in his second year will not have time to master his Science subjects by the end of the third. There will be much more chance of attracting students of Applied Science to Cambridge if they are excused from the classical portions of the "General" Examination for the ordinary degree.

IN the new scheme for the Classical Tripos at Cambridge, the advanced portion will include several groups of subjects, of which one only is to be selected by a candidate. Three of these groups are History, Archæology, and Language, and the knowledge and treatment required will be thoroughly scientific in character. Archæology will include papers on Greek and Roman

mythology and religion, on topography and monuments, and on art and handicraft and the inscriptions of the Greeks and Romans, in relation to their domestic and national life. The Language group will include elementary Sanskrit, the comparative grammar of the Indo-European languages, and the history of alphabets.

FORTUNATELY the demands of science are sometimes so urgent, that they cannot be resisted, as in the case of the School of human anatomy at Cambridge, which has so outgrown its accommodation that a new dissecting room must be immediately provided, pending the expected erection of really adequate buildings for the medical schools some years hence. There are sixty students dissecting this winter, under Dr. Creighton, and several assistant demonstrators. In the interests of health and education, a large room is to be built over the present lower rooms at a cost of 600*l*., which will supply the pressing need of space.

IT is satisfactory to learn that physical science will be represented among the three representatives of Trinity College sitting with the Cambridge University Commissioners, by Mr. Trotter, who has taken a very influential part in framing the new statutes of his college, and that Prof. Bonney is one of the representatives of St. John's College. We wish that we might hear that other colleges sent equally accredited men of science to strengthen the cause of physical science before the commissioners.

A VACANCY having occurred in the professorship of botany at the University of Innsbruck by the transference of Kerner to the important chair at Vienna as successor to Fenzl, Dr. Peyritsch, director of the botanic garden at Vienna, has been appointed to the professorship at Innsbruck.

THE Zurich University has just granted the diploma of Doctor of Philosophy to Miss Helene Druschkovitsch, from Vienna, after a brilliant defence of her dissertation on the "Don Juan" of Byron.

THE Geneva University numbers 391 students, of whom 208 are not matriculated. Out of the 391 students 212 are Swiss, and the others are strangers; there are forty-five ladies, of whom five, Russian, are matriculated.

SCIENTIFIC SERIALS

Zeitschrift für wissenschaftliche Zoologie, vol. xxxii., part 1. —J. Brock on the sexual organs of cephalopoda, first memoir, dealing with sepia, loligo, sepiola, eledone, pp. 116, 4 plates. F. E. Schultze, researches on sponges, sixth part, the genus spongelia, 41 pp., 4 plates.—L. Löwe, on the anatomy of the gills of serpula, 30 pp., 1 plate.

Morphologisches Jahrbuch, vol. iv. part 4.—Contribution to the anatomy and histology of the sexual organs of osseous fishes, by J. Brock, Erlangen, 68 pages, describing very many forms, 2 plates, with figures from eleven genera.—The folds of the mucous membrane in the human palate, by C. Gegenbaur, with 1 plate, giving a comparison between the palatal markings of human fœtuses and those of the orang, cercopithecus, and ateles. —On the female sexual apparatus of *Echinorhynchus gigas*, by A. Andres, 1 plate.—The extensor muscles of the calf and foot of mammals, by G. Ruge, a very extensive inquiry, 52 pages, 4 plates, followed by another from the same author on the deep muscles of the sole of the foot, with 2 plates.—On *Labyrinthodon Rütimeyri*, by R. Wiedersheim.—On the homology of segmental organs in annelids and vertebrates, by Max Fürbringer.

Kosmos, November.—On Bacon of Verulam, the founder of modern realism, by Fritz Schultze.—The origin and evolution of sensory organs (eye and ear), by Ernst Haeckel.—Colour in animals and plants, by A. R. Wallace, translated from the English.—On the political constitution in primitive grades of culture, by M. Kulischer.—Report of the meeting of the German Anthropological Society.

December.—On the discovery of the soul, by G. Jäger.—Colour in animals and plants, by A. R. Wallace, concluded.—The elasmotherium of the diluvium.

January.—Philosophic reflections on the nebular hypothesis, by Carl du Prel.—The mathematical basis of the structure of the plant body, by Dr. S. Gunther.—Dissimilarity between the male and female of *Epicalia acontius* by Fritz Müller.—Primitive constitution; part 2, federation, by M. Kulischer.

THE *Bulletin de l'Académie impériale des Sciences de St. Pétersbourg* (t. xxx. No. 3) contains the following papers of interest:—On an application of the finite differential calculus, by F. Minding.—On some extraordinary muscles, tensores fasciæ suralis, in man, by Dr. W. Gruber.—On a new species of ossiculum supernumerarium carpi in man, by the same.—Palæontological observations regarding M. Danilewsky's journey to the Manytsch, by V. Möller.—Supplementary observations to a monograph of the *Rhinoceros tichorhinus*, by J. F. Brandt.—New researches on the ichthyology of Central Asia, by K. Kessler.—On the tail of comets, by M. Bredikhine.

THE *Sitzungsberichte* of the Vienna Academy of Sciences (Physical, Chemical, and Astronomical Section, vol. lxxvi. parts 2–5, vol. lxxvii. parts 1–3) contain the following papers of interest:—On some maxims and proofs of the theory of the resultant, by Dr. B. Igel.—On a relation corresponding to the linear differential equations of the second order, by Dr. A. Winckler.—Researches on the componnds of the camphor group, by J. Kachler.—On the state of heat equilibrium of a system of bodies with reference to gravitation, by J. Loschmidt. —On a new radiometer, by Dr. J. Puluj.—On the substances found in crude anthracene, by Dr. O. Zeidler.—On the behaviour of camphor towards chloral hydrate, by the same.—On the orbit of Loreley (165), by Dr. G. Gruss.—On the behaviour of acetylene towards concentrated sulphuric acid, by S. Zeisel.—Researches on the heat-conducting capacity of cotton, sheepswool, and silk, by J. Schuhmeister.—On the action of ammonia upon isatine, by Dr. E. von Sommaruga.—On idryl, by Dr. G. Goldschmiedt.—On the action of hydrochloric acid upon resorcine, by L. Barth and H. Weidel.—On the behaviour of certain resins and resinous acids when distilled over zinc dust, by G. Ciamician. On the smallest absolute number of sound impulses which is necessary for the production of a tone, by Prof. Pfaundler.—Report on Egger's electro-magnetic motor, by Prof. R. Handmann.—On the stand-aneroid-barometer, by Dr. Anton Schell. —On citramalic acid, by Th. Morawski.—On the temperature of Vienna, deduced from observations during a century, by Dr. J. Hann.—On a partial differential equation of the first order, by Dr. Franz Hocevar.—On the connection of n different straight lines in a plane, and certain other mathematical maxims, by S. Kantor.—On the magnitude and position of the optical elasticity axes in gypsum, by V. von Lang.—On mononitropyrocatechine, by Dr. R. Benedikt.—On some problems in the theory of elastic after-effects, and on a new method of observing oscillations by means of mirrors, without incumbering the oscillating body with a mirror of considerable mass, by Dr. L. Boltzmann.—On the orbit of Laurentia (162), by K. Zeller.—On the application of Doppler's principle on the progressing motion of luminous gas molecules, by Prof. Pfaundler.—On some mathematical maxims relating to cone projections, by E. Weyr.—On the chemical nature of peptone and its relation to albumen, by Dr. E. Herth.—On the barometrical pressure at Vienna, by Dr. J. Hann.—On a new apparatus for the direct volumetric determination of the moisture of the atmosphere, by Prof. Fr. Schwackhöfer.—On the heat-capacity of mixtures of methylic alcohol and water, by E. Lecher.—On the electric after-currents of transversely magnetised iron rods, by Prof. H. Streintz.—On the velocity of transmission of spark-waves, by E. Mach, O. Tumlirz, and C. Kögler.—On the behaviour of propylglycol at a high temperature, by E. Linnemann.—On the direct transformation of isobutyl iodide into trimethylcarbinolamine, by B. Brauner.—On the artificial malic acid made from fumaric acid, by F. Loidl.—On Maxwell-Sympson's synthesis of acroleïne from acetone diiodide, by Dr. O. Voelker.—On the behaviour of β bibromopropionic acid towards iodide of potassium, by V. von Zotta.—Determination of the orbit of comet II 1874, by E. Wenzel.—On Ampère's electrodynamic fundamental experiments, by A. von Ettingshausen.—On bixine, by C. Etti.—On the decomposition products obtained by fusing hydrate of potash with an ammonia gum resin from Marocco, by Dr. G. Goldschmiedt.—On the action of bromine upon phenoldisulphonic acid, by M. von Schmidt.—On the construction of tangents to a rotation plane, by H. Drasch.—On some oxidation products of protocatechic acid, by Dr. M. Gruber.—On trisulfoxybenzoic acid, by Dr. M. Kretschy.—On the variation tone observed by Dvorak, by A. Haberditzl.—On the reduction of ellagic acid by means of zinc dust, by L. Barth and G. Goldschmiedt.—On a fluorescine-carbonic acid, by Dr. J. Schreder.—On the galvanic polarisation of platinum in water, by Franz Exner.—On trinitro- and trinitrophloroglucine, by Dr. R. Benedikt.—On the determination of the focus of the outlines of planes of the second degree, by C. Pelz.—On a synthesis

of pimelinic acid, by A. Bauer and J. Schuler.—New experiments to test Doppler's theory on the change of tone and colour by motion, by E. Mach.—On the magnetic declination and inclination at Vienna, by J. Liznar.—On the component parts of coralline and their relation to the colouring-matters of the rosaniline group, by C. Zulkowsky.—On the diffusion of carbonic acid by water and alcohol, by J. Stefan.—On the electromotive power of metals in the watery solutions of their sulphates, nitrates, and chlorides, by Dr. F. Streintz.

THE *Sitzungsberichte* of the Vienna Academy of Sciences (Physiological and Anatomical Section, vol. 76, parts 1-5) contain the following papers:—Observations on the origin of the cell nodule, by S. Stricker.—On the nerves of the cornea and its vessels, by Dr. L. Königstein.—On the properties of dialysed albumen, by Dr. M. Laptschinsky.—On the occurrence of two different knots of vessels in the kidney, by Dr. O. Drasch.—On some peculiar products of mycotic keratitis giving the amyloid reaction, by Dr. A. Frisch.—On the chemical reaction of the retina and the visual nerve, by Dr. A. Chodin.—On the laws of nerve irritation, by Dr. E. v. Fleischl.—On the termination of the olfactory nerves, by S. Exner.—On optional and cramp movements, by E. Brücke.—Researches on the perception of locality and its relation to the idea of space, by S. Stricker.—On the anatomy of the thalamus opticus and its surroundings, by Dr. F. Schnopfhagen.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, March 6.—"Preliminary Report upon the *Comatulæ* of the *Challenger* Expedition." By P. Herbert Carpenter, M.A., Assistant Master at Eton College. Communicated by Sir Wyville Thomson, F.R.S. Published by permission of the Lords Commissioners of the Treasury.

The collection of *Comatulæ* made by the staff of the *Challenger* includes specimens from 45 different localities, but few of which are deep-water stations. *Comatulæ* were only obtained seven times from depths exceeding 1,000 fathoms.

At lesser depths, 200—1,000 fathoms, *Comatulæ* were met with at 13 stations; but by far the greatest number both of species and of individuals were dredged at depths much less than 200 fathoms, and often less than 20 fathoms, at 26 widely distant stations.

The collection contains 111 species, mostly new; but as the work of examination and description progresses, it is not unlikely that forms now considered different may turn out to be merely local varieties of one and the same species, so that the number given above may be subject to alteration.

Of these 111 species, 59 belong to the genus *Antedon*, 48 to *Actinometra*, 1 to *Ophiocrinus*, and 3, which are peculiar in having ten rays to the calyx instead of only five, to a new genus for which is proposed the name *Promachocrinus* (*πρόμαχος Challenger*).

The distribution of *Promachocrinus* is as follows:—

P. Kerguelensis (20 arms).	Balfour Bay, Kerguelen,	20—60 fath.
	Royal Sound ,,	28 fath.
	Cape Maclear ,,	30 ,,
	Heard Island	75 ,,
P. abyssorum (10 arms).	Station 147	1,600 ,,
	,, 158	1,800 ,,
P. Naresii (10 arms).	,, 214	500 ,,

Ophiocrinus was obtained at four localities at depths varying from 565 to 1,070 fathoms, two in the South Pacific off South Australia and New Zealand respectively, and two in the North Pacific, one off Japan, and one just north of the Philippine Islands. All the specimens belong to one species, which is by no means so slender and graceful as Semper's Philippine species from shallower water, but has a much more massive arm skeleton.

The comparative distribution of the other *Comatulæ* is very striking. Relatively speaking, *Actinometra* is extremely limited in its range, both geographical and bathymetrical. It is almost exclusively a tropical genus, its northern limit being about 30° N. lat. and its southern 40° S. lat. Isolated species are known from the Cape of Good Hope, Natal, South Australia, and Port Jackson, but its chief home is Oceania, especially the Philippines and Moruccas. A few *Actinometra* species are also known from the west coast of the Atlantic, as South Carolina, the West Indies, Bahia, and St. Paul's Rocks.

The bathymetrical limit of *Actinometra* is likewise very slight. Nearly all the *Challenger* species are from depths less than 20 fathoms, while only three come from a greater depth than 100 fathoms. The individual species of *Actinometra*, like the genus itself, are very local in their distribution. Each of the forty-eight species of the *Challenger* collection has its own locality.

With *Antedon*, however, the case is different. Not only do nearly all the deep-sea *Comatulæ* belong to this genus, but some species of it have a fairly wide range. *Ant. rosacea* ranges from the north of Scotland to the Mediterranean, while *Ant. Eschrichtii* is found over a much wider area. It is well known on the American coast, and was dredged by the *Challenger* off Halifax, while the *Porcupine* met with it in the "cold area" of the North Atlantic.

Some *Antedon* species occur in duplicate from different localities. Two species from near the Kermadec Islands (S. 170), also occur in the neighbourhood of the Fijis (S. 174, 175). A third species was dredged at Stations 147 and 160, two localities in the Southern Sea, in nearly the same latitude, but separated by almost 90° of longitude. A fourth species came up from 1,070 and 775 fathoms, off the Admiralty Islands and Japan respectively.

The above facts would seem to show that, with few exceptions, the geographical range of the individual members of the family *Comatulidæ*, is exceedingly limited, nearly every species having its own locality, and that not a very extensive one.

The voyage of the *Challenger* has settled a curious question in connection with the Crinoids, the origin of which is due to Lovèn. It refers to *Hyponome Sarsii*, a so-called recent Cystid, which turns out to be nothing more than the disk of a *Comatula*, minus its skeleton. The anambulacral plating may be very extensive, forming a complete pavement over the ventral surface of the disc as in many *Pentacrini*; and the ambulacra are not wide and open as is usual in most *Comatulæ*, but almost entirely closed by the approximation of the marginal leaflets at their sides, so that the food-grooves radiating from the mouth are converted into tunnels.

The plates in the marginal leaflets are probably movable as unplated leaflets are in *Antedon rosacea*; so that they can be erected when the arms are spread out, leaving the grooves open for food particles to travel towards the mouth. On the other hand, when the arms are all contracted over the disk, the marginal plates fold over the grooves and cover them in. This is the condition of most spirit-specimens, but it is not in any way comparable to that of the palæozoic crinoids, in which the mouth is truly subtegminal while the ambulacra become real tunnels beneath the upper surface of the vault.

Sections through one of these plated *Hyponome*-disks show that all the various structures which underlie the grooves of ordinary *Comatulæ* are present and exhibit their usual characters.

The examination of the *Challenger Comatulæ* has entirely confirmed the opinions held by Dr. Lütken and the author respecting the distinguishing characters of *Antedon* and *Actinometra*. Both agree in referring forms with a (sub) central mouth, five equal ambulacra, and no terminal comb on the oral pinnules, to *Antedon*. On the other hand, species with an eccentric mouth, a variable number of unequal ambulacra, and a terminal comb to the oral pinnules, belong to *Actinometra*.

It will be seen at once that these characters are of no use in distinguishing the genera of fossil *Comatulæ*. But, there are very considerable differences in the shape of the radials and centrodorsal piece in *Antedon* and *Actinometra* respectively, and as these are exactly the parts which are most met with as fossils, the generic determination of a fossil form is almost as easy as that of a recent one, which has given up its disk to produce a *Hyponome*. The author has shown elsewhere that in *Act. polymorpha* and *Act. solaris*, half, or even more than half, of the arms may have neither ventral groove, tentacles, ambulacral epithelium, nor ambulacral nerve. No less than 23 out of the 48 species of *Challenger Actinometræ* may have more or fewer of such ungrooved arms, in which the ambulacral nerve is entirely absent. These arms are usually those which come off from the hinder part of the disc, but in one gigantic Philippine species with over 100 arms, there are several ungrooved arms on each radius. Evidence of this negative character appears to the author to be a serious objection to the German view, that the ventral bands constitute the sole nervous apparatus of the crinoids; and on the other hand, to strengthen the opinions held by Dr. Carpenter, and by the author, that the axial cords of the skeleton are also nervous in character.

"Observations on the Physiology of the Nervous System of the Crayfish (*Astacus fluviatilis*)," by James Ward, M.A., Fellow of Trinity College, Cambridge. Presented by Michael Foster, M.D., F.R.S., Prælector of Trinity College, Cambridge.

The experiments, of which this paper gave a brief account, consisted mainly in severing (1) one or (2) both of the supra-œsophageal commissures, (3) both the sub-œsophageal commissures, or (4) in dividing the supra-œsophageal ganglia longitudinally. From these experiments it was inferred:—

(*a*) That there is no decussation of the longitudinal fibres in the nervous system of the crayfish.

(*b*) That on the presence of the supra-œsophageal ganglion depend (1) the spontaneous activity of the animal as a whole, or what might be called its volitional activity; (2) the power to inhibit the aimless and wasteful mechanical activity of the lower centres; (3) the power to maintain equilibrium; and (4) the use of the abdomen in swimming.

(*c*) That the sub-œsophageal ganglion is the centre for co-ordinating (1) the locomotive, and (2) the feeding movements, and (3) for a peculiar rhythmic swing of the limbs seen as soon as the supra-œsophageal ganglia are removed, and (4) is the source of a considerable amount of motor energy.

(*d*) That there is much less solidarity, a much less perfect *consensus*, among the nervous centres in the crayfish than in animals higher in the scale. The brainless frog, *e.g.*, is motionless, except when stimulated, and even then does nothing to suggest that its members have a life on their own account; whereas the limbs of a crayfish deprived of its first two ganglia, are almost incessantly preening, and when feeding movements are started, the chelate legs rob, and play at cross purposes with, each other as well as four distinct individuals could do.

(*e*) That some stimulus from other centres is more or less necessary to the activity of any given centre.

(*f*) The "natural" discharge of a ganglionic centre (not exhibiting "volition") appears to be of a rhythmic kind; the rhythmic movements becoming converted into varied movements by temporary augmentation or inhibition.

Zoological Society, March 4.—Prof. W. H. Flower, F.R.S., president, in the chair.—Mr. Sclater exhibited and made remarks on examples of two rare Fruit Pigeons, of the genus *Carpophaga*.—Mr. L. M. D'Albertis exhibited some new and rare birds, obtained during his recent expedition up the Fly River, New Guinea.—Prof. Newton exhibited, on behalf of Mr. J. Robinson, of Trinity Hall, Cambridge, a specimen of *Sylvia nisoria*, believed to have been killed at Cambridge many years ago.—A communication was read from Mr. L. Taczanowski containing a list of the birds collected by Messrs. Stolzmann and Jelski, in Northern Peru in 1878. Fifty-six species were enumerated, several of which were new to science.—Mr. R. Bowdler Sharpe, F.Z.S., read some notes on birds obtained on Kina-Balu Mountain, in North-Western Borneo, by the collectors of Mr. Treacher, amongst which were several species new to science.—Mr. F. Jeffrey Bell read the first portion of some observations on the characters of the Echinoidea. The present paper contained remarks on the species of the genus *Brissus* and on the allied forms *Meoma* and *Metalia*.—A communication was read from the late Mr. F. Smith, F.Z.S., containing the descriptions of new species of *Hymenoptera* from Central America.—A communication was read from Mr. W. A. Forbes, F.Z.S., containing a synopsis of the Meliphagine genus *Myzomela*, to which was also added the descriptions of two new species.—A communication was read from the Rev. O. P. Cambridge, containing descriptions of some new and little known species of Araneidea, principally belonging to the genus *Gasteracantha*.

Chemical Society, March 6.—Dr. Gladstone, president, in the chair.—The following papers were read:—On the quantitative blowpipe assay of mercury, by G. Attwood. The method consists in distilling the compounds either alone or mixed with litharge or with oxalate of potash and cyanide of potassium in ingeniously contrived retorts of glass or steel, the whole apparatus being three to four inches long, collecting the mercury in water, and weighing it when dry.—On some points in the analysis of combustible gases and in the construction of apparatus, by J. W. Thomas. The author has succeeded in exploding marsh-gas, &c., with almost theoretical quantities of oxygen, by using a diminished tension, about 160 mm. As less oxygen is thus required, the author has shortened the eudiometer tube to 500 mm. and thereby increased the delicacy of the apparatus; he has also reintroduced a steel tap, of, however, perfect tightness, and has in several points perfected and simplified the ordinary Frankland's and McLeod's apparatus. The steel face plates connecting the laboratory and measuring-tubes have also been abandoned.—On the action of isomorphous salts in exciting the crystallisation of super-saturated solutions of each other, and some experiments on super-saturated solutions of mixed salts, by J. M. Thomson. The author finds that a crystal to act as a nucleus must be not only isomorphous, but chemically similar, as to the water of crystallisation and to the substance in solution. Interesting results were obtained by introducing a nucleus into a super-saturated solution of two non-isomorphous bodies; under certain conditions a separation of these two bodies could be effected.—On the isomeric dinaphthyls, by Watson Smith. The author has determined the vapour densities of the dinaphthyls by means of V. Meyer's new apparatus, and gives in his paper the results of the reaction of carbon tetrachloride, chloroform, &c., on naphthalene.

Geological Society, February 21.—Henry Clifton Sorby, F.R.S., president, in the chair.—George Bond, Francis Gaskell, and George Henry Hollingworth, were elected Fellows of the Society.—The following communications were read:—A copy of a letter from the late Acting-Governor of the Falkland Islands, relating to the overflow of a peat-bog near Port Stanley, in East Falkland. Communicated by H.M. Secretary of State for the Colonies.—Note on *Poikilopleuron bucklandi*, of Eudes Deslongchamps (*père*), identifying it with *Megalosaurus bucklandi*, by J. W. Hulke, F.R.S.—Note on a femur and a humerus of a small mammal from the Stonesfield slate, by H. G. Seeley, F.L.S., F.G.S., Professor of Geography in King's College, London.—A review of the British carboniferous Fenistellidæ, by G. W. Shrubsole, F.G.S.

Anthropological Institute, February 25.—Mr. John Evans, D.C.L., F.R.S., vice-president, in the chair.—A paper by Mr. C. Staniland Wake, on the primitive human family, was read by the Director. The author endeavoured to combat some of the views usually associated with the name of Mr. McLennan.—Mr. E. W. Brabrook, F.S.A., read a paper entitled "Notes on the Colour of the Skin, Hair, and Eyes." The paper accompanied an exhibition of the "Echelle de Couleurs," published by the Société Sténochromique of Paris. The accurate determination of the colours of the skin, hair, and eyes, is a matter of great interest to anthropologists, and the author considered that though the object of the publication of this scale of colours was not exclusively anthropological, yet its value to anthropologists would be very great. Forty-two colours are specialised, of each of which there are about twenty shades.

Victoria (Philosophical) Institute, February 3.—Prof. McK. Hughes, F.R.S., delivered a lecture upon the antiquity of man, in which he analysed the nature of the evidence brought forward by others.

CAMBRIDGE

Philosophical Society, February 24.—Prof. Liveing, president, in the chair.—Prof. Cayley gave an account of an investigation which he had been led to, relating to what he calls the "Newton-Fourier Imaginary Problem." The Newtonian process of approximation to the root of a numerical equation $f(u) = 0$, consists in deriving from an assumed approximate root ξ, a new value $\xi_1 = \xi - \frac{f(\xi)}{f'(\xi)}$ which should be a closer approximation to the root sought for; taking the coefficients of $f(u)$ to be real, and also the root sought for, and the assumed value ξ, to be each of them real, Fourier investigated the conditions under which ξ_1 is in fact a closer approximation. But the question may be looked at in a more general manner; ξ may be any real or imaginary value, and we have to inquire in what cases the series of derived values $\xi_1 = \xi - \frac{f(\xi)}{f'(\xi)}$, $\xi_2 = \xi_1 - \frac{f(\xi_1)}{f'(\xi_1)}$, . . . converge to a root, real or imaginary, of the equation $f(u) = 0$. Representing as usual the imaginary value $\xi, = x + iy$, by means of the point whose co-ordinates are x, y, and in like manner $\xi_1, = x_1 + iy_1$, &c.; then we have a problem relating to an infinite plane; the roots of the equation are represented by points $A, B, C, \ldots$; the value ξ is represented by an arbitrary point P; and from this by a determinate geometrical construction we obtain the point P_1, and thence in like manner the points $P_2, P_3 \ldots$ which represent the values $\xi_1, \xi_2, \xi_3 \ldots$ respectively. And the problem is to divide the plane into regions, such that starting with a point P_1 anywhere

in one region, we arrive ultimately at the root *A*; anywhere in another region we arrive ultimately at the root *B*; and so on for the several roots of the equation. The division into regions is made without difficulty in the case of a quadric equation, but in the next succeeding case, that of a cubic equation, it is anything but obvious what the division is, and the author had not succeeded in finding it.

MANCHESTER

Literary and Philosophical Society, February 4.—E. W. Binney, vice-president, F.R.S., in the chair.—The area of the middle drifts as determined by their contents, by Alfred Bell, F.G.S. Communicated by R. D. Darbishire, F.G.S.

February 18.—J. P. Joule, F.R.S., &c., president, in the chair.—On a chemical investigation of Japanese lacquer, or "urushi," by Sadamu Ishimatsu. Communicated by Prof. Roscoe, LL.D., F.R.S.—On the bursting of the gun on board the *Thunderer*, by Prof. Osborne Reynolds, F.R.S., Professor of Engineering, Owens College, Manchester.

BOSTON, U.S.

Society of Natural History, October 2, 1878.—Notes on the physical geography and geology of Trinidad, by W. O. Crosby.

October 16.—The peculiarities in the growth of the Swamp Cypress (*Taxodium distichum*).

October 23.—Museum pests observed in the entomological collection at Cambridge, by Dr. H. A. Hagen.

November 6.—A century of orthoptera. Decade viii. Acridii (Melanoplus), by S. H. Scudder. Decade ix. Acridii (Pezotettix).

VIENNA

Imperial Academy of Sciences, January 23.—The following, among other papers, were read:—Measurements on simultaneous oscillation, by Prof. von Ettingshausen. This relates to a suspended and swinging coil of wire, the currents of which set a galvanometer needle swinging.—On curves of the fourth order with three double points, by Herr Ameseder.—On the diffusion of liquids (second part), by Herr Stephan.

February 6.—On some new and rare fish-species in the zoological museums of Vienna, Stuttgart, and Warsaw, by Dr. Steindachner.—On the occurrence of chlorophyll in the epidermis of leaves of phanerogams, by Herr Stöhr.—On the phenomena in the circulation after temporary closure of the aorta; contribution to the physiology of the spinal chord, by Prof. Mayer.—On the transformation of iodide of phenol into dioxybenzol, by Prof. Lippmann and Herr v. Schmidt.—Variations in structure and growth of the mesentery of the human intestine, by Prof. Toldt.—On organic ferricyanide compounds, by Herr Bernheimer.—Action of the fusing hydrate of soda on phenol, and synthesis of phloroglucin, by Herren Barth and Schreder.

February 13.—On muscular sounds of the eye, by Prof. Hering.—Covellin as a superficial pseudomorphism of a Celtic axe of bronze found at Salzburg, near Hallstatt, by Dr. v. Hochstetter.—Oxidation of resorcin to phloroglucin, by Professors Barth and Schreder.—Remarks on Dr. Wangen's memoir on the geographical distribution of fossil organisms in India, by Herr Wynne.

PARIS

Academy of Sciences, March 3.—M. Daubrée in the chair.—The following papers were read:—Reply to M. van Tieghem concerning the origin of *Amylobacter*, by M. Trécul.—Researches on the fœtal envelopes of the armadillo with nine bands, by M. Milne-Edwards. Exceptionally to the rule with mammalia, the four fœtuses of this armadillo are all lodged in a common chorion.—The waters of the Cheliff; some observations regarding the interior sea of Algeria, by M. Balland. The Cheliff is the principal water-course of Algeria, and flows to the Mediterranean. At present it carries down over three million tons of earthy matters (chiefly silica and clay) in twenty-four hours; this would give a layer 1 metre thick, over 300 hectares. The numerous Saharan rivers lost in the Chotts also convey large quantities of earth and sand; then there is the sand displaced by winds. These considerations are urged against the interior sea.—Discovery of a small planet at the Observatory of Marseilles, by M. Stephan.—Extract from a letter from P. Ferrari, relating to the intra-Mercurial planet. This calls attention to an important observation by P. De Vico in 1837 (which seems to have escaped Leverrier's notice), on a planet-like body which then passed over the sun's disk.—Formulæ relative to the theory of planetary perturbations, by M. de Gasparis.—On the multiplication of elliptic functions, by M. Halphen.—Resolution of a class of congruences, by M. Pellet.—On the emissive power of coloured flames, by M. Gouy.—On the spectra of absorption of didymium, and of some other substances extracted from samarskite, by M. Soret. The facts indicate the existence, in the didymium from samarskite, of a substance at least different from didymium. The same substance seems to be in less quantity in terbine, and in least in the didymium from cerite.—Action of sulpho-cyanate of ammonium on monochlorised acetone, by MM. Norton and Tcherniak.—On amidised acids derived from butyric and isovaleric acids, by M. Duvillier.—Researches on digestion in cephalopod molluscs, by M. Jousset de Bellesme. The posterior salivary glands of the poulpe facilitate the digestion of albuminoids, laying bare the muscular fibre for action of the chief digestive juice. The upper salivaries are merely connected with mastication and swallowing. The animal has a digestive aptitude only for albuminoid and connective matters; and this is the more remarkable because some of its organs, *e.g.*, the liver, contain a large amount of fatty matters.—Researches on *Peronospora gangliiformis* of lettuce, by MM. Bergeret and Moreau. Water slightly acidulated with nitric acid is a good remedy; it poisons the Peronospora and is a manure for the soil.—Influence of oxygen on alcoholic fermentation by beer yeast, by M. Bechamp. In a first series of experiments pure oxygen was conducted into the fermenting mixture continuously. In a second series the electrodes from a battery of six or eight Bunsen elements were put in the mixture; the gases of fermentation were collected, and the oxygen proved to be mostly absorbed. Oxygen acts as an excitant, stimulating the life of the yeast and the mutations of its matter. In the first period of fermentation (with the current) the absolute quantity of alcohol formed was greatest; it diminished to the end. The acetic acid increased from the beginning. The sugar-water absorbs part of the oxygen. Pure yeast in water under weak electrolytic action, may absorb all the oxygen.—On a method of conservation of infusoria, by M. Certes. He employs a solution (2 per cent.) of osmic acid. The important point is to make the reagent act promptly and with a certain force. One way, suitable for most cases, is to expose infusoria on a glass plate to the vapours of osmic acid for ten to thirty minutes. For very contractile infusoria, a drop of the reagent is deposited on the cover before covering the drop of water which contains them. Excess of liquid is removed with Joseph paper; two opposite sides of the cover glass are luted with paraffin or Canada-balsam; and for coloration a mixture of glycerine, picrocarminate, and water (equal parts) is used.—On the unity of forces in geology (continued), by M. Hermite. He offers objections to the hypothesis of igneous fluidity. The present form of the earth is attributed to the presence of its seas. Volcanic phenomena do not agree with the existence of central fire, or even a sea of lava of small extent.—On the hurricane which traversed Switzerland on February 20, 1879, by M. Forel. He finds in the data strong proof of a gyratory motion of the atmosphere.—Theory of glazed frost; reclamation of priority, by M. Nouel.—On some former examples of glazed frost similar to that of January last, by M. Vogt. He gives an account of one instance of the phenomenon observed at Geneva in 1856.

CONTENTS

THURSDAY, MARCH 20, 1879

ROYAL AGRICULTURAL COLLEGE, CIRENCESTER

DURING the last few years the question of Agricultural Education has been very fully and fruitfully discussed. The experiment of an examination in the principles of agriculture, under the Science and Art Department, had an unexpected success; and showed that there was throughout the kingdom a demand for instruction in agricultural matters. At the present moment efforts are being made to satisfy this demand more completely by means of local organisation for developing and extending the facilities already offered by the Science and Art Department.

There is at Cirencester a college founded specially for the advancement of agricultural education. It has one—or more—Royal Charters; it has the power of granting diplomas; it is under Royal patronage, and has the advantage of being managed by numerous Earls and M.P.s. This institution ought to (and might) have been the centre of the movement to which allusion has been made; but, unfortunately, its own troubles seem to be enough to occupy the whole attention of the Committee of Management; and, for the second time in the history of the college, threaten to bring about its extinction. For the past few weeks the agricultural press has been teeming with letters and articles headed "Professor Church and the Royal Agricultural College." The facts, as to which there seems to be no dispute, are briefly these:—Prof. Church is about to be married. Other professors, his colleagues and juniors, had done the same, and non-residence in their cases was not found incompatible with the proper performance of their several duties; as a matter of fact each of Prof. Church's predecessors was non-resident. Yet the Principal intimated to Prof. Church that without residence he could "no longer discharge the duties of Professor of Chemistry in this college." It appeared that this decision on the part of the Principal was not authorised under the bye-laws: such a point could be determined only by the Committee of Management; and the case was referred to them. The result was, however, unaltered. While "fully sensible of the services rendered by Prof. Church during his sixteen years' residence in the College," the Committee "regret that they cannot accede to his recent proposal of non-residence." The consequence of this was two resignations. Prof. Lloyd Tanner regarding the decision "as showing that neither long and zealous performance of duty, nor special ability for work are duly recognised," has resigned the Chair of Mathematics and Physics; and Prof. Fream, "as the only protest it is in his power to make against the treatment his colleague has received," similarly vacates the Chair of Natural History.

Such are the circumstances under which the three senior resident professors at Cirencester College are leaving. Other matters have rendered the affair even more painful than it need have been, but we believe the simple, undisputed facts of the case are amply sufficient to enable our readers to form a just opinion of the mode of managing Cirencester College. Those who intend to become candidates for the vacant chair have had an opportunity of judging how one bye-law can be and is used against a man such as Prof. Church; we will only advise them to study the other bye-laws and guess how they may be used against younger and less known men. Having seen these bye-laws ourselves we are curious to know who will be induced to replace the vacancies just announced.

PROF. HUXLEY'S HUME

Hume. By Prof. Huxley. (London: Macmillan and Co., 1879.)

PROF. HUXLEY has given a clear and succinct account of the philosophy of Hume, in a style at once fresh and pointed. We should be thankful to him that, following the example of Locke and Hume himself, he discusses philosophical questions in genuine and idiomatic English, and consistently avoids the use of a lumbering phraseology, imported from abroad, amid which the thinking evaporates, for the most part, in pure verbalism. The volume before us is limited to a brief account of Hume's life and his philosophical opinions. It hardly touches what has been said on the other side in criticism or in correction of Hume's views. Here and there Prof. Huxley offers a criticism; but, though generally acute, it is seldom on anything but a point of detail. Indeed, the volume may be described as rather too much of a bare statement of Hume's principles and conclusions.

As Prof. Huxley may fairly be regarded as dogmatically accepting Hume's principles and boldly carrying them out to their results, while Hume may with probability be regarded as having only hypothetically held the principles, we might have expected a fuller vindication of them than is at all attempted in the volume. On all the metaphysical questions of greatest moment Prof. Huxley's position is a negative one; and if, as it seems, he accepts Hume's principles absolutely, it is one of complete negation.

In the opening chapter on the Philosophy (Chap. II.) Prof. Huxley has done good service in clearly stating the terms of the question. He very properly points out that the question regarding the limits of knowledge, or "What we can know," is not a primary but a secondary question. He is emphatic in showing that it implies the previous questions as to what we mean by knowledge, and how we come by the thing we call knowledge. And he very well points out that these latter questions are psychological, and that psychology, accordingly, is the only proper basis of assertions about knowledge, whether these refer to its nature, conditions, or limits. This clear and vigorous statement is not inopportune, for there is somewhat of a tendency at present, very inconsistently indeed, to ignore psychology. We have professions of "deducing" the conditions of "experience." It seems strange that it does not occur to the advocates of such a method that its basis is necessarily an accurate examination of what experience or consciousness in its fullest extent is; what, in a word, is the thing spoken of, whose conditions it is proposed to evolve. This implies a full and scientific psychology—the only safeguard against fantastic system-making, otherwise the so-called "deduction" becomes a method of *if* and *must*

—hypothesis and hypothetical inference; having no bearing on our experience.

What Hume really sought in philosophy was the ultimate element, out of which all valid knowledge might be shown to flow. This element was to be at once the source and the test of every conception of the human consciousness. This he supposed he found in the "simple impression" or "simple impression of sensation." The essence of Hume's method is to reduce all so-called knowledge of objects to this test; his constant demand is—show me the "impression" from which your alleged conception or idea is derived, and then, but then only, shall I admit the reality and validity of your knowledge. If our conception be meaningless, the object of it is unreal. It is easy to see how on such a method, whether adopted hypothetically or dogmatically, self-existence, self-identity, personality, and Deity must be given up.

But the question at once arises :—*What* precisely is this so-called "*impression of sensation*," or "*singular sensation?*" The psychological method has been admitted. And we must apply this method to find whether there is such a thing as an *impression per se*. It is at least a consciousness, or state of consciousness. If it be said that *impression* is not the full fact, but a mere abstract part of the complex fact which we call consciousness—this is a position which is quite as vindicable on Hume's psychological method as his statement of the fact is. We do not require to have recourse here to any "transcendental deduction," or to Prof. Huxley's "pure metaphysician." We only ask whether the psychological method is fairly applied to the fact. Here we do not think that Prof. Huxley has done any justice to those who say and seek to show that *impression per se* is a mere abstraction—possibly even a simple unintelligibility.

No doubt Prof. Huxley tells us that Hume omitted an entirely irresolvable element of consciousness, viz., relation, as of succession, co-existence, &c. But one does not see that Prof. Huxley apprehends the true force of his own admission. The *relation* of succession is still as much an abstraction as *impression* is, in fact, an unintelligibility, unless on the supposition of some one conscious being,—subsisting through varying times. An appeal to memory is of no use here. Memory itself is but a phrase for the act of one and the same conscious being subsisting and recognising impressions in successive times. The unity of the conscious being is the ground of memory; not memory the ground of it; as this unity is equally the ground of the possibility of a known relation of succession, or successive impressions. Prof. Huxley does not recognise this in its proper place; he even in the end gives in his adhesion to Hume's denial of a *self* or unity in consciousness at all. But by this he cuts away all ground of right to acknowledge relation in knowledge; all ground in fact to affirm or deny anything.

Hume at once naturally takes up the question as to the kinds of impressions conveyed, as he phrases it, through the senses. His answer to this question may be said to be that all we know through the senses is of the same kind, whatever be our natural belief to the contrary. Figure, bulk, motion, colours, tastes, smells, sounds, heat and cold—pains and pleasures, from application of objects to our bodies—are all simply impressions or conscious states—each class has but the same "interrupted and dependent being." They are "nothing but perceptions arising from the particular configurations, and motions of the parts of bodies." In that sentence lies the main inconsistency of Hume; and it is a key to the constant shifting of ground, which, with all deference to the admirers of the consistency and cogency of his reasoning, nullifies large portions at once of the "Treatise of Human Nature," and the "Inquiry Concerning Human Understanding." For if the senses can in no way give us more than a conscious impression, they are absolutely impotent to tell us of a body which is not itself merely a conscious impression. And to say, therefore, that bodily motions are the antecedents or causes of conscious impression is simply to say that conscious impression is the antecedent or cause of conscious impression. If Hume assumes that the senses do more than this, and distinctly inform us of objects called body and bodily motion, then he contradicts his own doctrine regarding the reach and sphere of the senses. And if he holds that body is the cause of impressions, he must admit a clear knowledge both of body and of what it can do.

But Hume is represented as stating and refuting with effect "the arguments commonly brought against the possibility of a causal connection between the modes of motion and the cerebral substance and states of consciousness" (p. 76). Hume's argument is as follows: Cause is simply constant conjunction; *à priori*, anything may produce anything; no reason is discoverable why any object may or may not be the cause of any other, however great or little the resemblance between them. Thought *may* therefore be the effect of motion; we may perceive a constant conjunction of motion and thought. Nay, it is certain we have this perception, "since the different dispositions of the body change the thoughts and sentiments." Hence "motion may be, and actually is, the cause of thought and perception."

In this so-called proof Hume evidently felt in a dim way the force of the objection, that, on his doctrine, thought and motion are really identical, that in fact he was only surreptitiously begging for motion, a character which his system denied it—the vulgar realistic view—in order to prove that thought as a distinct thing from motion was yet produced by it. Accordingly we find a clause, as is Hume's manner, quietly inserted to blunt this criticism by the way. "We find," he says incidentally, "by the comparing the ideas that thought and motion are different from each other." Possibly enough that is so; but the difference, whatever it may be, cannot, on Hume's doctrine at least, be allowed to extend beyond the common genus of conscious impressions; and it is, therefore, wholly irrelevant to his argument.

Prof. Huxley must know that all psychologists of note, and of the most different schools, from Hartley to Hamilton, have admitted the fact of "constant conjunction," of bodily organic impressions with conscious sensations and perceptions. But after all that Prof. Huxley has said, as to the place which this organic impression has in the production of the sensation, the questions remain whether it is the cause, or a concause, or merely a condition, on which a higher power comes into play. Prof. Huxley has surely read of the fact of mental absorption—that state of mind in which, when it is occupied by strong emotion, or by intense thought, all the organic impressions may take place,

and yet no sensation follow. When a person is writing, the clock may strike in the room, the impressions on ear, nerve, and brain being complete, and yet the next moment he may have not the slightest memory of the sound; certainly, at least, not the consciousness or memory which in ordinary circumstances he would have had. These organic impressions have thus to meet as it were with something other than themselves—something we call consciousness or mind—ere even sensation becomes actual, or a mental fact. This truly reduces them to the place of a simple concause, and shows that there is another factor which they do not necessarily command, and which must concur in the realisation of the very lowest form of mental life. Then these physical antecedents relate to but the lower phenomena of mind. Even if it can be shown that imagination and intellect use portions of the brain, it must at least be admitted that they are there to use them. Can it be said that the apprehension of relations, or the act of generalisation, or volition, is properly spoken of as a conscious *impression?* Does Prof. Huxley imagine for a moment that any careful psychological analyst would place such operations on a level with the consequent of a series of organic movements

Again, what is the real meaning of the phrase that "the operations of the mind are functions of the brain, and the materials of consciousness are products of cerebral activity?" (p. 80). Prof. Huxley quite sees and admits that this is what is called "materialism," and indeed it is nothing else. One ought to thank him for his candour. But I should like very much to know the precise meaning of the statement so characterised. When analysed, it means this: that the nervous current generated by the brain out of food and blood is transmuted into mind; that as a certain molecular motion is transmuted into heat, so a certain nervous motion is transmuted into consciousness or mind. Now it seems to me, on the other hand, that not even sensation, to say nothing of intellect or the apprehension of relations of succession, coexistence, similarity, has been shown to be the transmutation of nervous force. We observe that physical forces are transmuted into each other; we can even quantitatively determine equivalents in this case. But the method fails us the moment we seek to show that or how a state of consciousness is a transmutation of the unconscious. For now we are no longer dealing with forces of the same kind—forces equally objects of consciousness itself—and known to be, to a certain extent, numerically determinable; we are dealing with the unconscious and the conscious; we are trying to bridge a gulf, on the further side of which we have no basis. We have no measure or rule for showing how the unconscious and the conscious are convertible, or that they have any conceivable relation whatever. Besides, even if we get sensation out of nervous force, what of the relations of difference, resemblance, succession, and coexistence among those sensations? Mr. Huxley calls these *impressions of impressions.* This is a very inaccurate expression. An impression of an impression must at least be picturable in the imagination. It is not so here. These relations are discerned by the intelligence; they suppose impressions; their material or nerve-antecedent is not observable, and they can in no way conceivably be referred to physical movements. Further, a physical or brain-force, though it give one definite sensation, or even a series, cannot provide for the pervading unity of self-consciousness. Physical forces, which are perpetually changing, successive and different, cannot be made convertible with the sense of unity which pervades all our consciousness. And further, the consciousness of a series of impressions, even of two impressions, the recognition of this fact or relation, its being in our consciousness at all, implies a standing unity of consciousness, a self or being, one and identical, which may be awakened into conscious life in or through those impressions, but which is in no way made by them—rather, is necessary to their being made or known.

But is Prof. Huxley's conclusion at all consistent with the law of physical energy? According to the law of the transformation of energy, the energy represented by motion or molecular change in matter passes into a consequent, which is also a movement or molecular change. The antecedent and the consequent states are still only forms of molecular change; and the amount or quantity of the antecedent is represented by the amount or quantity of the consequent. There is transformation of energy; but there is no change in the kind of the consequent. Now according to Prof. Huxley, a state of consciousness called sensation, or emotion, or idea, is as much the result of "the molecular changes which take place in that nervous matter which is the organ of consciousness, as the nerve-vibrations are the result of the impact of the light-waves on the retina." At the same time Prof. Huxley holds that the state of consciousness is distinct in kind or quality from the physical movement. It is psychical, or a form of *psychosis* as opposed to *neurosis.* And indeed he must admit a distinction in quality in the two cases. For the physical movement is possible—nay, is actually carried on apart from consciousness; whereas the sensation, the very lowest form of consciousness, is possible, is actual only in consciousness itself. There is all the difference between the fact which depends on observation by eye-sight and the feeling which is self-guaranteeing while it lasts, between the unconscious observed and the conscious felt. But be this as it may, he admits the distinction, as in fact impassable in thought. How is it then consistent to say that the state of consciousness is the effect of the physical movement? Either the law of physical energy is observed, and then we have only a physical movement as the determined result; or it is not, and then we have a state of consciousness, something distinct in quality from a physical movement; that is, we have as the result of the given physical force that which was not contained in the force as a simple quantum of physical energy.

But Mr. Huxley, following, as he thinks, Hume, tells us somewhat singularly that this materialistic doctrine of the origin of mind "contains nothing inconsistent with the purest idealism" (p. 80). In other words, what we call matter turns out in the end to be a purely hypothetical entity, assumed as a cause of certain states of consciousness. The very conception of such an entity is inconsistent with the basis here given; for if our sense-knowledge, indeed all our knowledge, be restricted to states of consciousness called feelings, we are precluded from forming an idea even of matter as an

object transcending consciousness, or of anything but states of consciousness, their compounds, and relations among themselves. To speak of "matter" as a cause of our feelings is, on such a theory, meaningless; and such a cause as an inference is impossible. Matter and motion, then, are simply convertible with states of consciousness, in fact, with feelings. And when we are told that these phenomena precede and cause the states of consciousness we call sensations, emotions, thoughts, we say merely that one set of states of consciousness is antecedent and cause of certain others. We have, therefore, wholly given up the dualistic scheme and the aim with which we started, viz., that of explaining the feelings by material phenomena. We now really profess to explain the whole of our conscious states—or mind—by one set of its states or phenomena, viz., those we call matter and motion. But does Prof. Huxley not see the *petitio principii* involved in such an argument? When I am cognisant of the phenomena, matter and motion, have I not assumed consciousness and its states to account for consciousness and its states; or rather, which is worse, have I not assumed certain very elementary states of consciousness—to account for, in fact, to generate the whole contents of mind—in all their complexity and reach—intellect, emotion, desire, volition, and moral sense? This is cutting the knot coarsely with a hatchet. It is not even solving the problem as to how from rudimentary states of consciousness itself, mind can rise to its recognised fulness and complexity—rise, in a word, to that which we call matured consciousness.

J. VEITCH

SACHS'S VENEZUELA

Aus den Llanos. Schilderung einer naturwissenschaftlichen Reise nach Venezuela. Von Carl Sachs. (Leipzig: Veit, 1879.)

NO one who has a liking for natural history should omit to read Dr. Sachs' account of his adventures in the Llanos of Venezuela. German books of travel, though possessing a large amount of solid information, are often rather dry and heavy. But Dr. Sachs' volume is certainly an exception to the rule, and may, we think, be placed, as regards the interest of its narrative, nearly, if not quite, on a par with the well-known works of Bates and Wallace.

The late Dr. Carl Sachs, who was formerly assistant to the great physiologist of Berlin, Emil du Bois-Reymond, and lost his life in an unfortunate accident on the glaciers of Monte Cevedale in August, 1878, went out to Venezuela, not with the ordinary objects of the travelling naturalist, although no opportunity was lost of collecting specimens, but for the especial design of obtaining a better knowledge of that most wonderful of fishes commonly called the electric eel (*Gymnotus electricus*). No more appropriate use could certainly have been made of the "Humboldt-Fund," collected in order to preserve in memory that great naturalist, than the devotion of it to such a purpose. Humboldt's account of the electric eels and the mode of their capture, is among the best known portions of his travels. Nearly eighty years had passed without any naturalist having trodden in Humboldt's footsteps, or having attempted on the spot the further elucidation of the extraordinary properties of this fish, aided by the enormous development which the science of physiology had made since that period.

With this object, therefore, Dr. Sachs left Europe in October, 1876, determined to visit the home of the electric eels in the same streams that Humboldt had found them in the year 1800. To arrive at this destination is not in these days a matter of great difficulty. From Hamburg a swift ocean-steamer bore our naturalist to La Guayra, and a day's ride over the coast chain of the Andes brought him to Caracas, the capital of Venezuela. After a few days' spent in rest in this lovely city and in excursions in the neighbourhood, Dr. Sachs turned his face due southwards, and, accompanied by servants and baggage-mules, rode over the grassy plains, or Llanos, which cover the southern part of the republic. Ten days' travel brought him to the little village of El Rastro, situated on one of the small confluents of the Rio Sisnado, a branch of the Orinoco, the very spot where Humboldt had captured *Gymnoti* seventy-six years before.

Humboldt's account of the mode in which this operation was effected in his days is well known. The Indians "fished with horses." About thirty wild horses and mules from the Llanos were collected and driven into the river. The stamping of the beasts drove the eels out of their hiding-places in the mud into the middle of the stream, where they got under the bellies of the horses and attacked them with repeated discharges of their electric organs. The unhappy quadrupeds rushed out to the banks, but were driven back into the water by the shouts and sticks of the surrounding Indians, until many of them, exhausted by the repeated shocks of the *Gymnoti*, sank to rise no more. The eels thus lightened of their superabundant stock of electricity were easily captured by the Indians.

Such is Humboldt's well-known story. But strange to say the Venezuelans of the present day simply laughed when Dr. Sachs proposed to put a similar plan in operation, and said they had never heard of such a thing. Indeed Dr. Sachs after various inquiries on the subject, was at last driven to the conclusion that fishing for electric eels with horses, as described by his illustrious countryman, must have been quite an exceptional occurrence, and could never have been a recognised custom.

In fact, Dr. Sachs was altogether unsuccessful in inducing the people of El Rastro to procure him electric eels in any way, and, after some rather disheartening attempts, shifted his quarters to the neighbouring town of Calabozo, where he hoped to find better quarters and a more intelligent set of assistants. Here, also, although his offers for electric eels were raised to ten pesos (about 30*s.*) a head, the fishes did not "come in," and poor Dr. Sachs was almost beginning to despair, when he fortunately heard of a certain "Llanero"—General Guancho Rodriguez—the very man for the occasion. How under Don Guancho's generalship these redoubtable eels were at length captured and brought home to the doctor's laboratory at Calabozo, how the necessary experiments were conducted to the wonderment of the good Calabocenos, and how Christmas is passed in that city, is all well told in some entertaining chapters, which will be much appreciated by those who read Dr. Sachs's narrative. It musts suffice for us to say that during Dr. Sachs's stay at Calabozo, which lasted until March, 1877, the main objects of the expedition were fully attained, and a number of important researches

carried out, the results of which, owing to Dr. Sachs's untimely decease, will, we fear, never be given to the public.

Leaving Calabozo, Dr. Sachs continued southwards to San Fernando de Apure, and thence down the Apure and Orinoco to Ciudad Bolivar, the capital of this part of Venezuela. From Ciudad Bolivar steam quickly carried him to Trinidad, and thence back to Europe. Of this section of his journey, as of the former part, Dr. Sachs's narrative is full of interest—nor will any one who reads it fail to regret that so promising a life should have come to such an early conclusion.

OUR BOOK SHELF

Education as a Science. By Alexander Bain, LL.D. (C. Kegan Paul and Co., 1879.)

THIS work, belonging as it does, to *The International Scientific Series*, naturally calls for some notice in our columns. We must confine our remarks, however, to the portions which deal with Mathematical, Physical, or Natural Science. The author, though Professor of Logic and English Literature, has already appeared before the public as one of the Editors of *Arnott's Physics*, and has laid down the law in a somewhat peremptory way about Elementary Geometry. We expect to find, therefore, accurate science, and above all, clear and definite composition, in his work.

The first of the following extracts supplied a hint which enables us to make the book review itself. We have taken the liberty of italicising a few words, in other respects we quote *verbatim.*

"Definite descriptions of definite failures, without note "or comment, are a power to punish. When there "are *aggravations, such as downright carelessness*, a "damaging commentary may be added; but in using "terms of reprobation, still more strict regard has to "be paid to discrimination and justice. The degrees of "badness are sometimes numerical . . . . this very "definiteness *literally stated* is more cutting than "epithets."

"The phrase 'cæteris paribus' (other things remaining "the same) is a mathematical coinage, for guarding "against the error of supposing that a course (*sic*) will "produce its effect under all circumstances indiscrimi-"nately."

"The advantages above set forth are such as Mathe-"matics is peculiarly fitted to give, and *without which* "*they* are scarcely ever attained at all. In so far as the "physical sciences unfold similar advantages the way is "paved for them by Mathematics. To this short sketch "of what Mathematics does, we should, for the sake of "clearness, append what it does not do, *and must be left* "*undone*, if we stop with it."

"The *earlier* parts of such subjects as Geometry and "Algebra need the *longest* iteration: the progress should "be at an *accelerating* rate. The higher Mathematics "should not be commenced with immature or incapable "minds."

"How to embody the actual problems in mathematical "language,—for example, the problems of motion in the "scheme of differential coefficients,—is a standing em-"barrassment, not to be met by any of the arts of "ordinary tuition."

"Try a child to lift a heavy weight first by the direct "pull, ..."

"Many trials must be allowed to *get a child into a new* "*shade of vowel*, as, for example, when Scotch (*sic*) "children have to learn the English sound of 'all.'"

"A high wrangler is a man professionally fitted for some "special post involving Mathematics; but, if he turns to "one of the other professions—Law, Medicine, the "Church, the Public Service, *he has incurred* an irreme-"diable waste of human strength."

Having attentively perused these extracts, the reader will probably be prepared to consider the following statement as more than plausible:—

"A purely psychological or metaphysical education "*might* be the worst case of any . . . ." P. G. T.

Life in Asiatic Turkey. A Journal of Travel in Cilicia, Isauria, and parts of Lycaonia and Cappadocia. By the Rev. E. J. Davis, M.A. Map and Illustrations. (London: Stanford, 1879.)

MR. DAVIS resides as Chaplain at Alexandria, and the present thick volume is the result of a tour in Northern Syria, in the summer of 1875. It is surprising that a region so full of interest should have been so little visited, and therefore Mr. Davis's account of what he saw is specially welcome. That there is much to interest in these parts is evident from all that Mr. Davis tells us, and his quiet and painstaking narrative will well reward a careful perusal. The pictures, coloured, from drawings by Mr. Davis, are unusually good, and add greatly to the interest of the volume, which is likely to take its place as a standard reference-work on the region with which it deals.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

Tempel's Comet

WE find in NATURE, vol. xix. p. 347, some detailed particulars about the return of the comet 1867 II. (Tempel) in the course of the present year. In this article Sandberg's calculations are also taken into account. The real value of his studies about this comet seems to be but little known, as in other instances as well, new calculations are based upon them. In the *Astron. Nach.* Sandberg has only given a very short account of the results of his researches, and it is therefore but natural that their real value must be more or less concealed. Sandberg has published the details of the first determination of the orbit in a special treatise (Specimen Inaugurale de Orbita Cometæ II., 1867, Zwollae, 1869), which seems to be not very much known, and it is not necessary to read much of this work to make sure of the negative value of the calculations.

I now take the liberty to give here some short notices, which are, however, quite proof enough to keep astronomers eventually from unnecessary calculations. Sandberg makes use of all observations, and forms the normal places by the deviations of the different observations from the provisional ephemeris. In doing this he rejects, "prompted by the example of others," (*sic*) all observations which deviate more than 1·5s. in R.A., and 20″ in D. from the *ephemeris*, and not from the average. If, for instance, as with a normal place the mean deviation comes to + 14″ in D., he rejects observations which deviate 6″ from this average, whereas he accepts others to their full value, the deviation of which from the average is nearly 30″ (− 14″ from the ephemeris).

According to this proceeding is the accuracy of his calculations. An observation of Pulkowa deviates, according to his calculation, from the normal difference in D. (− 2″·2) 21″ (18″·9). If he had taken the parallax with correct sign, the observation would deviate 4″ from the average. In the same manner the above-mentioned great deviation from the average is wrong, and does in reality only come to about 3″. These facts are sufficient. It would be easy to mention many others of similar nature, but I do not think it necessary to take up more room in your esteemed periodical.

W. VALENTINER

Mannheim Observatory, March 10

Experiment with a Vacuum Tube

A TUBE like a radiometer tube contained a concave metal disk within the bulb; this disk could be connected with the pole of an induction-coil, and about a quarter of an inch above it was a small wire which could be connected with the other pole. The bulb was exhausted to such a point that a 5-inch spark could not pass from the wire to the metal disk. The wire and disk were connected for several minutes with an induction-coil giving 4½ to 5-inch sparks; although no spark passed between them, the glass on the side of the bulb, which was *just in the focus of the metal concave disk, was melted*, and the pressure of the external air forced the melted glass inward, and a minute hole was formed, of course destroying the vacuum. The diameter of the hole was about that of the finest sewing-needle; it was in the centre of a depression in the side of the bulb about a tenth of an inch in diameter. H. ALFRED CUNNINGTON

Devizes, February 28

[Having succeeded in melting platinum by the heat of molecular impact (*Proc.* Roy. Soc., No. 191, p. 110, and NATURE, vol. xix. p. 137), it is not surprising that the heat is sufficient to melt glass when the focus falls on it. In a paper communicated to the Royal Society in November last, now being printed in the *Philosophical Transactions*, I mentioned that by drawing the focus on to the side of the glass tube by means of a magnet, the glass became heated to redness. In December I wrote to Prof. Stokes that I had melted up a piece of Gorman glass in the focus of the rays, and at the same time I sent a piece of the melted glass to my friend Mr. Sorby, of Sheffield, for microscopic examination, as the fusion *in vacuo* had produced an unusual appearance on the surface of the glass.—WILLIAM CROOKES.]

Tides in the Bay of Fundy

HAVING resided for some years in the neighbourhood of this bay, I am able to give a little information respecting its tides. The bay splits into two at its inner end. One of these branches leads through a narrow channel into the broad basin of Minas. The other, called Chegnecto Bay, is not interrupted by any such contraction, and is therefore more favourable for the formation of very high tides. This bay itself divides at its upper end into two, and one of these, called Chepody Bay, contracts very gradually for some thirty miles inland, forming the estuary of the Petitcodiac River. This is the place where the highest tides occur, and as far as I have been able to learn, their maximum height is 70 feet. A powerful "bore" is formed by the incoming waters. The captain of the steamer *Emperor*, which plied between St. John, N.B., and Windsor, N.S., informed me that the highest tide in any part of Minas Basin was about 55 feet. This would probably be at the head of Cobequid Bay, near Truro. Noel Bay, which is mentioned in Dr. Haughton's letter (NATURE, vol. xix. p. 432), is in Minas Basin, rather more than half way from its narrow mouth to the head of Cobequid Bay. If the range here at ordinary spring tides is 50·5 feet, any one looking at the map and knowing the effect of funnel-shaped estuaries, would be prepared to learn that there is a range of from 60 to 70 feet in Chepody Bay and the estuary of the Peticodiac, at strong springs. J. D. EVERETT

Malone Road, Belfast, March 14

End-on Gas-Vacuum Tubes in Spectroscopy

WHILE nothing will give me greater pleasure and confidence in my own worked-out views than to learn, as you intimate in the editorial note (NATURE, vol. xix. p. 400), that so able a working scientist as Dr. Van Monckhoven had preceded me in pointing out the value of *end-on* gas-vacuum tubes, and had sent specimens similar to mine to several observers in England, allow me to inquire where I can find any published account in this country of his tubes, the parties to whom they were sent, and the work accomplished with them? And why, also, if the said tubes were found by those gentlemen as intensely superior for spectroscopic results as mine are proving themselves—they have not yet been described in any of the latest London books I have been able to look into on spectroscopy, natural philosophy, electricity, and instrument-makers' price lists, though the old, pale, imperfectly-lighted, transverse-vision tubes are referred to in all?

Your obliging answer to these questions will evidently be of interest to Dr. Van Monckhoven, as well as myself, while it will also have a far wider and more important bearing for many persons in Scotland. For they, conscientiously striving by all recognised public methods of study to keep up with progress in the south, and not having heard of *end-on* gas-vacuum tubes for the spectroscope before my recent paper on them, would very much like to have thereby and therein a practical demonstration of what a thing, and a good thing too, being, as you say of this, "already well known in England," really consists in; and to what extent, therefore, every member of the community here ought to have similarly known it on the 10th inst., and myself nearer to the same date in 1878, when M. Salleron made the first examples for me, on my then supposed new idea. PIAZZI SMYTH

Edinburgh, February 28

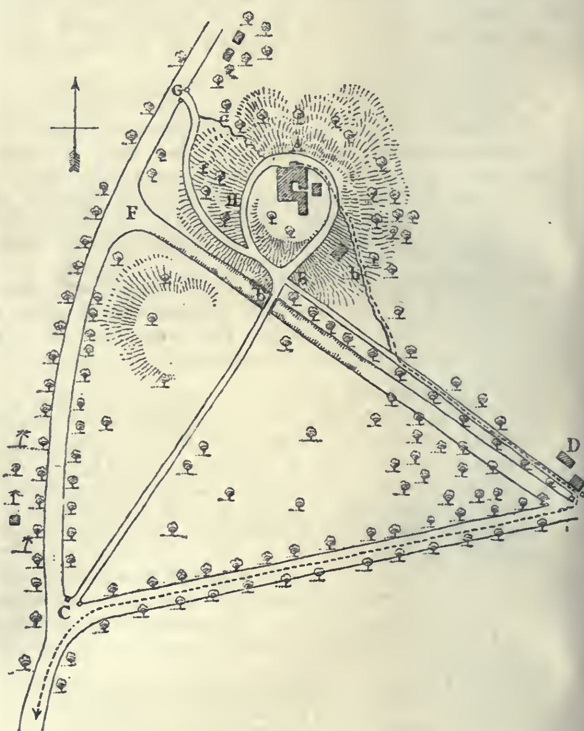
[Dr. Van Monckhoven writes that his new tubes were described to the Belgian Academy of Sciences in 1877, in a note, a copy of which he sends us. He states that he sent some of these tubes to Mr. Dallmeyer, who gave them to various English men of science. They give, he states, about 100 times more light than the ordinary spectrum tubes.—ED.]

Intellect in Brutes

DR. RAE has so fairly disposed of Mr. Henslow's examples of so-called "practical" and "abstract reasoning" that further comment is unnecessary. As, however, the subject of intellect in brutes is on the *tapis*, I will give an instance of sagacity in a dog that finally set at rest any doubts I ever entertained that the difference between human and animal intelligence is one of degree only.

If you have space for it, the accompanying plan will be of great value in describing the circumstances.

Mr. J. W. Cherry, of the Madras Forest Service, was owner of the dog in question, a bull terrier, called "Bully." We



lived in the bungalow (A), the compound of which was bounded south and west by public roads (D C) and (G F C) both leading to the cantonment of Mangalore in the direction C. There were three gates into the compound at (C) (D) and (G), the main approach to the Bungalow leading over a bridge (B), that spanned a branch public road (F D). The compound was filled with trees and shrubs, and bordered by dense lantana hedges, so that with the exception of a portion of the western road at F, neither of the cantonment roads were visible from the bridge, nor could the foot-paths (*a*) and (*b*) be seen thence.

Now Bully had a lady friend (canine) living in the canton-

ment, and at times she was so attractive that absences without leave on the part of the dog were frequent. After one of these excursions Bully had been brought back, and chained up for the night. Next morning, while his master and I were sitting at early breakfast, it was decided that he should be released, and to effectually stop further delinquency, a peon was sent down to the bridge with orders to intercept him if he started for the cantonment.

Bully was brought in and unchained; he had that unmistakable air of detected guilt deservedly punished, and spent some time in begging for scraps from the table in a most deprecating manner. Shortly, however, he strolled into the verandah, and then down the front steps on to the gravel walk. After wandering about aimlessly for a few minutes, he quietly started off down the approach (A H B). We followed, keeping out of his sight. At the turn of the road Bully met the unexpected apparition of the peon standing on the bridge. In a moment, though not a word was spoken by the man, the dog turned and came straight back to the room, whither we had in the meantime slipped back unobserved, and re-entered it wagging his tail violently and looking exceedingly sheepish. He now lay down and closed his eyes. The cocked ears showed that sleep was mere pretence, and he soon rose again, went out into the front garden, and hunted for buried bones, purely imaginary ones, I believe. His search gradually led him down the hill by the foot-path (*a*),—we keeping him in sight, as before—and he finally reached the road at the bottom. There all disguise was dropped, and he started off for the cantonment. As he neared the spot (F) the peon espied him, and shouted out his name. He turned at once, climbed the hill, and came into the bungalow, where the same farce of repentance was gone through.

Bully now seemed to have made up his mind that escape was impossible; he lay down on a mat in the verandah, and remained there for a long time. But for the persistent cock of the ears we should have imagined the animal really asleep. Mr. Cherry eventually went to his office-room, and I remained in the verandah reading the morning paper, and occasionally glancing at Bully. He lay very still, but once or twice I detected him opening his eyes and raising his head to look round him. Each time he caught my eye he wagged his tail vehemently for a moment or two, and then resorted to his sham sleep.

It may have been for half-an-hour, or thereabouts, that this state of things continued. I then became interested in an article in the paper, and when I next looked up Bully was gone. I called Mr. Cherry, and the house was searched. No Bully. The peon was sent for and interrogated; he had not seen the dog. As a last resource inquiry was made of the horsekeepers down at the stables (D). The reply was—"Yes, the dog had passed through the gate (D) some time before." Taking advantage of my occupation and the absence of his master, Bully had left the house, and taken his way to the cantonment by the only path by which he could have escaped unnoticed by the peon—that shown by the dotted line.

In this necessarily short account I have hardly done justice to Bully's diplomatic powers, but most of your readers will appreciate the intelligence that led the dog to successfully elude the watch set over him.

E. H. PRINGLE

A SMALL English terrier belonging to a friend has been taught to ring for the servant. To test if the dog knew *why* it rang the bell he was told to do so whilst the girl was in the room.

The little fellow looked up in the most intelligent manner at the person giving the order (his master or mistress, I forget which), then at the servant, and refused to obey, although the order was repeated more than once.

The servant left the room, and a few minutes afterwards the dog rang the bell immediately on being told to do so.

Royal Institution, March 14 JOHN RAE

OBSERVING the remarks of Mr. G. Henslow (NATURE, vol. xix. p. 433) in reference to "abstract reasoning" as not to be observed in the lower animals, it has occurred to me that the following facts may have a useful bearing on this subject:—My sister, who lives just opposite to my own house, possesses a cat (now about thirteen years old) whose intelligence is very remarkable. He has the habit of making use of the knocker of a side door, which is just within his reach as he stands on his hind legs, whenever he desires admission. A single knock is tried in the first instance, but if this is not answered promptly it is followed by what is known as a "postman's knock;" if this is not successful, trial is then made of a scientific "rat-tat" that would not disgrace a west-end footman. I should say that "Minnie" holds the knocker in his paw as we should hold it in our fingers, and not by simply tipping it up. How far this practice involves "abstract reasoning" I will not say, but something like an approach to it is suggested, for he was never taught to knock at the door, and adopted the habit some three years ago, evidently to gain admittance, very often to the annoyance of my sister's family, who have occasionally been disturbed in this way at unseemly hours. I should be sorry in thus referring to the sagacity of poor pussy (who is now also somewhat feeble) to reflect upon him by noticing some other of his peculiarities, one of which is his fondness for a little brandy and water and other alcoholic stimulants; but I think what I have referred to may be interesting to Mr. Henslow or some other of your correspondents, and it is within my own knowledge and observation. G. M.

March 15

MR. HENSLOW asks for "cases of purely abstract mental reflection in animals," and in reply I mention a case in Somersetshire of a kitten about half grown, at a house where I was stopping, having mental reflection of some sort.

I was sitting in one of the rooms, the first evening there, and hearing a loud knock at the front door, was told not to heed it, as it was only this kitten asking admittance. Not believing it, I watched for myself, and very soon saw this kitten jump on to the door, hang on by one leg, and put the other fore-paw right through the knocker and rap twice.

The knocker was an ordinary-shaped one fixed in the centre of the door, half way up; the top part of the door was glazed. I saw this performance dozens of times afterwards, and often used to put the kitten outside to see it done. It was never known to knock when any one stood in the garden, but if one went in-doors and shut it outside, in a few minutes came the usual knock.

A sister kitten to this one was never known to knock, but sat on the doorstep and entered when the door was opened, and in nine cases out of ten the knocks were successful.

This kitten was never taught in any way; it would knock at both front and back doors. I should like to know if Mr. Henslow considers this practical or abstract reflection; the result was *practical*. MAURICE BELSHAM

Simla Cottage, Barnes

THE explanations by Mr. Nicols (NATURE, vol. xix. p. 433) fail to convince me that the rats cut the pipes to get at the water. I have seen the edge of joists cut or gnawed about eight inches above the ground, where the rat would have to stand on its hind legs to do it—What was that for? Again, why does our cat scratch the legs of the kitchen table? It seems to me that rats are often like children, they must be doing something to work off the energy within them, and fill up the time, and they often do things without any definite reason. Lastly, if the water is at high pressure especially do they stop to drink the water at all? It also runs in my mind that the rats cut the lead pipes where there was plenty of clean water without doing so.

Glasgow, March 17 W. P. BUCHAN

I BEG to thank Mr. Nicols for his courtesy in supplying the missing links of evidence in the rat cases (NATURE, vol. xix. p. 433), cases which may, I think, be applied with reference to Mr. Henslow's difficulty concerning "abstract mental reflection;" for it seems to me now that the most probable supposition is that the rat-community had learned through experience (likely got accidentally in cutting pipes which obstructed their operations) that such-like pipes at times contain water, and by exercise of reason came to the conclusion that it was worth while to make the exploration in the instances given.

I give the following as told me by my wife—now dead—who personally witnessed the transaction on various occasions:—At her sister's house in Kent a donkey which, when not employed by the children, grazed in a field with some cows, was in the regular habit of acting as follows:—At the usual hour for the cows to come home to be milked the donkey lifted the latch of the field gate, opened and held back the gate (which would otherwise have swung close again) till all the cows passed out, then allowed the gate to shut, and went home with the cows. Of

course no one taught the donkey to do this; but the quadruped gave the biped a practical lesson, from which I am not aware that they drew the abstract verbally formulated conclusion that reason may be exercised without rhetoric.

March 14 HENRY MUIRHEAD

I BELIEVE that instances of rats gnawing through water-pipes are frequent. Two have come to my knowledge during the past fortnight. The one instance occurred at the house of a gentleman near West Hartlepool; in the other case a large hole, 3¼ inches long, and varying from 7/8ths of an inch to 1⅛th inch in breadth, was gnawed in the fresh-water pipe of the screw-steamer *Mary Coverdale*. A portion of this pipe, containing the hole, was cut off, and is preserved by me; it is a stout leaden pipe, a quarter of an inch thick, and with a diameter of 2⅝ inches. It is very doubtful whether there was any flaw before the hole was begun.

West Hartlepool

Distribution of the Black Rat

PERHAPS some of the readers of NATURE may be able to throw some light on the present geographical range of the Black Rat (*Mus rattus*, L.). In the early part of 1877 some individuals of this species came on board the steamship *Lady Frances* either at Bombay or at Rangoon, but, as the captain believes, at the latter port. The animals multiplied on board the vessel, and in August last I had the pleasure of receiving from the ship a living specimen, which was at once forwarded to the Zoological Gardens in Regent's Park, where, I believe, it may still be seen. In a "Catalogue of the Mammals of the Sahara," by my friend, Canon Tristram, F.R.S. (*vide* "The Great Sahara," p. 385), the author states that the "Far el Kla," as the black rat is called by the Arabs, "still maintains its position" in the Algerian Sahara. And I was yesterday presented by Mr. F. Donald Thompson, of Seaton-Carew, with a skin of *Mus rattus* from New Zealand. This example, like those from Burmah, was brought over by a vessel (the *Trevelyan*) which loaded grain at Lyttelton, in the province of Canterbury, New Zealand, where the rats embarked. In August, 1878, Dr. Sclater, F.R.S., was good enough to inform me that "*Mus rattus* has rather an extensive range over Europe and Western Asia," and added, "I fear it would not be possible to state it very exactly." But it is evident that the range of the species is much wider, as it is known to occur in North Africa, British India, and New Zealand; and it is also said, by Prof. Bell and Mr. Macgillivray, to have been carried to America and the South Sea Islands by ships. I should be glad to have further evidence as to its occurrence in Burmah, and it would be also desirable to know if it is found in the Malay Archipelago, China, Japan, or Australia. Dr. Peters, of the Zoological Museum at Berlin, assured me, in June last, that the species was extremely rare, if not actually extinct, in Germany, and showed me the only specimen in the fine collection under his care—an old and faded skin from Hanover. The animal lingers in one old building at Stockton-on-Tees, and there is clearly a possibility of its being reintroduced in many seaport towns through the agency of ships.

West Hartlepool, March 11 R. MORTON MIDDLETON

The United States Fisheries

IN your review of the report of the United States Commission of Fish and Fisheries, you say you are of opinion there is almost no difference between *Salmo salar* and *Salmo quinnat*. My friend Prof. Baird sent me his report some time since, and also forwarded several thousand eggs of *Salmo quinnat* for experiment in the hatching tanks of the Southport Aquarium. The eggs hatched out remarkably well, a very small percentage only being lost, and have proved much more hardy and tenacious of life than any *Salmo salar* I ever had to do with, and very much easier to feed. *Salmo salar* have never done well except when fed on the minute red worms found on the mud in the beds of some rivers and streams (our supply was obtained from the Thames). *Salmo quinnat*, however, live well, and grow faster on the roe of fish (refuse from the fish market), such as whiting, than *S. salar* will on anything. From what I have seen of them I quite agree with Prof. Baird in his admiration of this member of the salmon family, and I share his surprise that it has attracted so little attention among English fish-culturists. It would certainly be a most valuable addition to our food-fishes, stronger, and apparently of more rapid growth than our native species. On the continent, and in New Zealand and other countries, it is most greedily sought after, and each season for several years past an agent has carried from America to France, Germany, and other countries, large consignments of the ova. In England, so far, it appears to have been quite neglected.

Hill Fold, Bolton, March 15 CHAS. L. JACKSON

Plovers in the Sandwich Islands

I CAN vouch for the truth of the visit of golden plovers to the Sandwich Islands mentioned by Prof. A. Newton in NATURE, vol. xix. p. 433. They are very numerous during the winter from November until March. I do not know the scientific name, but I have shot a great many on Oahu and Hawaii.

If it will help Mr. Newton in the solution of the very interesting question he raises I may mention that M. Baillière, Consul-General for France at Honolulu, is in the habit of sending specimens of birds to (I think) the Jardin des Plantes, Paris, where doubtless a specimen might be found.

Hertford, March 15

Unscientific Art

IN the *Graphic* for December 28 there appeared a sketch of a man taking a reading on a marine barometer, on board the *Sarmatian*, during the voyage of the Marquis of Lorne to Canada. To see the scale better by the light of his lantern, the observer is represented as sloping the barometer at an angle of about 30° from the vertical.

JOHN W. BUCK

New Kingswood, Bath

ON THE POSSIBILITY OF EXPLAINING THE CONTINUANCE OF LIFE IN THE UNIVERSE CONSISTENT WITH THE TENDENCY TO TEMPERATURE-EQUILIBRIUM

THE idea of the ultimate final cessation of all physical change and life in the universe[1] has been contemplated by many physicists with some dissatisfaction, and with the desire if possible to find some explanation or physical means by which so apparently purposeless an end is averted, and of avoiding the necessity for assuming in past time a violation of physical principles at present recognised to exist.[2] Several attempts have been made to surmount the difficulty,[3] but apparently with no generally satisfactory result. Having given much time to physical problems having a relation more or less to this question, and having always kept the question itself in view, I should like to submit the following conclusion to the readers of NATURE as an attempt to solve the difficulty, though what I have to bring forward is probably not entirely new, as considerations partially tending towards the same final result have already been published by Mr. James Croll, *Phil. Mag.*, May, 1868, "On Geological Time;"[4] and Mr. Johnstone Stoney, "On the Physical Constitution of the Sun and Stars," *Proc.* of the Royal Society, 1868-69. The groundwork of what I have to suggest may be described in a few words.[5]

Taking a general view of the universe, we may consider it as so much matter, which contains a certain quantity of energy. Let us suppose for illustration the energy of

[1] Thomson, "On the Universal Tendency in Nature to the Dissipation of Mechanical Energy," *Phil. Mag.*, October, 1852; Clausius, Ninth Memoir, *Pogg. Ann.*, July, 1865; see also Tait, "Recent Advances in Physical Science," second edition, p. 22.

[2] The allied idea of the whole universe tending to agglomerate into one mass under the action of gravity, the notion of instability thus involved, all this has something incongruous and unnatural about it that appears to be scarcely in harmony with the orderly working of physical phenomena, and would seem to point to the necessity for some additional explanation.

[3] Grove, "Corr. of Physical Forces," p. 67; Rankine, "On the Reconcentration of the Mechanical Energy of the Universe," *Phil. Mag.*, November, 1852, &c., &c.

[4] Also *Quarterly Journal of Science*, July, 1877.

[5] The same problem was considered by the writer in special reference to Le Sage's theory of gravitation in the *Quarterly Journal of Science* for July last, but my present object is to deal with the question entirely independently of any special theories, and solely on the basis of generally accepted facts, or facts which if not known would be in harmony with or deducible from those which are known.

this matter to be raised to such a degree that the whole forms a gas, consisting of separate or dissociated molecules, filling space uniformly. This would evidently be the result of applying sufficient heat, just as for example a gas consisting of compound molecules breaks up into its elementary molecules when sufficient heat is applied, the molecules being unable to aggregate into groups on account of the expansive action of the high temperature. When the temperature of the gas is lowered the molecules (as is known) commence again to aggregate into groups, *i.e.*, to cluster about common centres in chemical union. So in the case of the universe, in the imaginary instance of an (adequately) extremely high temperature, we should have the entire universe consisting of separate molecules or forming a very rarefied gas, the molecules being unable to aggregate into distinct groups under the action of gravity, owing to the enormous velocities of the molecules. The molecules would simply rebound from each other in straight lines, according to the principles of the kinetic theory of gases.[1] Let us suppose, now, the excessive temperature to fall, or in other words the total energy to diminish. Then the molecules would commence to cluster into groups (forming masses) under the action of gravity, the mean size of such aggregated groups of molecules becoming greater as the temperature is less, and the number of such groups diminishing in the same proportion. At first, by a slight fall of temperature we should have a large number of small groups (or clusters) of molecules; by a further fall of temperature a further clustering of molecules under the action of gravity would occur, *i.e.*, the size of the separate masses would increase and their number diminish. The case is, in broad principle, exactly parallel to that of a compound gas when subjected to extreme variations of temperature, indeed as far as the purely mechanical considerations are concerned, it is only a question of scale.[2] We know that when a compound gas whose molecules possess a high complexity has been heated up to the temperature of dissociation, and the temperature is gradually lowered, then at first only a clustering of elementary molecules takes place; but as the temperature is further lowered, these compound molecules may cluster together to form compound molecules of a secondary order or higher degree of complexity (*i.e.*, molecular clusters of a larger mass). Thus the mean mass of the clusters of molecules in the gas increases as the temperature is lowered, and the number of such clusters (or centres of aggregation) diminishes correspondingly.

We will therefore suppose that the universe has attained a final state analogous to this, *i.e.*, such that the mean mass of a cluster of molecules (a stellar mass) and the number of such clusters (stellar masses) is such as exactly to represent that which must exist by the actual mean temperature of the universe. But it may be said, as far as we are able to appreciate and judge of the universe, it certainly appears as if the entire universe were losing its heat in the ether of space, and that this final state of things (equilibrium) were not yet attained. But it may be urged, in reply, we are judging of the entire universe from the point of view of a single stellar sun to which we belong. It is as if we were to judge of the temperature equilibrium of a gas from the point of view of a single molecule (or of a few others surrounding it), in which case it is certain we should be unable to form an idea of the state of temperature equilibrium of the gas. It is known to be a demonstrated consequence of the kinetic theory that the utmost diversity exists among the velocities of the molecules of a gas, or the temperature from molecule to molecule. In order to have a true idea of the state of temperature of the gas, we must investigate the conditions of a region containing some thousands of millions of molecules (any appreciable region or space actually containing this number). So in order to have an adequate idea of the state of temperature equilibrium of the universe, we should require the mean temperature (state of energy) of a region containing some thousands of millions of stellar masses, not the narrow view we have from one of these, and the velocities of the few we have measured—not to speak of the countless dark suns that may exist in space, and about whose velocities we know nothing. Mr. Croll has pointed out[1] how it is probable that such dark suns may possess exceptionally high velocities, as the bright (visible) suns would naturally have lost in the collisions which developed their heat part of their normal velocity of translation, the translatory motion having been partly lost by conversion into heat. In the parallel case of a gas, it is a known fact that even if the mean temperature of the gas be low (less than normal temperature), some molecules in certain parts must acquire in the accidents of collision enormous velocities, and are thrown into very forcible vibration at the encounters, such that they would become luminous if we were able to visualise single molecules. In other words, if *all* the molecules of the gas possessed the velocities of these single molecules (relatively few in number), the entire gas would appear like a flame. So in like manner, though single stars in the universe may be luminous, it (by analogy) by no means follows that this at all approximately represents the mean condition of the entire universe. This luminous state might be quite exceptional, and the mean temperature of the universe might be exceedingly low for aught we may know. We may happen to be in a part where the mean temperature of the component matter is exceptionally high, as, of course, from the fact of our being in existence, we must be in a part which is suited to the conditions of life. What is there, then, to oppose the inference that the mean temperature of the universe may be such that each stellar mass (or detached portion of matter, glowing or not) on an average receives as much heat from others as it emits itself, in analogy to the molecules of a gas in equilibrium of temperature; and this does not prevent single stellar masses (in analogy single molecules of the gas) from acquiring exceedingly high temperatures, indeed, they would naturally acquire this from the encounters in certain instances, according to the accepted principles of the kinetic theory.

As regards the state of aggregation of the matter of the universe as dependent on the energy, it would clearly in the same way be misleading if we were to attempt to judge of the mean state of aggregation from the point of view of the few masses in our immediate neighbourhood (or the narrow range of the universe overlooked by us). Thus, to recur to the smaller scale illustration of a gas. In the case of the molecules of a compound gas in a state of temperature-equilibrium, it is known that some of these compound molecules (representing a cluster of molecules aggregated about a common centre) must acquire now and then, in the accidents of collision, velocities corresponding to dissociation temperature. The compound molecule is thus broken up into its components at the collision, these components clustering together again in some other part of the gas, the *mean* state of aggregation remaining unchanged. Thus it would evidently be misleading to judge of the state of aggregation of the molecules of a compound gas from the point of view of an inappreciable region, containing a few hundred thousand molecules, which might in the accidents of collision have become exceptionally heated. In order to judge of the state of aggregation of the gas, we must investigate that of an appreciable region, containing some thousands of millions of molecules. So in the case of the universe, it

[1] The deflection from a straight line owing to the feeble action of gravity in the case of single molecules, would evidently be inappreciable.

[2] There is, of course, this detail of difference, viz., that while the aggregation of molecules about a centre in chemical action is limited, the aggregation in the case of gravity is unlimited. We merely apply in principle the same general considerations to molecules aggregated into clusters (lumps) under chemical action, as to molecules aggregated into lumps under gravific action (stellar masses).

[1] *Quarterly Journal of Science*, July, 1877.

would obviously be fallacious if we were to form an estimate of the general state of aggregation from that of the few masses we can judge of in our immediate vicinity; but we should require to know the condition of a region of an extent that we have no chance of overlooking, and under the principles of the kinetic theory, the local variations of the states of aggregation (themselves depending on local variations in the velocities of the masses) would fluctuate within wide limits. In order to have an idea of the actual (mean) state of aggregation, a being would be required that could (on comparative scale) sweep over the universe with the same facility as we sweep through or examine regions in a gas representing a multiple countless millions of times that of the mean distance of the detached portions of matter composing the gas.[1]

We are led to apply the principles of the kinetic theory to the case of the universe not so much as a speculation, but rather as a necessary deduction following from the known principle that detached masses moving freely in space (as the stellar masses are observed to do) and at such distances apart that gravity between the several masses is incompetent to deflect the path of the masses appreciably, must move in straight lines, and have their motions regulated under the mutual encounters in accordance with the principles of the kinetic theory. Only in the relatively near approach of the masses to one another does gravity come sensibly into play and deflect the path, causing under certain conditions rotation about a common centre (double stars), or, perhaps, by almost direct impact, nebulæ with but feeble rotation, &c.[2] To carry the analogy again to the smaller scale-case of a gas, it is there known that the molecules are in some cases feebly impelled towards each other at a near approach, the path of the molecule being thus deflected at its termination, whereby the conditions are given for causing a temporary rotation of the pair of molecules about a common centre, in an analogous way. The relatively vast distances of the stellar masses, compared with their dimensions, would involve, as a rule, an extremely long mean path before the encounters, corresponding to a proportionally long epoch of time adapted to the conditions of life. The apparent extreme simplicity of the means to the end by the application of the kinetic theory to the case would at least seem not to be out of harmony with its truth.

Thus the final conclusion to which these considerations lead would be that the universe has attained its final state of temperature equilibrium (if we set no fixed limit to its past existence), in the sense that if we were able to measure the temperature (or contained energy), of a sufficient number of masses through a sufficiently extensive region, we should find that in every such *equal* region throughout the universe the temperature (or contained energy) would be the same; just as (on a smaller scale) in the case of a gas, if we could measure the temperature of some thousands of millions of molecules in a given region, we should find that though the temperature differed to a practically unlimited extent from molecule to molecule, yet the temperature of every such equal region was the same.

[1] Just as in the case of a compound gas, the *uniformity* of temperature, of states of aggregation, &c., does not apply to the individual unit lumps of matter (molecules) forming the gas [which may be in vastly different states from one to the other]—but to unit *volumes* containing vast numbers of such units; so in the case of the universe, the uniformity of temperature, state of aggregation, &c., would not apply to the unit lumps of matter (stellar masses) but to unit volumes. In fact the universe may be regarded as a larger scale gas, with the difference that the central force producing the aggregated lumps of matter that move as wholes is not chemical action but gravific action. If we imagine (merely for illustration) a being on relative scale situated on a single compound molecule of a gas in a state of normal temperature equilibrium; this minute being would observe vast differences of temperature and of states of aggregation around him (some molecules in scattered parts glowing in a state of dissociation, &c.), and he would form a perfectly wrong judgment of the state of the gas from such a narrow point of view. So the observer connected with one unit lump of matter of the universe (stellar mass) can form no idea of the state of the rest from his narrow point of view.

[2] The occasional flashing out of stars, as if due to some sudden convulsion that might be referred to collision as a suitable cause, is a notorious fact in astronomy; though, from the extremely limited view of the universe that we possess, it would be unreasonable to expect such phenomena to be of frequent occurrence.

So in an analogous way as regards the *state of aggregation* of the matter of the universe, since this depends on the temperature, it would follow, assuming an indefinite past time, that the mean state of aggregation of the matter, like the mean temperature (mean energy), is the same throughout, *i.e.*, the average size of the separate masses, or the number in unit of volume (taking sufficiently large units of volume for comparison) would be equal throughout, though indefinite fluctuations of dimensions would occur from one mass to another, in analogy with the fluctuations of velocity from one mass to another.

It would further follow from the known principle that molecules of different densities (molecular weights) tend forcibly to become uniformly diffused, that by an indefinite past duration of the universe all the matter must be uniformly diffused if (as in the case of uniform velocity and uniform state of aggregation) regions of sufficient extent could be taken for relative comparison. This again resembles in principle the smaller scale case of a gaseous mixture, where it is known that the small detached portions of matter (molecules) are uniformly mixed, only when appreciable regions containing vast multitudes of molecules are examined, but that there is room for considerable local fluctuations of mixture (such as if only a few hundred thousand molecules were examined).

Thus it appears that the kinetic theory, applied to the universe, would have the peculiar characteristics of allowing almost indefinite local fluctuations of temperature, of states of aggregation, and of composition, of the matter forming the universe within regions very extensive, absolutely speaking, but infinitesimal, relatively speaking (*i.e.*, in comparison with the boundless universe), these regions being amply extensive enough to allow an amount of activity and variability of energy adapted to the conditions of life; while at the same time the principles of the theory, from their very nature, involve perpetually recurring and yet indefinitely variable changes within certain localised limits, the constitution of the vast whole (looked at broadly) remaining uniform throughout.

S. TOLVER PRESTON

FRITZ MÜLLER ON A FROG HAVING EGGS ON ITS BACK—ON THE ABORTION OF THE HAIRS ON THE LEGS OF CERTAIN CADDIS-FLIES, &c.

SEVERAL of the facts given in the following letter from Fritz Müller, especially those in the third paragraph, appear to me very interesting. Many persons have felt much perplexed about the steps or means by which structures rendered useless under changed conditions of life, at first become reduced, and finally quite disappear. A more striking case of such disappearance has never been published than that here given by Fritz Müller. Several years ago some valuable letters on this subject by Mr. Romanes (together with one by me) were inserted in the columns of NATURE. Since then various facts have often led me to speculate on the existence of some inherent tendency in every part of every organism to be gradually reduced and to disappear, unless in some manner prevented. But beyond this vague speculation I could never clearly see my way. As far, therefore, as I can judge, the explanation suggested by Fritz Müller well deserves the careful consideration of all those who are interested on such points, and may prove of widely extended application. Hardly anyone who has considered such cases as those of the stripes which occasionally appear on the legs and even bodies of horses and apes—or of the development of certain muscles in man which are not proper to him, but are common in the Quadrumana—or again, of some peloric flowers—will doubt that characters lost for an almost endless number of generations, may suddenly reappear. In the case of

natural species we are so much accustomed to apply the term reversion or atavism to the reappearance of a lost part that we are liable to forget that its disappearance may be equally due to this same cause.

As every modification, whether or not due to reversion, may be considered as a case of variation, the important law or conclusion arrived at by the mathematician Delbœuf, may be here applied; and I will quote Mr. Murphy's condensed statement ("Habit and Intelligence," 1879, p. 241) with respect to it: "If in any species a number of individuals, bearing a ratio not infinitely small to the entire number of births, are in every generation born with any particular variation which is neither beneficial nor injurious to its possessors, and if the effect of the variation is not counteracted by reversion, the proportion of the new variety to the original form will constantly increase until it approaches indefinitely near to equality." Now in the case advanced by Fritz Müller the cause of the variation is supposed to be atavism to a very remote progenitor, and this may have wholly prevailed over any tendency to atavism to more recent progenitors; and of such prevalence analogous instances could be given.

CHARLES DARWIN

Blumenau, St. Catharina, Brazil,
January 21, 1879

MY DEAR SIR,

If I remember well, I have already told you of the curious fauna which is to be met with between the leaves of our Bromeliæ. Lately I found, in a large Bromelia, a little frog (*Hylodes ?*), bearing its eggs on the back. The eggs were very large, so that nine of them covered the whole back from the shoulders to the hind end, as you will see on the photograph accompanying this letter, Fig. 1 (the little animal was so restless that only after many fruitless trials a tolerable photograph could be obtained). The tadpoles, on emerging from the eggs, were already provided with hind-legs; and one of them lived with me about a fortnight, when the fore-legs also had made their appearance. During this time I saw no external branchiæ, nor did I find any opening which might lead to internal branchiæ.

FIG. 1.

There is here another locality in which a peculiar fauna lives, viz., the rocks of waterfalls, which are of very frequent occurrence in almost all our mountain rivulets. On these rocks, along which the water is slowly trickling down, or which are continually wetted by the spray of the waterfall, there live various beetles not to be met with anywhere else, larvæ of diptera and caddis-flies, and a tadpole remarkable for its unusually long tail.

The pupæ of caddis-flies living on the rocks of waterfalls (I examined three species belonging to the *Hydropsychidæ*, *Hydroptilidæ*, and *Sericostomatidæ* [*Helicopsyche*]), as well as those living in the Bromeliæ (a species belonging to the *Leptoceridæ*), are distinguished by a very interesting feature. In other caddis-flies the feet of the second pair of legs (and in some species those of the first pair also) are fringed in the pupæ with long hairs, which serve the pupa, after leaving its case, to swim to the surface of the water for its final transformation. Now neither on the surface of bare or moss-covered rocks, nor in the narrow space between the leaves of Bromeliæ, the pupæ have any necessity, nor would even be able, to swim, and in the four species living on such localities which I examined, and which belong to as many different families, the feet of the pupæ are quite hairless, or nearly so, while in allied species of the same families or even genera (*Helicopsyche*) the fringes of the legs, used for swimming, are well developed.

FIG. 2.

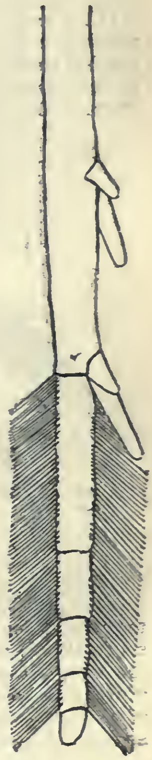

FIG. 3.

FIG. 2.—Tibia and tarsus of the two pairs of legs of the pupa of a species of Leptoceridæ, inhabiting Bromeliæ. FIG. 3.—The same of a nearly allied species inhabiting rivulets.

This abortion of the useless fringes in the caddis-flies inhabiting the Bromeliæ and waterfalls appears to me to be of considerable interest, because it cannot be considered, as in many other cases, as a direct consequence of disuse; for at the time when the pupæ leave their cases and when the fringes of their feet are proving either useful or useless, these fringes as well as the whole skin of the pupa, ready to be shed, have no connection whatever with the body of the insect; it is therefore impossible that the circumstance of the fringes being used or not for swimming, should have any influence on their being developed or not developed in the descendants of these insects. As far as I can see, the fringes, though useless, would do no harm to the species, in which they have disappeared, and the material saved by their not being developed appears to be quite insignificant, so that natural selection can hardly have come into play in this case. The fringes might disappear casually in some individuals; but, without selection, this casual variation would have no chance to prevail. There must be some constant cause leading to this rapid abortion of the fringes on the feet of the pupæ in all those species in which they have become useless, and I think this may be atavism. For caddis-flies, no doubt, are descended from ancestors which did not live in the water, and the pupæ of which had no fringes on their feet. Thus there may even now exist in all caddis-flies an ancestral tendency to the production of hairless feet in the pupæ, which tendency in the common species is victoriously counteracted by natural selection, for any pupa, unable to swim, would be mercilessly drowned. But as soon as swimming is not required and the fringes consequently become useless, this ancestral tendency, not counterbalanced by natural selection, will prevail, and lead to the abortion of the fringes.

I do not remember having seen, in any list of cleistogamic plants, the Podostemaceæ. These curious little aquatic plants, which Lindley placed near the Piperaceæ, Kunth between the Juncagineæ and Alismaceæ, and which Sachs considers as being of quite dubious affinity, cover densely the stones in the rapids of our rivers; on the branches which come above the surface of the water, there are pedunculated, open, fertile flowers; but there are numerous sessile flower-buds also on the branches,

which probably remain submerged for ever; I have not yet ascertained whether these submerged flowers are fertile; if they are so, they can hardly fail to be cleistogamic.

FRITZ MÜLLER

A STUDY IN LOCOMOTION[1]

II.

III. *The Paces of the Horse.*—Every one can recognise whether a horse is walking, trotting, or galloping, and yet few would be able to point out the rhythm and order of succession of the movements of the limbs in different paces. These movements, in fact, succeed each other

FIG. 8.—Registering apparatus for horse's paces.

too rapidly for the eye to follow them, and their rhythmic succession is more readily perceived by the ear than by the eye. It is indeed ordinarily by the ear that we become aware of a horse's pace. When at each return of the step (*revolution du pas*) we hear two distinct strokes of the hoofs, we call it an amble, or a trot; three

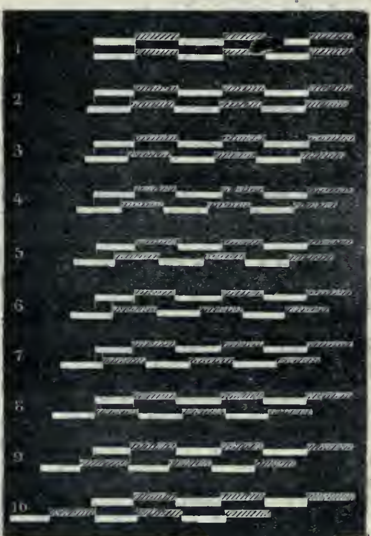

FIG. 9.—Synoptic table of the different paces of the horse, after the classic authors: 1, amble; 5, foot-pace; 8, trot, &c.

strokes unequally separated denote a gallop; lastly, four strokes indicate a foot pace. But these paces may be more or less irregular, variable, or crippled; besides that, when an animal passes in a very short space of time from one pace to another, how shall we decide upon the manner in which the transition is effected? To clear up these points great efforts have been made by horse-

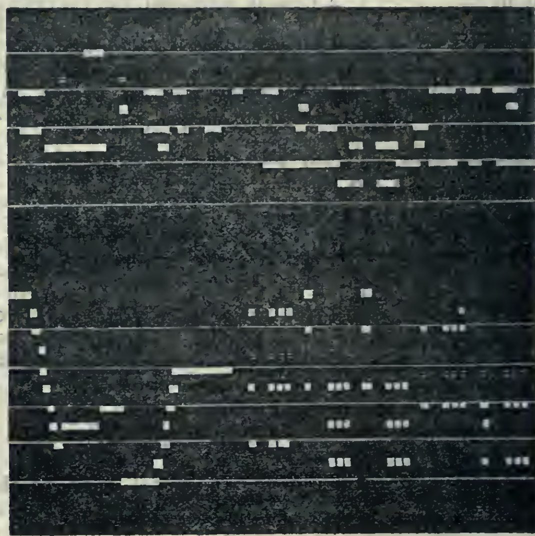

FIG. 10.—Notations of two airs, A and B, executed upon the keyboard of a harmonium.

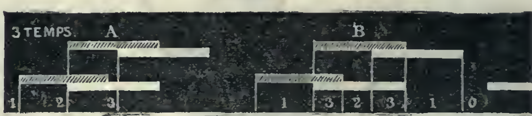
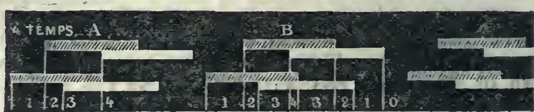
trainers and veterinary surgeons, to whom the questions involved are of considerable importance.

Now, as I have just said, the ear judges better than the eye as to the rhythm of successive movements, but in order to demonstrate the production of these rhythmic strokes in twos, and threes, and fours, it is essential to know to which foot each separate sound is to be attributed. Ingenious experimenters have attached to the four feet of the horse bells of different tones, but in perfect harmony with each other. Varied melodies or harmonies are thus produced, according to the succession or synchronism of the strokes. But such an arrangement would certainly not give the length of time each foot remained upon the ground, therefore the question of the paces of the horse has not been entirely resolved even by this method. Turn to any special treatises on the subject, and you will see that beyond the amble, the downright



Gallop of 3 steps. A, indications of the three steps; B, indications of the number of feet which form the support of the body at each instant of the gallop of 3 steps.



Gallop of 4 steps.

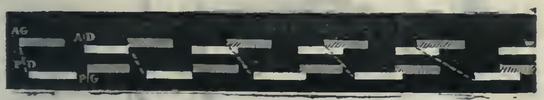
FIG. 11.—Notations of the gallop of 3 and 4 steps.

trot, and the three-step gallop, there is, perhaps, not a single pace respecting which contradictory theories are not held. In face of the difficulties of this problem, you will doubtless foresee what will be my conclusion; it will be necessary to have recourse to the graphic method which will solve the question in the simplest manner possible.

[1] "Moteurs animés; Expériences de Physiologie graphique." Lecture by Prof. Marey at the Paris meeting of the French Association, August 29, 1878.

Let us take up the question at the point to which it has been brought by the experimenters to whom I have just alluded. The succession of the movements of the horse's legs, since it is rhythmical, and since also we produce

Transition from the trot to the foot-pace.



Transition from the trot to the gallop of 3 steps.

Transition from the gallop of 3 steps to the trot.

FIG. 12.—Transitions between different paces.

from each foot a different tone, forms a sort of music. Now this music is very simple, because it is only composed of four tones. The following arrangement will

FIG. 13.—Diagram of the tracks of horses in different paces.

permit us to obtain the notation of this music, written by the horse himself. Under each of the horse's shoes we place a bag (*ampoulle*) full of air, which, by means of a tube is connected with another similar small bag, which, by its changes in bulk, acts upon a pencil. When the horse plants its foot upon the ground, it raises a pencil, which remains raised as long as the foot is kept down. Four pencils are placed in position, connected with the four under the horse's feet, and these pencils placed in a right line parallel with the axis of the cylinder, spontaneously trace the succession and duration of each setting down of a foot.

Fig. 8 shows the arrangement of the apparatus. The four limbs of the horse bear four india-rubber tubes, which converge to the hand of the jockey, and so to the inscribing apparatus on the cylinder which he holds.

The results thus obtained by the different paces are shown side by side to the number of ten in Fig. 9. Each foot, as in musical notation, has its characteristic sign, by the height of which the symbol of its stay on the ground is traced. We will agree that the fore feet shall mark upon the lines above, the rear feet upon the lines below. Now the horse can, with his four feet, execute the most rapid movements, and yet nothing will be wanting from the inscription. And in the first place, in order to give you confidence in the employment of this method, let us show you how it solves a problem still more difficult. When a clever pianist passes his fingers over the keyboard, who could describe the movements that he executes, say what note has been touched first, and for how long, then what notes followed, together or separately, with their rhythms and tones? But let us write down these movements, and when they are fixed upon paper we can analyse them with ease.

In the apparatus which I use, the keys act by pressure upon the bags of air connected by tubes with other bags, which cause pencils to move. See with what ease these little pencils reproduce all the movements of the fingers passing over the mute keyboard; you will presently see the instrument in operation. I present to you, first of all, what it has just written (Fig. 10). Observe these notes drawn up in gamuts and arpeggios, these varied accords, these changes of tone where sharps and flats reveal themselves by strokes drawn longitudinally. This instrument, which is now in action for the first time, has been constructed by our colleague, M. Tatin, whose skill has already excited the admiration of all who know him.

And now that you no longer doubt, I trust, the faithfulness of the method, let us analyse the tracings on the diagram I have just now shown you (Fig. 9). In order to understand it fully, let us borrow the ingenious idea of Dugès, and compare the horse or any other quadruped to two bipeds walking one behind the other. If the two walkers execute the same actions at the same time, that is to say, if they both simultaneously raise and set down the right foot and then the left, it is the *amble* (No. 1) which is produced. The ear only detects two sounds at each combined step, because two feet touch the ground together. This is an example of *lateral bipedal* movement. If the rearmost walker has half finished the resting of one of his feet when the foremost walker plants the same foot on the ground, it represents the *foot-pace.* Here the four footsteps are separate, and the ear distinguishes four equidistant sounds; the order of succession would be (commencing to count by the right foot), *foremost right*, *rearmost left*, *foremost left*, *rearmost right.* Let us imagine that the rearmost walker makes movements absolutely the reverse of those of the walker in front, that is to say, that one of the right feet strikes the ground when the other right foot rises from it, we shall then have the trot. Two feet will be always associated and will give but one sound, and these feet will exemplify *diagonal bipedal* motion.

Such, then, is our knowledge of the rhythm of paces, or at least the points upon which all are agreed. But if we desire to gather from divers authors the definition of more complicated paces, intermediary to those we have

just described, we shall only find, as I have before stated, a number of contradictions between writers holding different views. In the most rapid pace, the gallop, that of three steps,

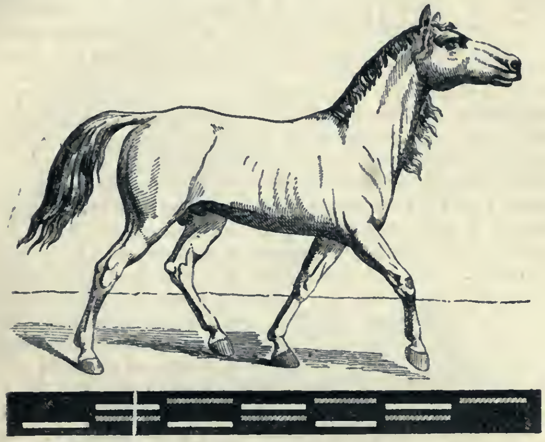


FIG. 14.—Trotting horse represented at the moment of diagonal support.

for example (Fig. 11), the first step is with the hind-foot, upon which the horse falls back after it has raised itself

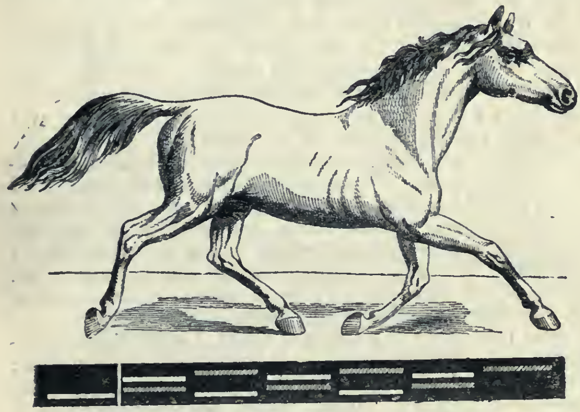

FIG. 15.—Trotting horse at the moment of suspension.

from the ground; then the other hind-foot and fore-foot which is associated with it diagonally fall together, and

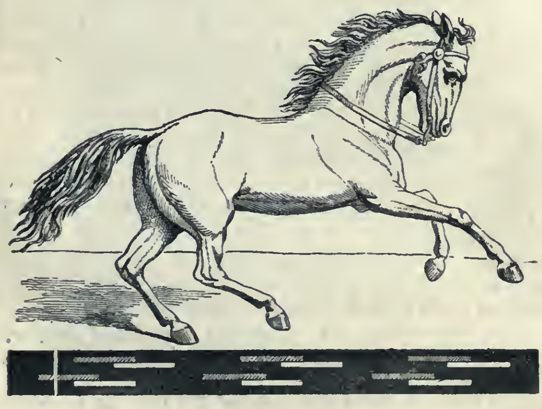

FIG. 16.—Horse at a gallop of three steps. Moment of the first step.

form the second step. Lastly, one hears the other fore-foot fall, and this is the third step.

The gallop of three steps may be distinguished in two forms; the right-hand gallop, in which the right-hand

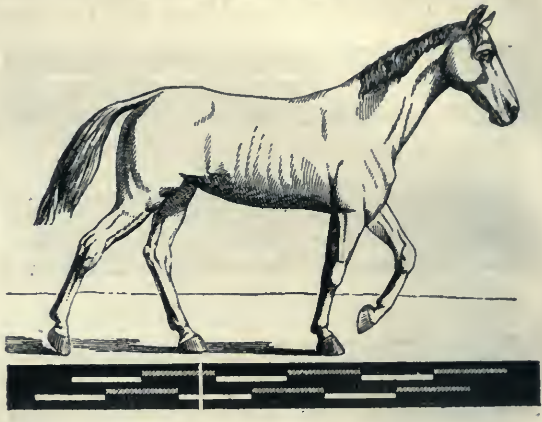

FIG. 17.—Foot pace, with effort of traction.

hind foot reaches the ground last; the left-hand gallop, in which the left fore-foot is the last to reach the ground.

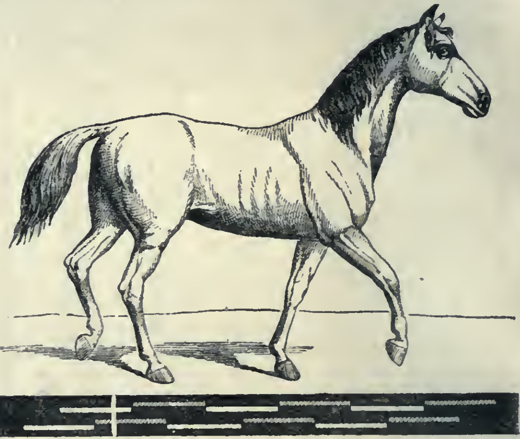

FIG. 18.—Foot pace, moment of diagonal support.

Do we desire to know upon how many feet a horse is supported at different moments of the gallop? Fig. 11

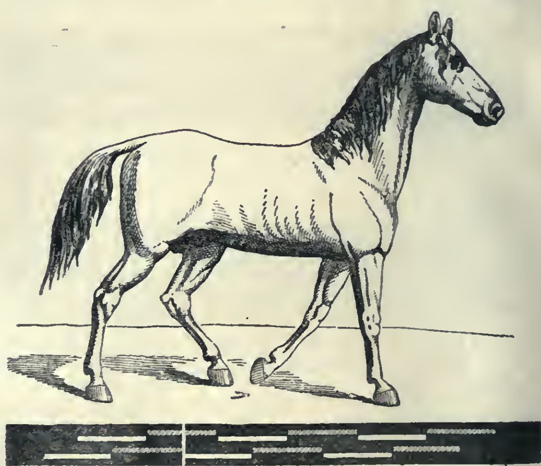

FIG. 19.—Foot pace, moment of lateral support.

responds to this question also. Just as the notation of a piece of music shows how many fingers rest at once upon

the notes on the keyboard, in the same way Fig. 11 shows that the horse, at the moment when he falls back upon the earth, is supported only by one foot; then, when the two diagonal feet strike the ground together in their turn, the horse has at this moment a triple support. Without the notation of paces we had certainly failed to distinguish this series of supports.

The gallop of the racecourse used generally to be considered as a pace of two steps, in which the horse struck the ground alternately with the two fore-feet and the two hind-feet. This gallop shows itself in the notation as a pace of four steps; the tracing dissociates the two fore-feet and the two hind-feet, although they follow each other at a very short interval.

The transition from one pace to another, impossible to determine by direct observation, is clearly inscribed in Fig. 12.

IV. *Artistic Representation of the Horse and other Animals.*—The artistic representation of animals requires a special and varied acquaintance with their peculiarities. Nothing can replace the patient study by which the painter or the sculptor acquires an anatomical knowledge of the limbs of animals and the aspects which they assume in different positions. But if the painter or the sculptor wishes to animate his work, if he wishes to show the horse putting forth its efforts in powerful traction, or to represent it urged rapidly forward in the race, it is necessary to have an exact acquaintance with different paces.

That which is true of the horse is equally so of other animals; but all present among themselves such great analogies in this respect, that if we are acquainted with the paces of the horse, we can represent those of any other animal.

The summary analysis we have just now made of the rhythms of steps in each pace is not yet sufficient to express the attitudes which represent them; we have as yet only examined in connection with these movements one of the two essential ideas. We are acquainted with the relations of time; it is necessary also to become acquainted with the relations of space, that is to say, to know at each moment in what place to find each of the members raised or planted upon the ground. Obliged to abridge this already long discourse, I will not tell you how one determines graphically the phases of the movement of a foot that is raised, but I will show you summarily how we determine the place where each foot is brought down. This indication is furnished by the imprint which the horse leaves upon the ground. M. de Curnieu, Capt. Raabe, and M. Lenoble du Teil have studied with particular care these imprints or tracks of the horse at different paces. The smooth sand of the sea-shore presents a surface admirably adapted for this study. Persons who have acquired the habit, easily decipher such imprints. But in order to render them easily read by every one, we have conceived the idea of giving a different form to the shoes of the fore-feet from those of the hind-feet by furnishing the latter with clamps. The principal paces represented by their tracks have been thrown together in Fig. 13, which I have borrowed from M. Lenoble du Teil. In combining with the idea of the rhythms, that of the place where each foot would be planted, the errors of attitude which disfigure so many *chefs d'œuvres*, would be avoided. You will, perhaps, say that few persons are capable of recognising faults of this kind. On this point one might repeat what Baron Dupin said with respect to perspective in its relation to the art of painting. "In proportion as exact knowledge becomes more widely diffused, many faults which to-day only shock a small number, will shock the general public, and artists will no longer be able to perpetrate them with impunity."

Those artists who at the present time make such praiseworthy efforts for the correct representation of the horse, would find great assistance from making use of the notation of paces. Let us see in what way. Take, for example, the notation of *the trots*. We all grant, in the first place, the possibility of dividing each step into a series of successive instants, ten or twenty, for example. At each of these instants the horse will have a different attitude, but throughout the time the limbs diagonal to each other will be executing the same motions at the same time.

Let us take one of these instants at random and mark it by a vertical line (Fig. 14). The notation shows us that at this instant the right hind-foot and the left fore-foot are planted upon the ground, but that the right fore-foot and the left hind-foot are still raised, and are about to be set down. That is exactly as represented in the figure.

Upon another notation (Fig. 15) we have chosen another instant, that in which the horse is suspended in the air, and when the hind-feet have already quitted the ground, whilst the fore-feet do not yet touch it.

Let us pass on to the pace of the gallop (Fig. 16). The moment chosen is that in which the horse falling back upon the hind-foot has just made his first step. Two limbs in diagonal relationship are about to strike the ground at the same time, namely, the right hind-foot and the left fore-foot, represented as already being lowered towards the earth. As to the right fore-foot, that will strike the ground last, accordingly it is shown as still the furthest removed from the earth.

With regard to the foot pace, which is the most difficult to explain, three instants have been selected on the notation: 1. That where the hind-foot is about to be raised, and where the fore-foot is in the middle of its elevation (Fig. 17). At this moment there are three feet at rest, which only takes place with horses when making an effort of traction. 2. The moment in which the two diagonal feet are raised, the one having just quitted the ground and the other being about to be placed upon it (Fig. 18). 3. The moment when the animal, supported by two feet on the same side, is raising one of its fore-feet and is about to set down one of the hind-feet on the same side (Fig. 19).

These pictures have no other pretensions than to be correct as regards the position of the members; it would be the artist's duty to add elegance of form. But is it not something to have a simple and sure means of representing a horse in any pace and in any phase of the steps in that pace? The employment of the graphic notation would give to the artist the double advantage of representing the paces with truthfulness and of varying them to an extent almost illimitable. Now, imperfection in art is not displayed solely by errors that may be committed, for too often an artist who is thoroughly acquainted with a correct attitude repeats it with regrettable monotony.

(*To be continued.*)

GEOLOGY OF NATAL AND ZULULAND

SOME years have now passed since Mr. Griesbach gave to the Geological Society his paper and map illustrating the geology of Natal and the borders of Zululand. Passing events now give to his investigations the greatest interest, not simply due to the possible light that may be thrown on unsolved, or partly known, problems by the sojourn in that area of the contingent that has lately left our shores, but from the fact that the safety and success of our forces in great measure depends on the surface contour and physical character of the country to be traversed, which are necessarily directly dependent on its geological structure.

Few can have studied a geological map, without noticing the close connection between long lines of escarpment and belts of level plains with particular rocks, or noticing the marked uniformity in direction of strike of geological formations over large portions of the earth's surface; rock series after rock series plunging beneath its neigh-

bour, and disappearing from view, only to be succeeded by higher and higher strata above them. No better example of this could well be found than the map of Natal of Mr. Griesbach; the rocks all run parallel to the sea-coast, striking into the Zulu territory, and dipping steadily the one after the other into high ground, forming the watershed between the Indian and Atlantic oceans. The eastern or seaward belt about fifty miles in width, consists of ancient mica-schists, resting on granite and gneiss seen at the bottom of the deeper valleys, the whole surmounted by the "Table Mountain Sandstone," of carboniferous age, forming extensive plateaux, lying perfectly flat on a horizontal surface of clay-slate, and broken by lines of fault, into a series of steps, plateaux rising above plateaux, with precipitous sides to a height of 2,300 feet between the sea and Pietermaritzburg, where the country again descends to 2,080. These table-lands are covered with extremely poor soil, supporting a dense grass vegetation, on which feed numerous herds of cattle; not a shrub occurs to enliven the endless uniformity of the scene, broken only by the ravines formed by the rivers cutting down through the sandstones to the granite and old rocks beneath, often forming precipitous cliffs several thousand feet high, the vertical drop, from the Krantzkop Mountain to the River Tugela being nearly 3,800 feet. The top of this mountain is composed of melaphyre; these melaphyre greenstones contain copper ores and strike south-westwards to the Ingeli range in Kaffirland.

At Pietermaritzburg, the next belt of country commences, the town being built on the basement beds of the Karoo formation, belonging to the *Dicynodon* beds of South Africa, of triassic age, the name being given from the "karoos," or immense plains of the interior, forming the largest part of South Africa, including the elevated tract of "Kalahari, the Free States, and the Transvaal, as well as the country to the north, as far as Limpopo." They are present in the Zambezi, and rise to a height of 12,000 feet in Mont-aux-Sources, in the Drakenberg Mountains. The base of the Karoo series rests unconformably on the carboniferous table mountain sandstone, and consists of large angular blocks of transported granite, greenstone, and gneiss, in a matrix of clay and grit. They occupy a large area, and pass under plant-bearing shales. These boulder beds have been ascribed a glacial origin by Dr. Sutherland, Surveyor-general of Natal. Mr. Griesbach points out the overlying plant-beds correspond to the plant-beds of Southern India, associated with *Dicynodon* remains, and also resting on a boulder bed (Talchir group).

The great Karoo plains, Dr. Grey is inclined to regard as the bed of an inland sea; salts of soda predominate largely in the salines of the soil, and assist in forming the "background" of this region (sandy soil, with salt, carbonate of soda, and some salts of magnesia and alumina). Its surface forms the sweet-grass country of the Dutch "Zout-Veldt," yielding the valuable Karoo plant (*Adenchœra parviflora*). In this tract the climate is most salubrious, and the higher the country ascends the more fruitful is the ground. The yellow wood flourishes, wheat and European fruits flourish, and the cold of the winter, though not so severe as that of northern Europe, braces the European settler, and agrees with his constitution.

Fringing the Natal shore, there is a narrow belt of the Karoo formation, resting unconformably on the table mountain sandstones and older rocks, so that the latter form an exceedingly low and flat-topped anticlinal arch, throwing off the Karoo beds on either side. Landward these rise to the Drakenberg, seaward they have for the most part been denuded away, though their presence in Southern India points to the former extension over what is now the Indian Ocean of a series of lakes fringed by lands covered with plant growths, extending over Southern India, and parts of South Africa. The investigations of Mr. Blanford in Southern India support the views of Prof. Huxley and Mr. Sclater as to the existence of an extending submerged mesozoic continent, "Lemuria," which was shadowed forth in Mr. Darwin's researches on coral reefs. Mr. Blanford comments strongly on the great relation between the plants of the Indian and Australian (New South Wales) coalfields, many of the species being identical, the two localities being no less than 5,550 miles apart. In India these plant-beds rest on the supposed glacial (Permian?) beds of the Talchir group, the included scratched blocks being often forty-two feet in circumference.

The Karoo boulder bed is described by Dr. Sutherland as containing well-scratched blocks, inclosed in a material which has since been metamorphosed, and resting on scratched old silurian sandstones. The characters of the various members of the Karoo series is well capitulated by Prof. Rupert Jones in Mr. Ralph Tate's paper on South African jurassic marine mollusca, the sequence being: Stormberg beds (Huxley); Beaufort Beds; Koonap beds, and Ecca beds. The Beaufort beds most closely correspond to the Dicynodon beds of India, the boulder beds in both countries, according to Mr. Blanford, being pre-triassic, and he carries back his Indo-oceanic continent to Permian times, and extending up to a late jurassic epoch—South Africa, India, and Australia being connected at the early part of the period, Africa and India, up to the end of the miocene.

In 1824, some caves called *Izinhluzabalungu* (white men's houses) were discovered by Mr. Fynn to be fossiliferous; the name, given by the natives, was due to shipwrecked sailors having taken up their abode in them. In 1851 Capt. Garden had his attention called to these fossils, especially some gigantic *Inocerami*, two feet by one foot, by his servant, named Thomas Souton, a Private in the 45th Regiment, after whom one of the fossils obtained was named by Mr. Baily, who examined them at the request of the late Prof. Forbes. The deposit occupies a small tract on the south end of the colony, and, as Mr. Baily pointed out, may be correlated with the lower cretaceous of Southern India, one species *Pecten quinquecostatus* being common to the English greensand. The investigations of Mr. Griesbach have largely added to the number of the species, and supported Mr. Baily's conclusions, twenty-two of the species occurring in India, thirteen being peculiar. Another patch of cretaceous rocks occurs at St. Lucia Bay, in Zululand, resting unconformably on the Karoo strata.

At the close of the jurassic period, the Indo-oceanic continent was submerged beneath a shallow cretaceous sea, surrounded by coasts, covered with vegetation, extending from India to Natal. At the close of this epoch elevation commenced, and is probably still going on, as raised beaches, coral reefs, and oyster banks may be seen twelve feet above the sea. Through this action the Port of Durban must inevitably be silted up, which will be the fate of most of the ports on this coast, except the large port of Delagoa Bay, which is naturally clean swept by the north and south Mozambique current, which has gradually hollowed out the Bay.

CHAS. E. DE RANCE

OUR ASTRONOMICAL COLUMN

PRIZES OF THE PARIS ACADEMY.—At the annual public sitting of the Academy of Sciences at Paris, last week, the medal on the foundation of Lalande was awarded to M. Stanislas Meunier for his researches on the constitution of meteorites, which, in the opinion of the Commission appointed for the consideration of claims, have led to results that occasion surprise, but at the same time appear justified by M. Meunier's investigations. Astronomers had followed with interest the labours of M. Daubrée, who has contributed so much to establish

a connection, little expected, between these bodies falling from the heavens, and the lower strata of our globe, and this circumstance has caused an increased amount of attention to the researches of his pupil and follower, M. Meunier, who finds by his recent work that the analogy alluded to is not confined alone to mineralogical constitution, but that it is extended to the relation which these cosmical materials, disseminated in space, present when compared amongst themselves, as is done for the constituent rocks of our globe. The Commission considered that M. Meunier had reason to conclude, from his experiences, that all these masses once belonged to a considerable globe, like the earth, of true geological epochs, and that later it was decomposed into separate fragments, under the action of causes difficult to define exactly, but which we have more than once seen in operation in the heaven itself. Such a conclusion, it is remarked, adds greatly to the interest attaching to these "minute stars:" the astronomer, once occupied only with their motions and their probable distribution in space, finds himself confronted with a sidereal geology, as he already was under the necessity of having regard to celestial physics, celestial chemistry, and celestial mineralogy. The medal is awarded with the view to encourage M. Meunier to follow up his studies, so interesting in regard to the constitution of the solar system.

The Valz prize was adjudged to Dr. Julius Schmidt, for his great chart of the moon, and the immense labour which its production has involved during a period of thirty-four years. The report of the commission for this prize contains a brief *résumé* of earlier work in this direction, concluding with a remark, the truth of which will be sufficiently obvious, that Dr. Schmidt's work, "aujourd'hui déjà si précieux, servira dans l'avenir de base à de nombreuses investigations, et nous pensons que le temps ne fera qu'en accroître la valeur."

The Damoiseau prize, first proposed in 1869 for a revision of the theory of Jupiter's satellites, discussion of the observations, and redetermination of the constants involved, with the formation of tables of the satellites, has been renewed without effect in 1872, 1876, and 1877, and is further remitted to 1879. The value of this prize is 5,000 francs.

FAYE'S COMET.—Dr. Axel Möller, continuing his elaborate investigations on the motion of Faye's comet, which he has conducted with so much success during the last twenty years, has communicated to the Stockholm Academy elements and an ephemeris for the next appearance, which it now appears will not take place under such favourable circumstances for observation as has been stated elsewhere. From November, 1874, to April, 1876, the distance of the comet from Jupiter was less than twice the mean distance of the earth from the sun, and in June and July, 1875, was not more than 1·5; the effect of this has been to retard the next perihelion passage by more than thirty-eight days, or to delay it till January 22, 1881, under which conditions the theoretical intensity of light can at no time be half as great as at the date of discovery by M. Faye in 1843. At the last return only four observations appear to have been secured, owing to the comet's excessive faintness, three by M. Stephan, at Marseilles, on September 3, November 28 and 30, and one by Dr. C. H. F. Peters, at Clinton, U.S., on December 23; so admirably had the calculations of the perturbations during the preceding revolution been effected by Dr. Axel Möller, that M. Stephan's first observation gave the comet's position only *four seconds of arc* from the predicted place. The chief disturber of the motion of this comet is, of course, the planet Jupiter, but Dr. Möller takes into account also the effect of the attraction of Venus, the earth, Mars, Saturn, and Uranus. The amount of perturbation during the actual revolution is greater than in any other since the comet's discovery. The next perihelion passage takes place 1881, January 22·665, G.M.T., the comet at this epoch moving in an ellipse with a period 56·526 days longer than at the previous perihelion passage in July, 1873. Dr. Axel Möller's ephemeris extends from 1880, July 1, to 1881, January 1; the comet will be nearest to the earth on October 3, distance = 1·09, and situate at this time some ten degrees south of α Pegasi.

BIOLOGICAL NOTES

FOSSILS OF THE AMAZONIAN DEVONIAN.—MR. R. Rathbun, late of the Geological Survey of Brazil, has published a list and description of the Brachiopods of the three Amazonian-Devonian localities, showing that of the twenty-one species recorded from the Mæcurú, thirteen were also found on the Caruá, including all the commoner species of the former. There is not so close a relationship between the Ereré fauna and the Mæcurú. Several of the commonest Mæcurú species do not occur at Ereré, and *vice versâ*. At Ereré there are five species of Lingula, four of Chonetes, four of Spirifera; at Mæcurú there are no species of Lingula, four of Chonetes, and six of Spirifera. Several of the Amazonian shells are identical with those of the North American Devonian; three in the Mæcurú, and Caruá, viz., *Spirifera duodenaria*, *Amphigenia elongata*, and *Strophodonta perplana*. Two forms of these are only known in the Corniferous limestone and Schoharie grit of North America. The Ereré beds are more closely related by their fossils to the Hamilton group than to any other North American group. In Pará, on the whole, there is the same general succession of species as in the Corniferous and Hamilton groups of North America, and a similar intermingling of forms. The lamellibranchs are not published yet, but it appears probable that many species are identical with New York State forms. Among the Trilobites are species of Homalonotus, Phacops, and other genera. (*Proc.* Boston Society of Nat. Hist., 1878.)

AUSTRALIAN FOSSIL CORALS.—The subject of Australian fossil corals has occupied much attention among palæontologists of late years. The investigations of the forms found in the deep sea has brought the tertiary forms into prominent notice. Following in the line of the researches of Prof. Duncan, the Rev. J. E. T. Woods has recently published (*Journal* and *Proceedings* of the Royal Society of New South Wales, vol. xi., 1878) a paper on some Australian tertiary corals, in which he describes some new species from Muddy Creek, near Hamilton, in Western Victoria. Some of the species are very interesting, and the author concludes his paper by asserting:—1. That there is no species of the genus Caryophyllia living in the Australian seas, or to be found fossil in its rocks. 2. That there are three well-marked and peculiar forms of Deltocyathus. 3. That of the two species known of Sphenotrochus in Australia, one is still living (*S. variolaris*, n.s.) at a depth of seventy fathoms. 4. That there are two fossil analogues of the living *Conocyathus sulcatus*, which itself is supposed to be identical with a European miocene form. 5. That there is a fossil form in the miocene rocks of Australia, of the cretaceous genus Smilotrochus. The Rev. W. Woods mentions that he is preparing a monograph of the recent species of Australian corals.

HERRING CULTURE.—Dr. H. A. Meyer has published an interesting contribution to the natural history of this important fish, as part 1 of a series of short papers to be issued by the Commission for the Scientific Investigation of the German Sea (Berlin, 1878). In this he supplements his previous researches into the influence of the temperature on the development of the spring herrings' eggs. It may be remembered that in the large report published by the Commission it was found that the escape of the herring from the egg, in the case of the autumn herring, could be very considerably delayed by keeping

the eggs in very cold water; and now experiments made with the same object in view prove that in this respect there is very little, if any, difference in the behaviour of the autumn and spring spawnings. As in the previous experiments eggs artificially fecundated were those operated with, and while some of the eggs were exposed to the salt water at its ordinary temperature at Kiel, others were placed in a wooden refrigerator, into which the same sea-water, but cooled down to the desired degree, was admitted. A most necessary precaution was keeping the eggs from being heaped together, as they then almost invariably became mouldy. Another series of experiments was made to test whether the eggs exposed to the very salt waters of the North Sea would ripen quicker or slower than those exposed to the less salt water of the Baltic, but the time of the development, the temperature of the waters being the same, was found to be very slightly, indeed hardly perceptibly different. A third series of experiments were of a very interesting nature, supplementing those already made, as to the rearing of the herring from artificially fecundated eggs. So far as is known, no one has yet succeeded in rearing the young herring, and even Dr. Meyer's repeated attempts broke down, owing to the impossibility of stopping the formation of the hyphæ of some fungus, and also in some measure to the difficulty of obtaining suitable food. Very soon after the yolk was altogether consumed they would die, so that most of the experiments on their growth were made on specimens freshly caught from time to time. Once he succeeded, in the spring of 1878, in rearing a few until they attained the size of 72 mm. However, as the result of these experiments, a great deal of insight has been obtained into the food—at first of almost microscopical dimensions—which the young herring consumes, and as to the enormous voracity of the little fish.

MADAGASCAR FORMS IN AFRICA.—At a recent meeting of the Society of Naturalists of Berlin Herr Eichler exhibited specimens of a new species of *Ouvirandra* lately discovered by Herr Hildebrandt in Eastern Africa. The remarkable form of water-plant known as the Lattice-leaf Plant (*Ouvirandra fenestralis*) with two other species of the same genus have been hitherto regarded as amongst the wonders of the peculiar flora of Madagascar, so that the discovery of a member of the same group in continental Africa is a fact of much importance in botanical distribution. The new *Ouvirandra*, although agreeing with the Madagascar species in all essential points of structure, does not present the singular holes in the leaves that distinguish the *Ouvirandra fenestralis*, but one of the other Madagascar species is likewise abnormal in this respect.

THE "DIGGER" MOLLUSC AND ITS PARASITES.—The little digger, *Donax fossor*, represents a countless mass of life off Cape May, New Jersey, large areas looking like barley grains lying on a malting floor when the tide retires. It gets uncovered by the breaking surf and instantly reburies itself with its powerful foot when the waves retire. The siphons are long and active, looking like so many wriggling worms. Although the prey of shore birds and fishes, and beset with parasites, they lie so thick as even to interfere with one another in burying themselves. The liver of these bivalves is always found beset by flukes, from half a dozen to several dozen, and a bell-shaped trichodina crowds the branchial cavity.

ACTION OF THE HEART OF THE CRAYFISH.—M. Felix Plateau, of Ghent, has succeeded in applying the graphic method to the study of the heart's action in the crayfish. A curve is obtained, of which the ascending portions correspond to diastole, and the descending to systole, contrary to what obtains in the vertebrate heart. It is strikingly like the trace of the contraction of a muscle; a rapid, almost sudden ascent, with a short flat summit, then a gradual descent, at first quicker, then slower. This, however, does not represent the whole truth; it is possible, also, to demonstrate a wave affecting the muscular wall of the heart, and travelling from behind forwards, thus demonstrating that this condensed heart is a true dorsal vessel. On the stimulus of the entrance of renovated blood, it is only the hinder half or two-thirds of the heart that contracts immediately. This forces blood into the forward half, which contracts only when the posterior division is again dilating. When the temperature is increased, as a general rule the diastolic phase is abbreviated, the number of pulsations rising at the same time. M. Plateau has also succeeded in making experiments on the action of the cardiac nerve of Lemoine, an unpaired branch of the stomatogastric ganglion. It is proved that excitation of this nerve quickens the pulsations of the heart, and augments their energy, while section of it slows the heart. Excitation of the thoracic ganglia always retards the heart, the converse of the cardiac nerve. Acetic acid applied to the heart substance arouses its contractions even when they have ceased, and maintains them for several hours. The action of a number of other substances is equally noteworthy, and M. Plateau's full communications to the Académie Royale of Belgium will be awaited with interest by physiologists.

GEOGRAPHICAL NOTES

THE various geographical journals to hand contain several papers of importance. In the January *Bulletin* of the Paris Society M. Maunier gives a full and intelligent sketch of geographical work during 1878, while Dr. Harmand gives a brief statement of the results of his recent journeys in Anam. The Paris Society seems to have followed the example set by the London Society, and has introduced a new feature, "Nouvelles," containing notes of geographical work beyond the limits of its own papers. The *Zeitschrift* of the Berlin Society contains two instructive papers, on the Andamans, by Ad. de Roepstarff, and an account of a journey in south-west Persia, by Dr. A. H. Schindler. In the two numbers of the *Verhandlungen* of the same society, the last for 1878 and first for 1879, the papers of most interest are those on the Mining Industry of Russia, by C. Skalkovsky; on the latest researches on the Aurora Borealis, by Herr Förster; and on the people of East Africa, by Herr Hartmann. In the *Mittheilungen* of the Vienna Society, No. 2 of this year, Herr Franz Heger gives some hints as to a solution of various geological questions,—glaciation, climate, coal-deposits, &c.—apparently seeking to account for many of the great geological problems by a change in the earth's axis. The March number of Petermann's *Mittheilungen* contains several papers of interest. From the journal of a Bremen merchant a narrative is given of a journey up the Jenissei, from its mouth to Jenisseisk, in the summer of 1878; and M. N. Latkin gives a detailed account of our knowledge of the Lena and its basin. Exact news of Nordenskjöld's position is given from the San Francisco whaling captain, who was the first to hear of him, and a statement as to the course to be followed by the steamer *Nordenskjöld*, now building at Malmö, and which will start in May, first to succour the Swedish expedition, and then to proceed to the mouth of the Lena. If it cannot return through Behring's Strait, the staff will spend the winter in collecting all possible data in various departments of science. Nos. 3 and 4 of the *Bulletin* of the American Geographical Society contain, the former a paper by Rear-Admiral Ammer, on the Inter-oceanic ship canal across the American Isthmus, and the latter an interesting sketch of the life and work of Mercator, by Mr. E. F. Hall.

NEWS of two African expeditions are to hand, in one case telling of misfortune, and in the other of success. The Belgian expedition, unfortunate from the beginning,

has met with another disaster in the death, from dysentery, of M. Wautier, at a place called Kekongen (? Ukonongo). On the other hand, Major Pinto, the leader of the Portuguese African expedition, telegraphs to Lisbon from Pretoria, that he has virtually crossed Africa from the west coast, after struggling with hunger, thirst, beasts, natives, floods, drought. His route must have to some extent almost coincided with that of Livingstone, and he tells us he has saved all his papers, twenty geographical charts, many topographical maps, several vols. of notes, drawings, meteorological data, a diary of the exploration of the Zambesi's seventy-two cataracts and rapids. He says he has discovered the secret of the Cubango, by which he seems to mean the river which, under various names, was for a time taken by some to be the upper course of the Congo. He lost many followers, and his expedition seems in a small way to have been modelled on that of Stanley's.

THE *Times* Roman correspondent writes that Menotti Garibaldi and Achille Fazzari intend, if England does not object, to sail in summer or autumn with 3,000 Italians for the south coast of New Guinea, to establish a colony there, and found a new city under the name of Italia. The arrangements, it is said, are almost completed, the 30,000,000 francs required ready, and that applications to join the party are more than can be granted. Part of the equipment will be a telegraph cable, to place the colony at once in communication with North Australia. Men of all ranks and callings (except lawyers) are included in the party, and among them several men of science. The proposed colonists express the greatest good will towards England, and it seems to us the trial would be worth making. The Italians make better colonists than the French, and Italians have done so much for the exploration of New Guinea that it seems only fair that they should be allowed to reap some benefit from the labours of such men as D'Albertis and Beccari.

AT the last meeting of the Société Commerciale de Géographie at Paris Dr. Raffray gave some particulars respecting his recent explorations in New Guinea, and called attention to the fact that that country offered a vast field for discovery and study to the traveller, especially from an ornithological and entomological point of view. A report on the subject of a railway across the Desert of Sahara was afterwards read, being the result of the labours of a committee, of which M. Gazeau de Vautibault is president. M. Deloncle also made a communication respecting the Volta region in West Africa, which has been explored by M. Bonnat, and he announced that two Lyons merchants had already determined to establish business houses there.

MGR. LAVIGERIE, Archbishop of Algiers, has forwarded to *Les Missions Catholiques* the commencement of the journal of the Algerian missionaries, recording the incidents of their march towards the Nyanzas and Lake Tanganyika. This portion of their journal stops at Mukuduku in Ugogo on August 20, and the first instalment of this is now published. It had been intended to accompany it by a map of Equatorial Africa, sent home by Père Charmetant some time back, but it has been thought better to delay the publication, in order that the itinerary of the missionaries and the additional geographical information contained in their journal may be included in it.

IT is stated in an Italian newspaper that the Duke of Genoa will go on an exploring expedition, and will sail from Venice in the *Vittore Pisani* at the end of this month. The programme of the route is to be Port Said, Suez, Aden, Ceylon, and Singapore, where a longer sojourn will be made. Afterwards the traveller will proceed to the Chinese and Japanese coasts; in 1880 he will visit Australia and direct his special attention to the exploration of New Guinea. On the return journey the *Pisani* will cruise in the Persian Gulf. Capt. Sebastian and Count Antonela have started on an exploring tour through Africa.

A POSTCARD was received at Berlin on February 15 from Dr. Gerhard Rohlffs, dated January 27 and posted at Sokna, some 250 miles south of Tripolis, at the foot of the Black Mountains, stating that he was in perfect health. The postcard bears the stamp of Dr. Rohlffs's desert post, and a prettily-drawn postage-stamp with African palm-leaves.

TO accompany the map of Zululand, noticed last week, Mr. Stanford has published a few useful notes on the physical features and population of the country.

THE *Jeannette* is fitting up in San Francisco harbour, and will leave for polar exploration in the month of June. Mr. Bennett, who is now in Europe, has been making inquiry at Paris as to the best means of constructing and inflating balloons in the Arctic regions. It is thus likely that aërial navigation will play a part in this new effort to solve the mystery of the north.

EDISON'S TELEPHONE

OUR readers may remember a few months ago we stated, in an article on the Carbon Telephone (NATURE, vol. xix. p. 56), that Mr. Edison had devised an entirely new form of receiver, for use with his telephone, which delivered the voice as loudly as if the words were spoken at the distant end. This receiver has now arrived in England in charge of Mr. Edison's nephew, and to judge from its performances last Friday, it is likely to accomplish all that Edison has stated concerning it.

The principle of this new receiver is that of the *electro-motograph*, and to those of our readers who may not be acquainted with this instrument the following extract from a recently published lecture, on Edison's inventions, by Prof. Barrett will explain what the electro-motograph is.[1]

"Mere ingenuity in contriving machines does not add to the sum of human knowledge, and if Mr. Edison were merely a clever inventor and nothing more, I should feel less interest in the man. It is, however, a noticeable feature of Mr. Edison's inventions that they, in general, contain some new principle, some original observation in experimental science, which entitles him to the rank of a discoverer. Such is the character of the next invention we must consider, the so-called *electro-motograph*. This is an entirely new method of receiving telegraphic messages, discovered by Edison in 1874. As every one is aware, the ordinary system of telegraphy depends upon the production of magnetism by means of an electric current, the current either attracting and releasing a movable piece of iron, or deflecting a magnetic needle to the right or to the left. By the to-and-fro movements of the iron or the needle the conventional signals are produced which are employed in telegraphy. Now Mr. Edison made the curious and important discovery that messages could be received by the well-known Morse recorder without the use of any magnet. This, to a telegraphist, would be like attempting to perform the play of "Hamlet," while omitting the part of *Hamlet* himself. In fact, all that is necessary in this simple telegraphic instrument is a band of moistened paper drawn beneath a metal style. The accident of holding his finger against the style of a Morse instrument led Mr. Edison to notice that when an electric current passed from the paper to the point resting upon it the friction of the moving paper was lessened. Hence, if the paper were drawn with a uniform force it would slip more easily beneath the point the moment the current passed. The slipping of the

[1] "Science Lectures for the People," No. 5, Tenth Series. (Manchester, Heywood.)

paper is converted into a to-and-fro motion of a lever to which the point is attached, and which is made to actuate a bell, or "sounder," and give rise to audible signals in the usual way. It is necessary to moisten the paper with a solution of certain chemicals. Potash was at first used, but a solution of sulphate of soda or of common salt and pyrogallic acid is found to be best.[1]

"The advantage of this instrument, which Mr. Edison calls an *electro-motograph*, is said to be its extreme sensitiveness, it having been worked over a circuit of two hundred miles with only two cells, so that with weak currents, unable to affect ordinary instruments, the electro-motograph can receive messages. More than this, the speed of its working is greater than with the ordinary instruments. Using it as a relay, that is, an instrument for translating weak currents into strong ones, no less than 1,200 words per minute have been transmitted by its means, or five times as fast as it is possible for any person to read the message which comes through the instrument. So prompt and delicate is the motion of this machine that Edison has applied it to the purposes of the receiving instrument for the Reiss telephone, a musical telephone that was made many years ago. The slipping of the paper causes a slight sound. If, then, we sing a certain note into the Reiss transmitting instrument, which vibrates in unison with that note, we obtain the same number of electric currents produced per second as we had of sonorous vibrations in the moving diaphragm. Thus, if we sounded the middle C we should get 264 vibrations, and there would be 264 electric currents, and 264 slips of the paper, thus producing a note of the same pitch in a distant room. The cause of the curious slipping has not been fully ascertained. It may possibly be due to that peculiar repulsive effect to which Mr. Crookes has lately drawn attention, and which produces the dark region around the negative electrode during the continuance of an electric discharge in a vacuum tube, or it may simply be due to electrolytic action."

It is, then, this principle which Edison has made use of in his new receiver, which is of the simplest construction. A diaphragm, preferably of mica, some four inches in diameter, held in a suitable framework, has attached to its centre a spring, or "pawl," the free end of which rests on a little cylinder of chalk, capable of rotation by the hand or other means. The chalk cylinder replaces the paper in the electro-motograph, and is necessarily impregnated with sulphate of soda, or other suitable solution. As the cylinder is rotated, the friction of the spring on the chalk causes the diaphragm to be pulled in or pushed outwards, according to the direction of the rotation. So far the operation is purely mechanical; as soon, however, as the current passes, either owing to electrolytic action or the friction, it is lessened, and the diaphragm tends to spring back to its normal position; on the cessation of the current the friction is restored, to be lessened on the recurrence of another electric wave. Thus, a series of tremors are given to the diaphragm corresponding to the swiftly changing character of the electric waves, and these again faithfully express the motion of the diaphragm at the transmitting end. It will thus be evident that the incoming current has simply to do the work of liberating the already strained diaphragm. As everyone knows, in Bell's telephone the voice has to do the work of creating the current at the transmitting end, and the feeble magneto-electric currents thus generated throw into motion the diaphragm at the receiving end. In Edison's telephone this is not so. The voice at the transmitting end has simply to vary the *electric* resistance in the path of a current generated by an ordinary voltaic battery; stronger currents can thus be sent along the line, and these arriving at the receiving end, have merely to vary a *mechanical* resistance, and not to do the work of overcoming the inertia of the diaphragm. It is probable the rotating chalk cylinder acts on the diaphragm with its attached spring like a resined bow on a violin string; vibrations are set up, the extent, rate, and manner of which are modified by the varying friction due to the telephonic currents. Whether these new receivers will retain their present efficacy when in constant use remains to be seen. We should be inclined to think the soft surface of the chalk will eventually wear with the friction, and that a more permanent arrangement will have to be devised. No invention, however, reaches perfection at once, and the present receivers, excellent as is their performance, were, we understand, hastily made in a few days, in compliance with the urgent request of Mr. Edison's courteous representative in London, Col. Gouraud.

The instrument has the appearance of a small box attached to the wall, and from which there projects a single funnel. Sounds of singing, speaking, whistling, sent from the other end, quite a mile off, were heard in every part of a moderately sized room. Telephonic connections, now so common in America, have been established by Col. Gouraud between various business houses in the city; and we believe that shortly this method of communication must become quite common.

[1] Practical difficulties have, we believe, been found in the working of the motograph, so that it has not come into telegraphic use.

NOTES

Dr. Miclucho Maclay, the eminent Russian Naturalist and New Guinea explorer, has been trying to rouse the Linnean Society of New South Wales and the scientific public of Sydney to the necessity of founding a zoological station, similar to that at Naples. He tells of the great inconvenience he himself has suffered during his residence at Sydney from the want of such a station, even though the Hon. Mr. Macleay placed his museum at his disposal. But Dr. Maclay's scheme embraces much more than a station at Sydney. He has written to the German Eastern Asiatic Society at Japan and to Mr. August Godeffroy at Samoa, urging that similar stations be founded at these places, and he has reason to believe that his proposals will not be without result at both places. Thus should zoological stations be instituted at Sydney, in New Zealand (as Dr. Maclay also proposes), in Japan, and at Samoa, we might hope in a very few years to have a fairly complete knowledge of the fauna of the Pacific. Dr. Maclay's proposal deserves the heartiest encouragement, and we trust that ere long it will be fully carried out. We hope the people of Sydney, at any rate, will take Dr. Maclay's appeal to heart; he tells them, moreover, that he will judge of the intensity of the scientific life of Australia by the interval which elapses between the reading of his paper on the subject and the actual foundation of the station. He shows what valuable results have followed the foundation of the Naples station, and gives a few hints as to how such a station at Sydney should be organised. We shall be curious to see what will be the result of Dr. Maclay's fervent appeal.

We are requested to state that on and after April 1 any person may obtain by telegraph from the Meteorological Office the latest information as to the weather in any district of the United Kingdom by payment of a fee of 1*s.* in addition to 2*s.* the cost of the message to the Meteorological Office and the reply. The telegram containing the inquiry must not exceed twenty words in length, and must be addressed, "Meteorological Office, London." The Meteorological Office does not undertake to give any information which is not substantially included in the latest notice posted at its own doors, nor does it give forecasts of the weather on the Atlantic coasts of the British Isles; although it is ready to furnish any information it possesses as to the actual state of the weather on those coasts. The Meteorological Office is open for such inquiries between the hours of

11 A.M. and 8 P.M. on week days, and between 6 P.M. and 8 P.M. on Sundays.

THE Emperor of Germany has confirmed the election of Sir G. B. Airy as a foreign member of the Berlin Academy.

RUSSIAN astronomers seem determined to outstrip their *confrères* in other countries in the matter of telescopes; we are informed that funds have been subscribed for the construction, for Pulkowa Observatory, of a refractor of thirty-two inches aperture.

WE have received a circular from the Research Committee of the Institution of Mechanical Engineers, drawing attention to three subjects which they have selected for first investigation, and asking for any information, bearing on all or any of them, which any one interested may be willing to communicate: *e.g.*, records of unpublished experiments, references to authorities on the question, copies of books or papers in which it is treated, &c. The Committee would be glad to receive such information in full detail, and at the earliest convenient date; and it will be suitably acknowledged in their report. The subjects are:—Subject A. The hardening, tempering, and annealing of steel. Subject B. The best form of riveted joints to resist strain, in iron or steel, or in combination. Subject C. Friction at high velocities, specially with reference to friction of bearings and pivots, frictions of brakes, &c. The address of the Institution is 10, Victoria Chambers, Victoria Street, Westminster.

IN the Monthly Weather Report of the U.S. Signal Service for January, 1879, are many points of great interest to meteorologists. The particular report before us belongs to the division of "Telegrams and Reports for the Benefit of Commerce and Agriculture," and contains a multitude of well-arranged data received up to February 14. The charts accompanying the Report are of special interest. One of them shows the tracks of ocean-storms from November 23, 1878, to January 16, 1879, and exhibits the paths of seven storms. No. 6 of these is shown to have commenced in California on January 6, to have come down to the Gulf of Mexico by the 8th, to have gone north-east through the United States to Newfoundland, between the 8th and 11th, across the Atlantic between Scotland and Iceland, the storm expending itself off the coast of Norway on the 15th, one week after starting from California.

EXPERIMENTS in electric signalling and reconnoitring have been made at Mont Valérien on a large scale. Details are wanting, as the French Government think it prudent to keep secret almost all experiments relating to military matters.

WE have received an interesting sketch, with portrait, by Prof. Ehlers, of Göttingen, of the late Wilhelm Engelmann, so long the head of the well-known Leipzig scientific publishing house, and who did so much for the advancement of scientific knowledge in Germany.

The Science Index is the title of "A Monthly Guide to the Contents of the Scientific Periodicals," the first number of which we have just received, though dated January. This delay is apologised for, on account of the difficulty of getting together a first number. The aim of the journal is highly to be commended, and if carried out on a thoroughly well-considered plan, ought to prove of great service. We are not disposed to criticise this first number too severely, though we think there is considerable room for improvement. It is by no means exclusively devoted to science, including as it does Art, Architecture, Strikes, Baking and Confectionery, Bells, Commerce, and other miscellaneous topics. Indeed, on the principle which has been partially followed, we do not see where the line is to be drawn short of an index to everything. We hardly think the plan has been well considered, and we think that many of the subjects indexed might be omitted with advantage if it is meant to be really a Science Index. Judging from the number of misprints, this number seems to have been hastily got out. In geography alone we meet with such horrors as "Afkanistan," "Leybian Desert," "Oxies" for Oxus, &c. References to the Swedish Arctic Expedition occur under different headings, as if the compiler did not know that the items referred to the same thing. Still, the index is a step in the right direction, and we hope the editor will take competent council, and introduce such improvements as will make his *Science Index* what it might and ought to be.

MAJOR MAJENDIE, as the result of a series of experiments with dynamite, has come to the conclusions that frozen dynamite is considerably less sensitive to explosion by a blow than unfrozen dynamite; that cartridges of dynamite having small quantities of exuded nitro-glycerine within them are decidedly more sensitive to explosion by a blow than cartridges in which there is no such exudation; that frozen dynamite is much more susceptible to explosion by simple ignition than unfrozen dynamite; that frozen dynamite is much less sensitive to explosion by the impact of a bullet than unfrozen dynamite; that the danger attending the mere breaking in two of a frozen dynamite cartridge does not seem to be of the formidable character indicated by the Austrian regulations; and that frozen nitro-glycerine is not susceptible of detonation by detonators of the same strength as those with which the detonation of unfrozen nitro-glycerine may be readily and certainly effected.

THE *Bradfordian* is the title of a magazine "written and supported by the two Grammar Schools" of Bradford. It has a varied programme, in which, we are pleased to see, science finds a place.

THE *Times* Geneva correspondent writes that M. A. Borel, of Chaux-de-Fonds, has just had the good fortune to find in the Lake of Neuchatel, between Bazuge and Chatelard, a prehistoric canoe, probably the finest specimen of the sort that has yet come to light in Switzerland. Hollowed out of a single piece of oak, the vessel is 8 metres long, 90 centimetres wide, and 65 centimetres high. It is well finished, and in a perfect state of preservation. The stern carries a spur, and the prow is curved in the form of a hook, probably for the purpose of attaching it by a rope to a landing-place. The canoe is sufficiently large to carry twelve persons. There is no appearance of rowlocks, but the supports on which the thwarts formerly rested are still plainly to be seen. M. Borel proposes to present this interesting "find" to the Museum of Chaux-de-Fonds.

A PETROLEUM spring, one boring of which has yielded 2,000 kilos in twenty-four hours, has been discovered at Pohar, in Austrian Poland.

ACCORDING to the report of H.M.'s Consul for Hiogo and Osaka, the Japanese claim that petroleum has been known in Japan for over 1,200 years, and it would certainly be curious if the numerous springs which exist in certain localities should have escaped notice in their immediate neighbourhood. It is doubtful, however, whether it was ever utilised, and certainly no attempt was made to refine it before the arrival of foreigners. The first efforts in that direction were made near Niigata in 1875, but the petroleum then refined failed to stand a higher test than 75° F. Accordingly Prof. Lyman, who had previously performed a similar service for India, was sent for from America to conduct a professional survey of the region. His report, however, was unfavourable, chiefly on the ground of an insufficient supply. This opinion the Japanese are now about to test, for which purpose they have established a refinery near Hiogo. Its supplies of crude oil are to be drawn from the province of Potomi, distant about 100 miles to the north, the transport being conducted by sea.

AT the evening meeting on Monday, the 31st inst., at 8.30, at the Royal United Service Institution, D'Arlincourt's telegraph will be exhibited and worked, illustrative of a means of communicating orders in the field. The paper of the evening is on "Orders in the Field and the Means of Communicating them," and will be read by Major Webber, R.E.

A PAMPHLET has just been issued at Quebec, compiled under the auspices of the Boards of Trade of that town and Montreal, dealing with the subject of telegraphy with the coasts and islands of the Gulf and Lower River St. Lawrence, and the coasts of the maritime provinces, considered from the point of view of its relation to the shipping, to the fisheries, and to the signal service. The *brochure* is accompanied by a large-scale coast telegraph chart of the region named, delineated under the direction of the Hon. P. Fortin, on which are shown existing and projected telegraph lines and the ordinary tracks of vessels.

AT the last meeting of the Eastbourne Natural History Society an interesting paper was read by Dr. Murdie on sea-water, its adaptations to various purposes, and its management in reference to marine zoology.

MR. TEGETMEIER has published a facsimile reprint of Moore's "Columbarium" from the original edition of 1735. The work, the source from which all subsequent works have taken their rise, ought to interest both fanciers and naturalists; by its aid, as Mr. Tegetmeier says, the latter may trace the alterations produced in varieties of the same species, continued for 150 generations. Moore was a well-known doctor of the City of London, and was so eminent in his way as to merit a bantering satire from Pope.

PROF. EDWARD MORSE, of Tokio, announces that he has discovered undoubted evidences of the practice of cannibalism among the early inhabitants of Japan. These evidences he describes in a paper read at the Biological Society of the Tokio Dai Gaku.

THE *Colonies and India* has an interesting note on the subject of Vanilla, which appears to be mainly supplied by Mauritius, Brazil, and Mexico, but could probably be grown in many of our colonies. The parasitical plant which yields this aromatic bean will climb up any tree that gives sufficient shade; it attains a height of about a foot, and thrives for thirty or forty years, producing some fifty pods each year after the second. The beans take eight or nine months to mature, and are gathered between October and December; they are oiled occasionally to prevent excessive shrinking, and dried in the sun; when warm they are wrapped in woollen cloths to absorb the evaporation, and during the process attain their black silvery hue. Vanilla is the most costly, in proportion to weight, of all vegetable productions, and only a few hundredweights reach England annually.

MASSON, of Paris, has published in a collective form, under the title of "Revues scientifiques publiées par le journal *La République Française*," a large number of papers on subjects of scientific interest published at intervals in that paper, under the direction of Prof. Paul Bert.

THE comparative effects of pressure and hammering in changing the volume of soft masses, has been investigated by Herr Kick (*Ding. Pol. Jo.*). A carefully cast lead cylinder 100·3 mm. high, 70·2 mm. diameter, and 387·85 ccm. at 15°, was compressed in a Gollner's machine to 69 mm. and 50 mm. height respectively. The volume was found to be hardly altered at all (it became 387·814 ccm. in the second case). A lead cylinder 59·7 mm. high and 50 mm. diameter was now beat down by means of a steam hammer to 16·7 mm. height. The volume was reduced from 117·56 to 117·33 ccm. Thus, to condense metals, it is necessary to resort to beating, or to use extraordinary pressure on inclosed material.

SOME interesting experiments with regard to tension of carbonic acid in blood have recently been made by Herr Gaule in the physiological laboratory of Prof. Ludwig (Du Bois Reymond's *Archiv*). He notes the following differences between blood and serum in this connection:—1. The proportion of carbonic acid in serum is higher than that in blood. 2. The tension of carbonic acid in serum is less than that in blood. 3. If in serum the quantity of free carbonic acid diminish, there is decomposed only the quantity of bicarbonate of soda which corresponds to this diminution, but in blood more. 4. On addition of simple carbonate of soda, the tension of free carbonic acid diminishes in the serum, but in blood it does not. 5. In blood there exists a substance which is capable of dissolving the entire combination between carbonic acid and soda, but in serum not. This substance, which attracts the carbonate of soda, is very probably hæmoglobin, which then further decomposes the combined salt into soda and carbonic acid, and thus maintains with the bicarbonate salt and the free carbonic acid a series of complicated exchanges, which probably render possible and promote the giving out of carbonic acid and the removal of it from the tissues and the lymph.

CARL'S *Repertorium für Experimental Physik* (xv. Band, 2 Heft) contains an illustrated account of the new meteorological magnetic observatory for St. Petersburg at Pawlowsk. In the same number we note a useful simplification of the spectroscope, by Herr Hüfner.

THE measuring of sea-depths with the lead leaves much to be desired in point of accuracy. Dr. Rühlmann is of opinion (*Annalen der Physik*) that reliable results will be had, only when it is practicable to measure the weight of the water column. This weight, and therewith the height of the column, might be easily ascertained from pressure on a manometer. And the point is, to combine with the pressure-measuring instrument an arrangement whereby one may read off what the apparatus indicates at that point, the depth of which below the surface is to be determined. To construct such a manometer need not, he thinks, greatly puzzle the mechanician. The various forms of aneroid barometer are a good direction. Suppose, *e.g.*, a manometer made after this fashion, and available for very high pressure, and let there be adapted to it an electro-magnetic arrangement, wherewith, when a current is sent through it from the ship, the index is pressed so forcibly against the scale, that a mark is produced on this. In this way, closing the circuit at different times, it would be possible to determine the pressure in different parts of the sea. If, at the same time, there were sunk a junction of a thermo-element, the other junction of which was kept at constant temperature, and if the current of this thermo-element were conducted through a sensitive marine galvanometer on the ship, one could ascertain the temperature of the water at the points for which measurements of pressure were obtained. Very accurate results could only be expected, when not only the pressure at the sea-bottom, but also the temperature of the water at as many points of less depth as possible, were known. Dr. Rühlmann is not aware if such a method has been put into practice, but he gives an exposition of the theory of it.

THE additions to the Zoological Society's Gardens during the past week include an Indian Fruit Bat (*Pteropus medius*) from India, presented by Capt. F. P. Millett; a Mule Deer (*Cervus macrotis*) from Ottawa, Illinois, U.S.A., presented by Judge Caton; two Gaimard's Rat Kangaroos (*Hypsiprymnus gaimardi*) from Australia, presented by Mr. Ernest E. Harrold; a Spotted Ichneumon (*Herpestes auropunctatus*) from India, presented by Miss H. Boteler; a Brent Goose (*Bernicla brenta*), European, presented by Mr. H. A. Dombrain; a Black-faced Spider Monkey (*Ateles ater*), a Black-handed Spider Monkey (*Ateles melanochir*) from South America, received in exchange; a Black

necked Stilt Plover (*Himantopus nigricollis*) from South America, purchased; three Common Badgers (*Meles taxus*) born in the Gardens.

THE PARIS ACADEMY PRIZES

LAST week the Paris Academy held its annual public meeting, when the prizes for 1878 were awarded. According to old custom, M. Fizeau, the president of last year, was in the chair. He remarked on the unprecedentedly large number of prizes that were not awarded, either because there was no competition or because there were no competitors of sufficient merit. On this account several of the most important prizes have not been awarded this year, and it seems to be the common opinion that some of the problems proposed are much too difficult. M. Dumas read an *éloge* on M. Balard, the discoverer of bromine, and M. Bertrand did the same for Leverrier. M. Bertrand made no allusion to the part taken by Leverrier in the public affairs of his time, and made but slight allusion to his organisation of the Meteorological Service, and that almost as if it were not a thing quite worthy of encomium. M. Bertrand's address does not seem to have given universal satisfaction, and several of the audience on leaving the hall were heard to say: "Quant à l'éloge de Leverrier il est encore à faire." The following are the principal prizes awarded at the meeting:—The Extraordinary Prize of 6,000 francs for the greatest prgress in naval construction, to M. Perroy and Lieut. Baills; the Poncelet Prize in Mechanics to M. Maurice Lévy; the Montyon Prize of 1,000 francs, in Mechanics, to Mr. George H. Corliss, for his well-known engines; the Plumey Prize to Capt. Vallessie, for his differential counter to regulate the progress of steamships. In Astronomy the Lalande Prize was awarded to M. Stanislas Meunier, for his researches on meteorites; the Valz Prize to Dr. Julius Schmidt, for his lunar charts. In Physics the Bordin Prize was awarded to M. Reynard for his researches in connection with Ampère's law. In Chemistry the Jecker Prize was awarded to M. Reboul, specially for his memoir on the isomers in the propylene series. In Botany the Barbier Prize was given to M. Ch. Tauret, and encouragements of 500 francs each to M. Cauvet and M. E. Heckel; the Desmazières Prize to Dr. Bornet; the Shore Prize to Prof. Ardissone for his "Floridee Italiche;" in Anatomy and Zoology the Serres Prize was awarded to Prof. Alexander Agassiz, for his various embryological and other investigations; and the Montyon Prize in Physiology to M. Charles Rechet, for his researches on gastric juice. The Tremont Prize was given to M. Marcel Deprez for his application of electricity to the solution of various problems in mechanics; the Gegner Prize to M. Gaugain; the Delalande Guérineau Prize to M. Savorgnan de Brazza, for his exploration of the Ogové River; and the Prize founded by Mdme. de Laplace to be awarded to the pupil who leaves the Polytechnic School with the highest honours, to M. de Béchevel.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

M. FERRY, the French Minister of Public Instruction, has presented a project for the reorganisation of the Superior Council of Universities. According to the proposals of the minister, which are sure to be adopted by the Assembly, the bishops and other religious members are to be excluded, and the Council exclusively composed of persons belonging to the teaching profession. Moreover, it is proposed that all degrees be henceforth granted by the State, and only to those who have taken the curriculum of a recognised university.

THE examiners for the Burdett-Coutts' Scholarship (Oxford) have awarded it to Mr. Algernon Philips Thomas, B.A., Scholar of Balliol College; and they consider Mr. Henry Nicholas Bidley, B.A., of Exeter College, worthy of honourable mention.

SCIENTIFIC SERIALS

Bulletin de l'Académie Royale de Belgique, No. 12, 1878.—In this number is a paper by M. van Beneden, giving a historical sketch of whale-fishing and of the first Arctic expeditions.—A lecture by M. Houzeau, the president, has for its subject certain enigmatical phenomena of astronomy.—M. van Rysselberghe describes a parabolic regulator, rigorously isochronous, and the velocity of which can be varied at will. Regarding it, M. Folie reports that it has too many articulations and movable rings for common use, and it hardly realises ideal perfection for physical and astronomical apparatus.—M. Malaise announces the discovery of a mineral species new for Belgium, viz., arsenopyrite or mispickel, and M. Monier describes a hydrophane opal and hydrated transparent silica, obtained by action of oxalic acid on alkaline silicates.—There are also several mathematical papers and reports on prize competitions (subjects chiefly botanical).

Reale Istituto Lombardo di Scienze e Lettere. Rendiconti. Vol. xii. fasc. ii.—We note the following papers in this number:—Considerations on a letter of Tyndall's regarding heterogeny, by Prof. Giovanni.—On the causes of asphyxia and the agglutination of the blood corpuscles in diphtheria, by S. Trevison.—The Sanitary Office of the German Empire, by Dr. Zucchi.—Studies on milk (continued), by Drs. Pirotta and Riboni.—On cortical psycho-sensory centres, by Professors Luciani and Tamburini.

SOCIETIES AND ACADEMIES

LONDON

Mathematical Society, March 13.—C. W. Merrifield, F.R.S., president, in the chair.—Mr. J. D. H. Dickson was admitted, Mr. R. Hargreaves and Prof. W. E. Story were elected, and Mr. Donald McAlister was proposed for election into the Society.—Prof. Cayley, F.R.S., spoke briefly but in high praise of the late Prof. Clifford's work as a mathematician, instancing more particularly his papers "On the Canonical Form and Dissection of a Riemann's Surface," "On Mr. Spottiswoode's Contact-Problems," and "The Classification of Loci."—The chairman, the Rev. A. Freeman, and Dr. Hirst, F.R.S., added a few remarks on the loss the Society and the mathematical world generally had sustained, and expressed the hope that steps would be taken to secure the publication, if desirable, of any mathematical papers Prof. Clifford might have left.—Dr. Hirst made a statement respecting the "De Morgan Memorial" Medal to be presented to the Society to be awarded in such manner as the council shall hereafter determine; it appeared that the bust and die for the medal had been executed by Mr. Woolner, and that after all claims had been met there would still be a small sum required to make up the requisite total for the purpose contemplated. The late Prof. De Morgan was the first president of the Society and always took a warm interest in its advancement. It was resolved that a subscription list should be opened in order that old pupils and members of the Society might have an opportunity of aiding in the above design. Subscriptions for this special purpose may be sent to Mr. Tucker (Hon. Sec., University College School, W.C.), or to Mr. Alfred Wills, Q.C., 12, King's Bench Walk, E.C., the Hon. Sec. to the general fund. Copies of the medal were exhibited (Profile with dates of birth and death, on the reverse, Pascal's hexagram, surrounded by the "Zodiac of Syllogisms," and the title President of the London Mathematical Society).—The following communications were made:—On differential equations, total and partial, and on a new soluble class of the first and an exceptional case of the second, by Sir J. Cockle, F.R.S.—Discussion of two double series arising from the number of terms in determinants of certain forms, by Mr. J. D. H. Dickson.—Two geometrical notes relating to surfaces of the second order, by Prof. H. J. S. Smith, F.R.S.

Physical Society, March 8.—Prof. W. G. Adams in the chair.—Dr. Hurst and Mr. Jacob were elected Members.—Prof. Ayrton brought forward a new theory of terrestrial magnetism originated by himself and Prof. Perry of the Imperial Engineering College, Japan. It is well known that metal cages act as screens against induction in the case of static electricity or electricity at rest, and hence Clerk Maxwell, at the British Association meeting for 1876, suggested that no earth connection was necessary for lightning conductors, since a cage would be sufficient. But dynamic electricity is different from static in this respect, and Professors Ayrton and Perry found that even a thick block of copper will not screen a coil of wire from the induction of a *current* flowing in a neighbouring one. Some experiments of Dr. Muirhead, not yet published, would seem to favour the view that a current is a series of intermittent changes of potential, and that the inductive effect was due to a difference in the epochs of the currents in the two coils. It was found by Helmholtz that a quantity of static electricity in mechanical

motion performs work. Conversely Mr. Crookes finds that the stream of molecules from a − pole *in vacuo* is electrified, and may be deflected by a magnet. It is upon that fact that Professors Ayrton and Perry have based their theory, which is easily explained by supposing the earth to be an isolated sphere with a static charge residing on its surface. Then, since each electrified particle at the surface will be moving relatively to a point in the interior, it follows that the interior must be magnetic. The theory is independent of the substance of the interior; but in order to simplify the working the authors treated the case of a solid iron ball, and curiously enough arrived at the result expressed by Biot's law for the distribution of magnetism on the surface of the earth—

$$I^2 = M \sqrt{1 + 3\cos^2\theta},$$

and similarly they found that if the earth were electrified to the potential of 10^8 volts, relatively to interplanetary space, its magnetisation would be as it is. If the earth were alone in the universe, then, by this theory, it would have its own magnetic state by virtue of its electric charge and axial rotation. If other bodies in the universe, however, had their magnetic states too, these would influence the earth's, and hence we should have terrestrial tides and storms of magnetic force, such as are known to exist, as, for instance, when changes take place in the sun's atmosphere by approach of planets or other causes. Lastly, the iron in the interior of the earth may give it a certain amount of coercitive force, but the theory does not rest on this.—Dr. J. Hopkinson then read an account of some experiments made with the quadrant electrometer, which showed that Clerk Maxwell's formula for the sensibility of the electrometer—

$$(A - B)\left(C - \frac{A + B}{2}\right),$$

where A and B are the potentials of the two pairs of quadrants, and C the potential of the needle, only holds good when C (the charge of the jar or needle) is less than 200 Daniell elements. Above that a different law appears to hold. Dr. Hopkinson also remarked that any degree of low sensibility down to zero could be got from the electrometer by connecting a condenser to each pair of quadrants and adjusting their capacities.—Mr. F. D. Brown described his apparatus for maintaining constant temperatures and pressures. A constant temperature can be obtained if the pressure can be kept constant. The vessel in which the constant pressure is desired communicates with an air-pump by a pipe in which a movable tap or valve is placed. By opening or closing this tap the pressure is regulated. This is effected by an electric clutch arrangement. A mercury anemometer sends a positive or negative current from a battery through the clutch according as the pressure is too high or low, and this current actuates the clutch to close or open the valve. The clutch consists of an axle driven by a turbine to get power to work the valve, and the current, by means of electromagnetism, connects the tap to the axle, which then opens or closes it as the case may be. In this way a pressure varying no more than one-fifth millimetre each way can be obtained.

Linnean Society, March 6.—William Carruthers, F.R.S., vice-president, in the chair.—Mr. Thos. Christie exhibited and made remarks on a series of specimens illustrating the little-known and remarkable Australian Pituri plant; also the *os sepia* of a rare Australian cuttle-fish, obtained by Dr. Bancroft.—Mr. R. Irwin Lynch showed a growing example from Kew and dried leaves of *Xanthosoma appendiculatum*, bearing pouch-like excrescences from the midrib of the leaves.—The Vice-President announced from the chair an alteration in the Bye-laws, Chap. XIII., proposed by the Council.—A letter was read from a correspondent referring to the increased production of beet-root sugar by careful artificial selection of the beet. The saccharine produce of sugar-cane, on the contrary, remains stationary, if not retrograde, and its continual multiplication from stolons some regard as giving rise to various diseases. Crossing and selection are now suggested as worthy of a trial in the interest of commercial results.—A short paper on Entozoic Florideæ growing within living Bryozoa and Sponges, by Dr. P. F. Reinsch, was read, and Mr. A. W. Waters exhibited in connection therewith, under the microscope, specimens of Polyzoa containing parasitic algæ.—In a note on the fruiting of *Wistaria sinensis* in Europe, by Mr. W. T. Thiselton Dyer, the author avers from his own and others' observations that plants trained on a garden wall at Glyon, east end of the Lake of Geneva, yield abundance of brown tomentose pods annually. Near the town of Geneva, however, fruiting is of rarer occurrence, but again more frequent at Lyons and the Rhone valley. Fruiting, he suggests, may be a question of temperature and not of nutrition, dependent on presence or absence of support to the stem and branches. From the above and other data, Mr. Dyer fails to see the evidence of the antagonism of the vegetative and reproductive forces, as asserted to be the governing law, according to Mr. Thos. Meehan's experiments, and lately quoted by the Rev. G. Henslow. If such barrenness were the case with its scandent habit, then *Wistaria sinensis* would probably already be extinct.—The Secretary read a paper by Mr. Edward J. Miers, on the classification of the Maioid crustacea or Oxyrhyncha. The Maioid crabs have been placed by nearly all carcinologists at the head of the Brachyura, from the high degree evinced in their sensory organs and nervous system, and the group, moreover, is interesting on account of the variety of types. Though closely related to the Oxystomata, the Oxyrhyncha differ from them in their triangular buccal cavity and position of afferent branchial channel; but Mesorhœa approximates on the part of the Parthenopidæ to the Oxystomatous type. From the Cancroid crabs (Cyclometopa) typical Maiidæ are distinguished by longitudinal antennules and position of basal antennule joint, the Parthenopidæ occupying an intermediate place between the rest of the Oxyrhyncha and certain Cancroidea. The author reviews the various classifications, and then gives a new synoptical arrangement founded on certain anatomical configurations, &c., of their buccal cavity, situation of afferent and efferent canals, antennules, genital appendages, &c. He divides the group into 4 families, 12 sub-families, 106 genera, and 14 sub-genera, giving short diagnoses of each.—Prof. J. Reay Greene, Dr. P. H. Stokoe, Mr. R. Johnston (of Tasmania), Mr. B. S. Williams, and Prof. J. Wood Mason, were balloted for and elected Fellows of the Society.

Entomological Society, March 5.—J. W. Dunning, vice-president, in the chair.—The chairman referred to the great loss sustained by the Society in the death of Mr. F. Smith, of the British Museum.—Mr. C. Brogniart, of Paris, was elected a Foreign Member and Mr. J. T. Harris, of Burton-on-Trent, a Subscriber to the Society.—Sir Sydney Saunders exhibited a series of bees belonging to the genus *Halticus*, from Greece, containing several remarkable new forms. The following papers were communicated:—On some new species of British hymenoptera, by Mr. Peter Cameron, and descriptions of some new species of coleoptera from New Zealand, by Dr. Sharp.

ORGANISATION AND INTELLIGENCE

Habit and Intelligence: a Series of Essays on the Laws of Life and Mind. By Joseph John Murphy. Second Edition, illustrated, thoroughly revised, and mostly rewritten. (London: Macmillan and Co., 1879.)

Life and Habit. By Samuel Butler. (London: Trübner and Co., 1878.)

THE first edition of Mr. Murphy's work was reviewed in NATURE, vol. i. pp. 288 and 315, a little more than nine years ago, and on reading the article we find little or nothing in the remarks and criticisms then made which require modification on account of subsequent discoveries. The present work is, however, very largely new, about one-third of the matter in the first edition, which treated of physical questions, being omitted, and replaced by a series of new chapters on biological subjects. It is to these new chapters that we shall mainly confine our present notice.

Chapter XI. gives a very good summary of the facts of variation from Darwin's "Domestication of Animals and Plants," and other works; and in Chapter XII. we have these facts discussed in regard to the sufficiency of natural selection for the origin of species. The greatest use is here made of the argument (said to be Prof. Tait's) in the *North British Review* (June, 1877), and which another writer has summed up as follows:—"The final establishment of the superior type is dependent at each step upon three accidents. First, the accident of an individual sort or variety better adapted to the surrounding conditions than the then prevailing type; secondly, the accident that this superior animal escapes destruction before it has time to transmit its qualities; and thirdly, the accident that it breeds with another specimen good enough not to neutralise the superior qualities of its mate." Put in this way, the difficulty staggers most persons who are not practical naturalists; yet it has always seemed to me to be really beside the question, and by no means of the importance which Mr. Darwin himself has given to it by acknowledging that the argument had not occurred to him. Even acute writers like Mr. Murphy do not see that individual variations or "sports" are of no importance whatever to the theory of natural selection, or he would never bring forward the argument at p. 380, that with an animal born of two parents "there is an almost overwhelming probability that the favourable variation is found only in one," and will therefore diminish in each succeeding generation till it disappears, unless the same favourable variation recurs again and again to counteract this tendency. In what may be termed normal variation, however (which Mr. Darwin has always considered the main agent in supplying materials for natural selection), none of these difficulties occur, and as it is very important to make this clear, I will give a few illustrations of it. There is no part, organ, or character of an animal or plant but what is sometimes more sometimes less developed in different individuals. The whole population of a species in any given year may therefore be divided into two equal portions, with regard to any such organ or character—the less developed and the more developed. Thus, for example, all the foxes of the species *Canis vulpes* are necessarily divisible into a lighter and a darker coloured group; into a longer and a shorter tailed group; into a fleeter and a less fleet group; into a group with more developed and less developed canine teeth; and so on with regard to every character, external and internal. This can only be denied by asserting that there are characters which in the species in question are *absolutely unvarying*, an assertion which I am not aware that any one has made or attempted to prove, while it is certainly contradicted by the observations of all who have ever studied nature.

But if so, what happens when changed conditions occur, rendering the increased development of some faculty or organ beneficial? Can any one doubt that the one or five, or twenty per cent. of individuals which annually survive will belong, wholly or almost wholly, to the moiety in which that organ or faculty is better developed rather than to that in which it is worse developed? It matters not at all whether the *most* perfect individual or the twenty most perfect individuals survive or not; but the survivors will certainly be found among the better adapted rather than among the worse adapted half, and most likely will include a majority of individuals in the better half of the better half. And this process will be repeated *every year* without fail. There is thus no waiting for favourable variations to occur; no series of coincident improbable accidents is required; but the process goes on continuously with ever increasing power owing to the influence of heredity, till the species is modified up to the requirements of the changed conditions. By this process, leading to a decided advance *every year*, we can quite understand how any dominant species (that is, one which occupies a wide area and has a large population) may be modified quite as rapidly as is required by all ordinary changes of conditions, although extraordinary changes may lead to the extinction even of dominant species. It is hardly possible to conceive any improvement or modification of a species which might not be brought about by so powerful a selection as this, acting on variations which seem to us very trivial; while, on the other hand, the effect of greater individual variations or "sports" is very uncertain, and may perhaps never be used in nature as a means of modifying species.

These considerations also show the true bearing of "Delbœuf's Law," to which Mr. Murphy attaches much importance. It is proved mathematically that if, in any species, several individuals are in every generation born with any particular variation which is neither beneficial nor injurious to its possessors, and if the effect of the variation is not counteracted by reversion, the proportion of the new variety to the original form will constantly increase until it approaches indefinitely near to equality. But as, in every species, there are not one only, but hundreds of distinct variations in every generation, all subject to change in amount and direction in each succeeding generation, and as each of these will by the above law tend to equality with all others, the result must be that every slight recurrent variation will maintain itself in the species on terms of approximate equality with all other variations; and this will evidently be useful, by keeping up a vast stock of slightly varied forms within the species, which will be ready at any moment to furnish the material

on which selection may work when variations of a particular kind are needed.

The next three new chapters, on "Fixation of Characters," on "Effect of Change of Conditions," and on "Mimicry, Colour, and Sexual Selection," contain much interesting matter, with a number of suggestions of difficulties mostly dependent upon our total ignorance of the peculiar conditions or laws under which certain characters first arose. Such difficulties are of little importance, because they are always liable to disappear with an increase of knowledge. What, for instance, is the value of such a criticism as this: "The abnormal position of the left carotid artery in some groups of parrots is as good an instance as can be mentioned of a character which is constant throughout an entire group, which *must* have arisen suddenly, and *cannot* have been fixed by natural selection, because it *cannot* be useful." The three words I have italicised mark three positive statements which cannot possibly be verified, and which may very probably all be wrong. The parrots form not a *family* only, but a very distinct *order* of birds, and, from the occurrence in the miocene of France of a parrot of a living genus, are probably of immense antiquity. Not only do we know nothing of their early history, but, owing to their so rarely breeding in this country we know nothing of their embryology, and can therefore have no grounds for assertions as to what could or could not have been in the remote past, when they were developing into the varied forms that now exist, under conditions of which we are perfectly ignorant.

Another new chapter, on "Metamorphoses and Metagenesis" gives an interesting outline of the metamorphosis of insects, crustacea, and hydroids, illustrated by a number of excellent figures, and remarks on the difficulty of explaining many of the facts by variation and natural selection, the conclusion being that "many of the transformations, especially among the crustacea and the hydrozoa, do not consist in adaptations to any new or special mode of life, and consequently cannot be accounted for by the Darwinian or any similar theory, but must be due to a formative impulse impressed on living matter at the beginning."

The next chapter, on "Structure in Anticipation of Function," is not so good as some of the others, and here again objections are brought forward whose whole weight depends on our ignorance of the conditions under which certain structures were modified. Thus, it is said to appear impossible to account for the transition from the fin of *Ceratodus* to the simple fin-ray of *Lepidosiren* by any means which Darwinism admits, because it seems impossible that the loss of the membranes of its fins can be beneficial to a fish. But in this case there seems to be a difference of habits which may show how the "impossible" occurred. The *Lepidosiren* of the Gambia burrows in the mud, where it remains during the dry season, and for this "burrowing" the cylindrical rays may be better adapted than the broad fins of *Ceratodus*.

In the chapter on the "Origin of Man" Mr. Murphy replies to my argument that the brain of savage man is an instrument beyond his needs, by pointing out that "the real superiority of man consists in the faculty of language, and that the mental power implied in this unique faculty is represented by the very great excess in the size of the human brain over that of the highest apes;" and he goes on to say: "If, then, the Darwinian theory is true of man, the difference between the highest ape and that of the lowest man is due to the exercise of the brain during the period while the power of language was in process of evolution, aided by the natural selection of the largest brains, in which, of course, this new power would be most highly developed." This appears to me a very forcible objection, and I must acknowledge that it is "a sufficient answer" to my argument, so far as regards the difference between the brain of savage man and apes. The question remains, however, of the latent powers in the brain of savages; and Mr. Murphy maintains that the languages of many savages—of the Kafirs, for example, are so much in advance of their needs that they could not have been evolved by natural selection. In most other respects he agrees with the arguments in my essay on "The Limits of Natural Selection as applied to Man."

This concludes the new matter in the physiological part of the book; but before passing on to the psychological portion, I must notice one passage embodying a very common source of confusion as regards the geographical distribution and mode of origin of species. Referring to the marine lizard of the Galapagos, *Amblyrhynchus*, Mr. Murphy remarks: "This singular species is found nowhere except in the Galapagos, and consequently has, most probably, been evolved there; but on Darwinian principles, how can so peculiar and aberrant a form have been evolved during the geologically short time that has passed since these islands first rose above the ocean?" The difficulty thus raised, with many analogous cases, I have endeavoured to explain in the February issue of the *Nineteenth Century*. The idea that this peculiar lizard has been "evolved," in the Galapagos really implies spontaneous generation; for what was it evolved out of? A remote ancestral form *must* have reached the islands from the main land, if there is to be any "evolution" in the case, and if a remote why not a near ancestor? It appears to me, not a mere probability but almost a certainty, that the generic type, if not the actual species, was "evolved" in America; that it was once an abundant, and, in fact, a dominant group; that it then spread to the Galapagos; that the entire group then died out on the main land, but was preserved in the islands, *owing to the absence of enemies and competitive forms*. On this principle almost all the supposed difficulties of geographical distribution may be rationally explained; and this mode of explanation is in accordance with palæontological evidence whenever it is procurable.

The remaining chapters form the psychological part of the work, in which the author develops his theory of the organising intelligence in animal forms. The only new chapter here is that on "Automatism," in which the various questions connected with the automatic motions of plants and animals, and with the instincts and the habits of animals, are set forth and commented on; and here it is very interesting to compare the conclusions arrived at with those of Mr. Butler in his very original and suggestive book on "Life and Habit."

Mr. Murphy says that the actions of a sea-anemone in seizing on its prey with its tentacles, or in closing itself

when left uncovered by the receding tide, are probably purely automatic, and completely independent of sensation, consciousness, or will; and further, that there is probably no difference whatever between these motions and those of the leaves of *Dionæa* and *Drosera* which crush insects to death and suck their juices. But though independent of consciousness they are not independent of intelligence: they are instinctive, and instinct is intelligence unconscious of itself. All such actions as these are classed as *primarily* automatic, having no relation to consciousness; but there are also actions which are *secondarily* automatic, which were once conscious actions but have become unconscious through habit. These habits may become hereditary, forming instincts, and can then in some cases not be distinguished from primary automatism. Elsewhere he speaks of "a principle of intelligence which guides all organic formation and all motor instincts, and finally attains to consciousness in the brains of the higher animals, and to self-consciousness in the brain of man."

We will now turn to Mr. Butler's work, and see how he deals with these and analogous facts. He first discusses acquired habits, showing that, as we do things more and more frequently we do them with less thought and effort, till at last, when we do them perfectly we also do them unconsciously. He then shows that the same law applies to knowledge and beliefs, which are only complete and unwavering, when we have ceased to doubt or to think of reasons or facts in support of them, when, in fact, they have become unconscious. We then come to habits acquired at or soon after birth, as walking, or eating, which, though they continue to be voluntary, are often performed quite unconsciously. Swallowing and breathing, though very complex acts, are acquired by the infant a few minutes after birth, and thence performed unconsciously, and we endeavour to explain this by the terms "hereditary instinct," and the "experience of the race." Mr. Butler concludes that these terms are unmeaning, and that, because we see that all actions when performed sufficiently often become automatic, we ought to conclude, whenever we see actions performed automatically, that there *has* been this repeated performance of them somehow or other. He thus sums up his facts on this phase of the question: "We are most conscious of, and have most control over, such habits as speech, the upright position, reading and writing, which are acquisitions peculiar to the human race, and always acquired after birth. We are less conscious of, and have less control over, eating and drinking, swallowing, breathing, seeing, and hearing, which were acquisitions of our prehuman ancestry, but which are still, geologically speaking, comparatively recent. We are most unconscious of, and have least control over, our digestion and circulation, which belonged even to our invertebrate ancestry, and which are habits, geologically speaking, of extreme antiquity." These principles are then applied to a great variety of facts in biology with extreme and, as some may think, perverted ingenuity, of which we can only give a single illustration: "We say of the chicken that it knows how to run about as soon as it is hatched. So it does; but had it no knowledge before it was hatched? What made it lay the foundations of those limbs which should enable it to run about? What made it grow a horny tip to its bill before it was hatched, so that it might pick all round the larger end of the egg-shell, and make a hole for itself to get out at? And is it in the least agreeable to our experience that such elaborate machinery should be made without endeavour, failure, perseverance, intelligent contrivance, and practice? In the presence of such considerations it seems impossible to refrain from thinking that there must be a closer continuity of identity, life, and memory between successive generations than we generally imagine." This is the "unconscious organising intelligence," says Mr. Murphy, ultimately becoming conscious in the complete animal. "It is the result of often repeated conscious acts," says Mr. Butler, "which are now performed unconsciously after countless repetitions."

At first sight we seem to have here only the "ancestral experience" which has already been objected to as unmeaning. But this difficulty is overcome by the strange assumption that "it is the same chicken which makes itself over and over again; for such unconscious action is not won, so far as our experience goes, by any other means than by frequent repetition of the same act on the part of one and the same individual." Let no reader throw the book aside on coming to this astounding sentence, till he has read the two succeeding chapters on "Personal Identity," which are full of curious facts and subtle reasoning, and which lead to the conclusion that life is the one great personality, of which all living things are but differentiated offshoots still retaining a latent memory of a long succession of ancestral habits and experiences. This idea is carried further in the next chapter, on "Our Subordinate Personalities," in which it is shown that the highest authorities maintain the distinct individuality of the countless cells or physiological units of which our bodies are composed, and Mr. Butler remarks: "With the units of our bodies it is as with the stars of heaven, there is neither speech nor language, but their voices are heard among them. Our will is the *fiat* of their collective wisdom as sanctioned in their parliament, the brain; it is they who make us do whatever we do. When the balance of power is well preserved among them, when they respect each other's rights, and work harmoniously together, then we thrive and are well; if we are ill, it is because they are quarrelling among themselves, or are gone on strike for this or that addition to their environment, and our doctor must pacify or chastise them as best he may."

Passing on to Chapter IX.—on the "Abeyance of Memory"—it is shown that we remember best two classes of phenomena, either very unfamiliar objects or combinations—as if we were once in our lives shipwrecked on an iceberg, or very familiar object or acts, which produce their effect by repetition. These last, however, are apt to become unconscious, or to be wholly lost sight of, except when the usual conditions call them up, an amusing illustration of which is given as follows:—"Men invariably put the same leg first into their trousers—this is the survival of memory in a residuum; but they cannot, till they actually put on a pair of trousers, remember which leg they *do* put in first; this is the rapid fading away of any small individual impression." It is on the same principle that every act of growth of cells

and organs is said to be unconsciously remembered, when the same or analogous conditions recalls it to the dormant memory.

In another very ingenious and suggestive chapter entitled "What we might expect," it is maintained that the preceding facts and principles lead up to and explain all the curious phenomena of growth, reproduction, variation, and heredity, as set forth in the works of Darwin, Spencer, and other writers; and the same principles are applied in succeeding chapters to the phenomena of instinct, and the theories of Lamarck, Darwin, Mivart, and others. The argument is then summed up, and the conclusion arrived at that "Life is that property of matter whereby it can remember. Matter which can remember is living; matter which cannot remember is dead. The life of a creature is the memory of a creature. We are all of the same stuff to start with, but we remember different things. As for the stuff itself of which we are made, we know nothing save only that it is 'such as dreams are made of.'"

Such a brief notice as this can give no adequate idea of the originality and the logical completeness of Mr. Butler's remarkable work, which is far less known than it deserves to be. It may be truly said of it that it is more amusing than most novels, while it contains more material for thought than is to be found in most books of double the size. It will be seen that there is a certain agreement with Mr. Murphy, but Mr. Butler goes much further, in tracing the former writer's vague and unlocalised "unconscious intelligence" to the physiological elements of all organisms; and, however wild and improbable the theory may seem, it receives, strange to say, considerable support from the views of Haeckel and other German physiologists of the most advanced school. If the reader will turn to NATURE, vol. xix. p. 115, he will find Haeckel maintaining that "in the *Infusoria* a single cell performs all the different functions of life, including the mental functions." . . . . "By the same right by which we ascribe an independent 'soul' to these unicellular *Infusoria*, we must ascribe one to all other cells, because their most important active substance, the protoplasm, shows everywhere the same psychic properties of sensitiveness (sensation) and movability (volition). The difference in the higher organisms is only that there the numerous single cells give up their individual independence, and like good state citizens, subordinate themselves to the 'state-soul,' which represents the unity of will and sensation in the cell-association."

We have here an extraordinary agreement with Mr. Butler, although, as we are informed, he was quite unacquainted with Haeckel's works when he wrote his book; and this fact should induce us to give a more careful consideration to the views of a writer who, although professedly ignorant of all science, yet possesses "scientific imagination" and logical consistency to a degree very rarely found among scientific men. The want of a practical acquaintance with natural history leads the author to take an erroneous view of the bearing of his own theories on those of Mr. Darwin. There is really nothing to prevent their harmonious combination, and they may even be said to be in great part complementary to each other. Mr. Butler's book is so full of strange fancies and witty conceits, as to have led some readers to look upon the whole as an elaborate jest. Beneath this sparkling surface there is, however, much solid matter, and though we can at present only consider the work as a most ingenious and paradoxical speculation, it may yet afford a clue to some of the deepest mysteries of the organic world.

ALFRED R. WALLACE

RODWELL'S ETNA

Etna: a History of the Mountain and of its Eruptions. By G. F. Rodwell, Science Master in Marlborough College. With Maps and Illustrations. Pp. 142. (London: C. Kegan Paul and Co., 1878.)

IN this little volume Mr. Rodwell has essayed to do for Etna that which the late Prof. Phillips accomplished so successfully in the case of Vesuvius, namely, to write a popular and at the same time accurate account of the past and present conditions of a mountain, which from the very earliest periods to which human history and tradition go back, has powerfully arrested the attention and excited the imagination of mankind. The scope and aim of these two works being so nearly the same it is hard to avoid drawing a comparison between them.

The first and fifth chapters of the work of Mr. Rodwell, which deal with the past history of the mountain and the record of its eruptions, indicate much learning and careful research on the part of the author, and indeed these portions of his volume may compare not unfavourably with the equivalent parts of Prof. Phillips' work; higher praise than this can scarcely be given to it. Almost equally praiseworthy are the second and fourth chapters, which give a general sketch of the physical features of Etna and an account of the origin, the past history, and the present condition of the numerous towns which are crowded about the flanks of the great volcano. The third chapter, giving details concerning the author's own ascent of the mountain, though sufficiently interesting in itself, is perhaps better fitted for the pages of a popular journal than of a work like the present, since ascents of Etna are now sufficiently common and every-day occurrences.

It is when we come to the more purely scientific portions of the volume that a comparison of the work of Mr. Rodwell with that of Prof. Phillips places the former in such a disadvantageous light. It is rather startling to find the more general and popular descriptions occupying five chapters, including 113 pages, while the account of the geology and mineralogy of the mountain is condensed into a single chapter of 29 pages, and when these pages are read we cannot help feeling that the questions treated of in them are handled in a somewhat imperfect and perfunctory manner. Any one turning to a treatise professing to deal with the geology and mineralogy of Etna might fairly expect to find a fuller and clearer account than Mr. Rodwell gives us of the exact relations of the volcanic masses to the stratified and highly fossiliferous deposits with which they are so intimately associated. Equally disappointing is it to find that the important question of the elevation hypothesis of von Buch is so summarily dealt with by Mr. Rodwell, especially when we remember that in the discussion on this subject which took place between Élie de Beaumont and Dufrenoy

on the one hand, and Scrope and Lyell on the other, Etna supplied so crucial a test. Nor can we regard the few notes of Mr. Rutley on the microscopic characters of several specimens brought to him by the author, excellent as they are in themselves, as affording anything like an adequate discussion of the nature of the Etnean lavas.

There are not, indeed, wanting indications in the work before us that the author has scarcely succeeded in so far mastering the scientific questions connected with his subject as to qualify himself for giving anything like authoritative opinions concerning them. Thus on page 111 we find him speaking of a crater as "composed of a prehistoric grey labradorite, and of doleritic lava." Again, so far as can be gathered from the work before us, the hypotheses of elevation craters and eruption craters are of about equal value. We are informed simply that "the opinion of geologists is divided as to the manner in which a volcano is formed;" and then follows a statement of the two rival hypotheses. Surely after the convincing reasoning of Scrope, and the patient observations of Lyell on Etna itself, as detailed in the celebrated memoir read before the Royal Society in 1858, it is strange to find such language used upon the subject, more especially when we recollect that no attempt was ever made by Lyell's opponents to discredit his observations or to reply to his deductions. We should almost as soon expect to read in a modern work on astronomy that the opinion of astronomers is divided as to whether the earth moves round the sun or the sun round the earth.

We find so much to praise in this little book, especially in the clear *résumé* of the history of the mountain and its eruptions, and the illustrations so carefully selected and reduced from those of larger works which are not easily accessible to general readers, that we regret we cannot express more unqualified approbation of that portion of the book which calls for especial notice in the pages of this journal. We can only hope that in a second edition the author may find an opportunity, which he will not neglect, of considerably lengthening and very greatly strengthening this scientific portion of his work; and in order to do so, without at the same time impairing its popular character, we can scarcely suggest a better example for him to follow than the work of Prof. Phillips, to which we have alluded at the commencement of this article.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

The Trans-Neptunian Planet

THE explanation given by Prof. Peters (*Astr. Nach.*, 2,240) of the observations made at Washington in 1850 of this supposed planet is put beyond doubt by the examination of Mr. Ferguson's observing-book. It is due, however, to Mr. Ferguson to say that his record is full and complete, and that his changes in the reductions were honestly made. The record is in pencil, and no figures were erased or rubbed out. They are crossed out, and the assumed figure is put by the side of the original one, while at the bottom of the page is a note with pen and ink, and in Mr. Ferguson's handwriting, stating the changes that were made. Prof. Peters's ingenious discovery of the truth was made without knowledge of the observing-book.

Such criticisms are instructive, showing how unsafe it is to build theories before we are sure of the facts. They may also be a means of avoiding a waste of labour. It is known to me that at least two American astronomers, armed with powerful telescopes, have been searching quite recently for a trans-Neptunian planet. These searches have been caused by the fact that Prof. Newcomb's tables of Uranus and Neptune already begin to differ from observation. In this connection the note of Mr. Dunkin on the errors of Leverrier's tables of Saturn is interesting. But are we to infer from these errors of the planetary tables the existence of a trans-Neptunian planet? It is possible that such a planet may exist, but the probability is, I think, that the differences are caused by errors in the theories of these planets. My observations of the satellites of Saturn are not yet discussed, but they indicate that Bessel's mass of Saturn is nearly correct. Now Leverrier has diminished this mass by about $\frac{1}{115}$th, and it seems probable that this diminution was caused by some error in his theories of Jupiter and Saturn.

A few years ago the remark was frequently made that the labours of astronomers on the solar system were finished, and that henceforth they could turn their whole attention to sidereal astronomy. To-day we have the lunar theory in a very discouraging condition, and the theories of Mercury, Jupiter, Saturn, Uranus, and Neptune, all in need of revision; unless, indeed, Leverrier's theories of the last two planets shall stand the test of observation. But after all, such a condition of things is only the natural result of long and accurate series of observations which make evident the small inequalities in the motions, and bring to light the errors of theory.

Rats and Water-Casks

MR. NICOLS says, in NATURE, vol. xix. p. 433:—

"A ship's carpenter told me that, in the old days, before the use of iron tanks on board ship became general, the rats used to attack the water-casks, cutting the stave so thin that they could suck the water through the wood without actually making a hole in it. If any one could substantiate this it would have an important bearing on the question under consideration."

Capt. Wickham, when First Lieutenant on board H.M.S. *Beagle*, told me that when he was a midshipman it was his duty, on one of the king's ships to see that certain vessels on deck were always kept full of water, in order to prevent the rats gnawing holes through the water casks, and that through such holes nearly all the water in a cask would leak away.

CHARLES DARWIN

Tides at Chepstow

I OBSERVE two letters in NATURE lately upon this subject. Many years ago I took some pains to ascertain the greatest known rise of tide at Chepstow, for I doubted the accuracy of the common statement that it was seventy feet and upwards. At the time I made the inquiry the large railway bridge at Chepstow to carry the South Wales Railway across the River Wye was being constructed. I was acquainted with Mr. Oakden, one of the engineers on the work, and he, with great care, took levels of the marks which had been made from time to time recording the very high tides, some of them going back many years. He found the highest of them to be some decimal (of which I have no record) above fifty feet above ordnance datum. I think this may be relied upon. It is corroborated in a paper by the present Astronomer-Royal, on "Tides and Waves," in the "Encyclopædia Metropolitana," vol. v. p. 242, paragraph 7, first edition. He says: "Thus, at the entrance of the Bristol Channel the whole rise at spring-tides is about eighteen feet, at Swansea about thirty feet, and at Chepstow about fifty feet." W. B. CLEGRAM

Migration of Birds

PROF. NEWTON in his article on Migration of Birds (NATURE, vol. xix. p. 433) has omitted one, and a very important limit to the height at which birds of passage can perform their journeys. This is *temperature*. The following table of Daniell's will show

how little probability there is of migratory birds flying at great elevations, and that even in low latitudes, the temperature at altitudes exceeding four and a half miles would be prohibitory to the existence of the majority of migrants :—

Altitude.	Temp. F.	Temp. F.
′	°	°
0	+ 80	0
5,000	+ 64·4	− 18·5
10,000	+ 48·4	− 37·8
15,000	+ 31·4	− 58·8
20,000	+ 12·0	− 82·1
25,000	− 7·6	− 109·1
30,000	− 30·7	− 140·3

Calculations by Mr. Glaisher's rule for approximate temperature (decrease of 1° F. for every 300 feet elevation) give less startling results than the above, but even then, with the thermometer marking 80° at sea level, we find that a temperature of 40° of frost must exist at five miles in height.

The advocates of the "sight theory" have rather more in their favour than Prof. Newton has conceded to them. It is not necessary that birds should fly at such heights as to literally view the land they guide their course to or by. The "loom" of land, so well known to sailors, is visible when the land itself is below the horizon; and I do not think we are entitled to say that birds would not, equally with mariners, notice the indication. Then again the action of one flock of birds when in sight of land, might guide other more distant flocks, and these might influence birds still further off. We know how the circling downward swoop of a vulture on some discovered carrion will draw to the feast vultures from all parts of the sky. We know the power of our own vision, certainly inferior to that of many birds; and it is therefore well within the bounds of possibility that migrating birds, watchful because weary and hungry, may see and be influenced by the movements of flocks of their companions thirty to forty miles distant. A few flocks might thus bridge a wide expanse of barren ocean.

It is not necessary, however, to insist that sight alone is the guiding faculty in migration. The majority of, if not all, animals possess that marvellous "sense of direction" that has become so blunted in civilised man. Both savages and lower animals will find their way back in a "bee-line" through unknown country, to places whence they have been led by tortuous tracks. Why should not this "sense of direction" then guide birds over oceans without landmarks. The case of first migration of young birds (cuckoos and starlings) quoted by Prof. Newton, is, it must be confessed, a problem difficult to solve; but when the journey has been once made by an individual bird in a flock I cannot see more mystery in the arrival of that flock at their destination than there is in the perfect accord between the hand and the eye of a good shot or a good billiard player.

We must all concur with Col. Donnelly in desiring further observations, with facility for publication and discussion, and I venture to hope that we shall see many more papers from Prof. Newton's pen on the subject. E. H. PRINGLE

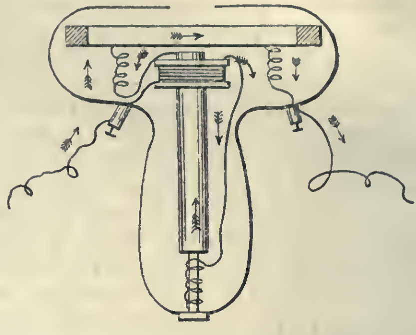
The Microtelephone

TOWARDS the end of last year I got constructed a telephonic apparatus which gives results much superior to those of the ordinary Bell telephone. Its construction is based on four principles, two of which have not yet been applied to telephones :—

1. The magneto-electric principles of the Bell telephone.
2. The microphonic principles of Hughes (different quantity of the points of contact).
3. The principle discovered by Beatson and De La Rive (1845), and which explains the experiments of Messrs. Blyth and Hughes with the speaking microphone (production of sounds by the passage alone of a discontinuous or undulating electric current).
4. The principle that the intensity of the sound depends on the density of the air in which it is produced.

All the principles are combined in so simple a manner that the microtelephone differs from the Bell telephone only in the three following points :—

1. The electric current engendered by the approach or withdrawal of the iron membrane, traversed not only the bobbin, but also the magnet and the membrane itself.
2. The communication of the current with the vibrating plate of iron is effected by means of two small springs, which are lightly pressed by the membrane, and as this pressure may be more or less strong during the action of the apparatus, the latter acts as a microphone of a relatively weak sensitiveness, but which permits the telephone to be spoken to at a distance of several centimetres, and of hearing the ticking of a watch, or the sounds of a musical box with the aid of a carbon microphone.



3. Three millimetres above the iron membrane is another membrane of caoutchouc (which should not be very fine), and both membranes inclose a layer of air, moderately compressed, which in this way must vibrate, together with the two membranes.

The microtelephone is regulated once for all, aud transmits the feeblest word with a truly perfect precision.

Vacuum Tube Phenomena

HAS it been observed that the area of the exposed surface of the negative electrode in a highly exhausted vacuum tube exerts an important influence on the facility with which the discharge takes place?

I have recently been observing Crookes's molecular shadows with a tube constructed by Mr. J. Marr, of Liverpool, in which one electrode is a flat disk about 1 inch in diameter, and the other a piece of platinum wire about ⅜ inch long. When these electrodes are connected with the terminals of an induction coil capable of giving a 4½-inch spark in air, and the contact-breaker arranged so that the shadows can just be seen when the disk is in connection with that terminal which becomes negative when the current in the primary wire is broken, a reversal of the commutator causes the discharge to cease.

If, now, the coil power be increased by the proper manipulation of the contact-breaker, a condition of things is reached in which the dark shadows flash out intermittently, even though the disk is connected with what is called the positive terminal of the induction coil.

This is evidently caused by the passage of the inverse induction current; I mean that current which is produced when the circuit of the primary is completed. It thus appears that a condition of things can be obtained in which the effect of the greater electromotive force produced on the breaking of the primary circuit is counterbalanced by the influence of the relative size of the electrodes.

The above observation appears to be interesting, and as it may possibly be new, I venture to send you an account of it.

Nottingham, March 8 J. J. H. TEALL

Leibnitz's Mathematics

PROF. TAIT has recently given your readers one mathematician's opinion of Leibnitz as a discoverer. The following extract is serviceable in the same direction, while it has the further merit of attesting to the existence of a still later "vestige of presumption" than has yet been referred to. The extract is from a review by M. Bertrand of Dühring's "Kritische Geschichte der allgemeinen Principien der Mechanik" (Berlin, 1873). M. Bertrand says :—

Les sévérités de M. Dühring sont impartiales, et l'un des plus grands génies de l'Allemagne semble précisément le plus maltraité de tous. Les *Actes* de Leipzig, de 1684, donnèrent, est-il dit dans le texte, la première publicité à la théorie des fluxions de Newton, et en note, on ajoute: "Il n'a pas été possible d'opposer à Leibnitz des preuves complètes qui le

forçassent à avouer son emprunt ; mais la connaissance de son caractère donne à l'acte qu'on lui reproche une probabilité voisine de la certitude. Une lettre d'Huyghens à L'Hospital est sur ce point fort instructive.

"'M. Leibnitz,' dit Huyghens, 'est assurément très habile, mais il a avec cela une envie immodérée de paroître, comme cela se voit, lorsqu'il parle de son Analyse des infinis . . . , des lois harmoniques des mouvemens planétaires, où il a suivi l'invention de M. Newton, mais en y meslant ses pensées qui la gastent . . . Encore suis-je fort en doute, pour des raisons que je pourrois alléguer, s'il n'a pas tiré sa construction (de la chaînette) de celle de M. Bernoulli.'

"Dans la préface de son 'Calcul différentiel,' Euler n'attribue à Leibnitz que la réduction des principes de Newton en système. Lagrange, qui cherche chez Fermat l'origine du Calcul différentiel, ne manque pas, dans ses 'Leçons sur le Calcul des Fonctions,' de signaler les concordances de l'écrit de Leibnitz de 1684, avec la théorie antérieure de Fermat. Gauss pensait, comme on le voit dans l'écrit de Sartorius de Waltershausen, que Leibnitz, même de loin, ne doit pas être comparé à Newton."

It is satisfactory to quote Herr Dühring through his reviewer, because the introductory sentence of the extract makes evident to those not already aware of M. Bertrand's historical leanings that it is on Dr. Ingleby's side the eminent French mathematician would give his voice. THOMAS MUIR

High School of Glasgow, March 17

Blue Flame from Common Salt

SOME time ago the question was raised in NATURE (vol. xiii. p. 287) concerning the origin of the blue flame produced when common salt is thrown into a hot fire.

Among the suggestions that were advanced, no one offered the only explanation that is at all feasible, viz., that it is due simply to hydrochloric acid.

The blue flame is not produced by sodium chloride only, but by other chlorides as well. Those I have tried are $BaCl_2$, $SrCl_2$, KCl, AmCl, Hg_2Cl_2, and HCl, the last both in solution and as gas.

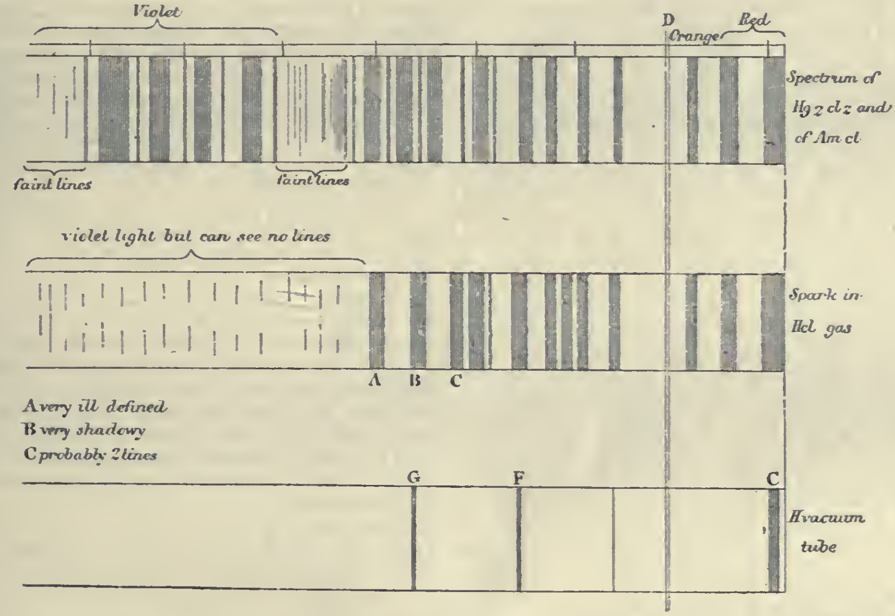
It would be waste of time and space to enumerate all the experiments I have made on this subject ; many of them were for the purpose of proving that neither carbon nor sulphur had any share in the reaction.

One of my methods of obtaining the flame was to burn pure hydrogen from a glass jet, and allow a mingled stream of HCl and NH_3 from two other jets to pass into it. The best source, however, is calomel, heated on wire gauze by a Bunsen burner ; the next best, AmCl.

The spectrum of the "chloride" flame is characterised by a series of double bands in the green, blue, and violet, the least refrangible of each pair being the broadest. The four pairs in the violet are especially prominent. There are two red bands or lines, and one orange. The least refrangible red line occupies the place of the hydrogen line C.

A spark between carbon points in a bottle of HCl gas yields a spectrum similar in appearance to that obtained from a chloride, but I was unable to see any violet bands, only a faint continuous spectrum.

I was able to ascertain that the red lines coincided exactly,



but I cannot affirm with the same positiveness that all the green lines and bands coincide. Some undoubtedly do, but the spectrum of the HCl was so faint, and the spectrum of the chloride so transient, that measurements were very difficult, and I do not pretend to any high degree of accuracy in my delineations of the lines, besides the different conditions under which the two were compared might account for considerable variations. For the HCl I used a coil (capable of giving a 2" spark) with Leyden jar, worked by six Smees. The carbon points were ½ inch apart. The spark was tried both focussed and unfocussed on the slit of a 2-prism spectroscope. When comparing the two spectra side by side it was difficult in some cases to be sure of coincidence, because the flame from the Hg_2Cl_2 would flash out brilliantly for a moment and quite overpower the more feeble lines of the HCl ; it would then disappear entirely, and more chloride would have to be placed on the gauze.

I have no doubt in my own mind that HCl is the cause of the blue flame. I have proved that Cl is a necessary constituent, and I have not been able to get it in the absence of hydrogen (the spectrum of pure Cl is very different), and besides the red H-line is present in both cases, and probably the other two as well. I do not think that the presence of aqueous vapour is sufficient to account for the red line.

I subjoin the spectra *as I mapped them*, but it must be borne in mind that I do not vouch that they are free from error. I intend to photograph them when I have sufficient leisure, and I hope the results will be more definite. I may be able to find violet lines in the spectrum of HCl.

Temple Observatory, Rugby, March 15

Unscientific Art (?)

IN NATURE, vol. xix. p. 460, Mr. Buck complains of the drawing in the *Graphic* for December 28, wherein the observer is represented as "sloping the barometer at an angle of about 30° from the vertical," in order to take a reading on a marine barometer by means of the lantern for better illumination. May not the artist be correct, and Mr. Buck have discovered a mare's nest? The barometer may be placed entirely horizontal for reading the scale, *after* the vernier has once been set when the instrument was vertical.

CHAS. COPPOCK

OUR ASTRONOMICAL COLUMN

THE DISTANT HERSCHELIAN COMPANION OF γ LEONIS.—In 1861 Prof. Winnecke, writing from Pulkowa, drew attention to a star of the ninth magnitude near the double-star γ Leonis, which M. Otto Struve had found to have an annual proper motion exceeding 0″·5. The star was observed with the Dorpat transit-instrument, on April 12, 1820, and once by Bessel in zone 502, on April 12, 1831, and from these observations compared with two at Pulkowa in April, 1861, and with micrometrical measures from γ Leonis by M. Otto Struve, Prof. Winnecke concluded that the proper motion of the small star with respect to the neighbouring binary, was very nearly 0″·85 in R.A. and 0″·10 in declination, annually. Sir W. Herschel observed a distant companion of γ Leonis, the mean of two angles giving 297°·5 for about 1782·9, with a distance of 111″·4, which he thought was "pretty accurate," though as we are now aware, many of these wider measures of Sir W. Herschel require material correction.

We refer to this star from having remarked that M. Flammarion, in his recently published "Étoiles Doubles et Multiples en Mouvement relatif certain," has made it the subject of a strangely confused article, which is calculated to mislead the reader who cannot refer to original authorities. The star had been measured by Secchi in 1856, and by Powell in 1861, and M. Flammarion states that "the enormous difference between the measure of 1782 and that of 1856" had induced him to search for other observations and to reobserve it himself, which he did, in 1877. He says he had found five observations by Flamsteed in 1691, ten by T. Mayer in 1755, and fifteen by C. Mayer in 1777; these, it is added, are not very precise, for they consist only of differences of right ascension, without taking account of the declination; nevertheless he considered they had their value, and comparing his own measures of 1877 with previous observations separately, he deduces "a very surprising result," viz., that the distant star is remarkable for its motion, which, if one may judge by the totality of observations, has a mean value of 1″·08, but which appears variable, as "at present it certainly has not that value."

The main cause of M. Flammarion's difficulty is his having confounded two quite distinct objects: we have not referred to the work of C. Mayer, but the star observed by Flamsteed, which he more than once calls "Comes γ," and that observed by Tobias Mayer, is really the bright neighbour of γ, or 40 Leonis; Flamsteed did observe the declination, as will be seen in his column "Distantiæ a vertice correctæ;" and Mayer also noted the declination on one occasion, though generally recording only the right ascension. M. Flammarion says he found five observations of Flamsteed in 1691, which is a greater number than we recognise in the "Historia Cœlestis," but there are observations in 1690 and 1692. The zenith distances of γ Leonis and *Comes* on April 6, 1691, and the names of the stars on January 23, 1692, are interchanged in the "Historia Cœlestis." Tobias Mayer's observations do not apply to the year 1755, when his observatory at Göttingen was not yet erected, but to 1756 and 1757, chiefly the former year. Bessel's observation applies to 1831, not 1825, as M. Flammarion assumes.

The star in question is No. 90, in Argelander's valuable treatise, "Untersuchungen über die Eigenbewegungen von 250 Sternen, &c.," where he deduces for the annual proper motion in arc of great circle, 0″·512 in the direction 270°, or the proper motion is entirely in R.A. He observed the star upon the meridian at Bonn, once in 1857 and four times in 1862-63. It was also meridionally observed at Greenwich in 1862. It is No. 234, Hour X., in Weisse's Bessel. Thus we have three stars situate within half a degree, with large proper motions, very divergent, however, in direction:—

	Secular P.M.	Direction.	Authority.
	″	°	
40 Leonis	32·2	229·0	Mädler.
W. B. X. 234	51·2	270·0	Argelander.
γ Leonis	32·3	118·6	Mädler.

A METEOR WITH SHORT PERIOD OF REVOLUTION.—In the very interesting report of the "Luminous Meteor Committee" of the British Association for 1877-78, we find a note by Capt. G. L. Tupman, referring to a fire-ball seen on November 27, 1877, which he considers to have been moving in a nearly circular orbit, with short periodic time. Capt. Tupman observed this meteor from a position about half a mile east of the Royal Observatory, Greenwich; it began as a first or second magnitude star, but suddenly increased in brilliancy and size to a fine bluish white fire-ball ten or twelve minutes in diameter, emitting a train, coloured blue, red, and green, many degrees long. It moved very slowly, so slowly, indeed, towards the end of its course, that it appeared to come almost to a standstill. The duration was considered to be fifteen or sixteen seconds. The meteor was observed by Mr. H. Corder, at Writtle, near Chelmsford, and by Mrs. Ware, at Clifton Down, Bristol, and the positions for beginning and ending, estimated at these stations, were found to be in remarkable agreement, the true path deduced from these satisfying them all, both azimuths and altitudes, within 1°.

It appears that the meteor first became visible at a real height of fifty-six miles vertically over a point off the mouth of the Thames in long. 1° 21′ E., lat. 51° 33′, and disappeared when it had descended to a height of thirteen miles vertically over a point, about twelve miles west of St. Omer, in France, in long. 2° 0′ E., lat. 50° 45′, the length of the entire path being about eighty miles.

Capt. Tupman thinks the radiant point was pretty accurately determined in R.A. 285°, Decl. + 64°, or in longitude 340°, and latitude + 83°. The elements of the real orbit, which, with the aid of the other corresponding data depending upon the earth's position in her orbit, are thence deduced, are as follows, taking the real duration at fifteen seconds:—

Perihelion distance	0·9858	Excentricity ...	0·1568
Longitude of perihelion ...	70° 6′	Inclination ...	15° 0′
,, ,, ascending node	245° 50′	Anomaly ...	−4° 16′
Semi-axis major	1·1691	Periodic time...	462 days

Motion—direct.

The precise Greenwich time of the occurrence of the meteor was 10h. 26m.

If the duration of visibility is diminished to 7½ seconds the elements are still very similar to the above; the semi-axis major becomes 1·3785 and the period 591 days. Capt. Tupman remarking that such favourable conditions for inferring the orbit of a meteor may rarely happen, adds, it is sufficient for the establishment of a short periodic time (such as 500 days) that "the meteor moved slowly from a fairly well-determined radiant distant about 90° from the point of the heavens towards which the earth's motion was directed."

We may mention that there is one singular circumstance not alluded to in Capt. Tupman's note: the elements defining the position of the orbit of the meteor

have a striking general resemblance to those of the orbit of Biela's comet, in the descending node of which body the earth was precisely situated at the time.

FOSSIL CALCAREOUS ALGÆ

THE very important memoir of M. Munier-Chalmas, "Sur les Algues calcaires appartenant au groupe des Dasycladées Harv. et confondues avec les Foraminifères," which was published in the *Comptes Rendus Hebdomadaires* of the French Academy of Science for October 29, 1877, opens up quite a new or almost a new field of research, which has been followed up by the same author in a note presented last month to the Geological Society of France, "On the genus Ovulites." Though regarded by some of the most eminent palæontologists as a monothalmic foraminifer related to Lagena, the genus Ovulites is herein clearly demonstrated to be neither more nor less than an articulation of a siphonaceous alga having very close affinities to Penicellus.

Ovulites margaritula is described by Messrs. Parker and Jones "as a common Foraminifer of the 'Calcaire grossier.' Shaped like an egg, and when full grown about the size of a mustard-seed, it is one of the most elegant of the fossil forms. The large terminal apertures, moreover, curiously impress upon the mind its resemblance to a 'blown' bird's egg. [Written in 1860; nowadays bird's eggs are not thus blown.] It is the largest of the monothalamous Foraminifera. As a species it appears to have been short-lived. Fully developed in the deposits of Hauteville and Grignon it breaks in at once in the Eocene period. It lingers as an attenuated form in the Miocene beds of San Domingo. A recent Ovulite has not been met with. Scarcely another Foraminifer presents us with a similarly brief history—an undescribed form allied to Dactylopora affording almost the only parallel (namely, *Acicularia pavantina*, d'Arch.)."

In passing it may be noted that without doubt this last-mentioned form is also only a portion of a calcareous alga.

The earlier memoir, of which the *Comptes Rendus* publishes only an abstract, reminds us that it is not so very long ago (1842) since Prof. Decaisne demonstrated that a number of marine forms known as zoophytes, Corallina, Cymopolia, Neomeris, Penicellus, Udotea, Halimeda, &c., were in reality veritable algæ. But we may remark that Prof. Schweigger, of Königsberg, had, from actual observation of living specimens of several species of these calcareous algæ at Villefranche, come to the same conclusion in 1818 ("Beobachtungen auf naturhistorischen Reisen. Anat.-phys. Untersuchungen über Corallen," Berlin, 1818). To go back to the pre-Linnean times, Ray (1690) described Corallina as "plantæ genus in aquis nascens," and Spallanzani, Carolini, and Olivi even maintained the same against the peculiar reasonings of Ellis, the authority of Linneus, and despite the conversion of Pallas; but so influenced by authority were, apparently, the botanists down to 1842, that a Professor of Botany in the Edinburgh University (Graham) once politely requested the zoologists to keep *their* cryptogamia to themselves, and a Professor of Botany in the Dublin University (Harvey), in the first edition of his "Manual of British Algæ" (1841), did not include any of the Corallines. Since the memoirs of Decaisne and Chauvin, all this has changed, and we imagine that there is now no difference of opinion existing among botanists as to the general affinities of the living forms of calcareous algæ.

M. Munier-Chalmas in his memoir demonstrates that there must be also added to this group a numerous series of fossil forms which the old authors placed among the polyps, and which most of the modern writers on the subject have ranked among the foraminifera. Bosc in 1806 described and figured (*Journal de Physique*, Juin 1806) some fossil organised bodies under the name of *Rétéporites ovoides*, for which bodies Lamarck in 1816 established the genus Dactylopora. "The most singular varieties of opinion have existed," writes Dr. Carpenter in his well-known "Introduction to the Study of the Foraminifera," "as to the true character of these fossil organisms. In separating them generally from Retepora Lamarck still associated them in the same group of supposed zoophytes; this position was also accepted for the genus by De Blainville and Defranc." [It is but justice to De Blainville to point out that he quotes without disapproval the statement of Schweigger, "que les dactylopores et les ovulites ne sont rien autre chose que des articulations d'une grande espèce de cellaire, analogue à la cellaire salicorne"]. "In 1852 Dactylopora was included among the Foraminifera by D'Orbigny, who showed, notwithstanding, by the place he assigned to it, a misapprehension of the real nature scarcely less complete than that under which his predecessors had lain; for he ranks it in his order Monostègues, next to the unilocular Ovulites, and says of it: 'C'est une Ovulite également percée des deux bouts, pourvue des larges pores placés par lignes transverses.' How utterly erroneous is this description will appear from the details to be presently given, yet D'Orbigny's authority has given it currency enough to cause it to be accepted by such intelligent palæontologists as Pictet and Bronn, who in the latest editions of their respective treatises have transferred Dactylopora to the place indicated by him, not, however, without the expression of a doubt on the part of Bronn as to whether the true place of the genus is not among the Fistulidæ in alliance with Synapta and Holothuria—a suggestion that indicates a perversion of ideas on the subject for which it is not easy to account. The complex structure of the organism in question was first described and the interpretation of that structure on the basis of an extended comparison with simpler forms was first given, by Messrs. Parker and Jones in so unobtrusive a manner as scarcely to challenge the attention which their investigations deserve, and I gladly avail myself of the opportunity which the present publication affords to give a fuller account, with the requisite illustrations of this remarkable type, the elucidation of which seems to me not unlikely to lead to a reconsideration of the place assigned to many other organisms at present ranked among Zoophytes or Polyzoa;" and then follow nine pages of a most elaborate description of every ridge and furrow, of every elevation and depression to be met with in any of the so-called species, so that probably no single vegetable cell was ever before so minutely described.

The genus is placed the eleventh in order of the family Miliolida, a family which contains some of the most typical of Foraminifers. "It may be conjectured without much improbability," writes Dr. Carpenter, "that Dactylopora is only the single representative of a group whose various forms filled up the hiatus which at present intervenes between itself and its nearest allies among the ordinary Foraminifera." But, writes M. Munier-Chalmas, "the study and comparison of species of Dasycladus, Cymopolia, Acetabularia, Neomeris, &c., in the herbarium of the museum, and in that of M. Ed. Bornet, who placed without reserve at my disposal his library and collections of these plants, proved to me that the species of Dactylopora, Acicularia, Polytrypa, &c., are decidedly Algæ, very nearly allied to species of the recent genera just quoted, if not identical therewith. The accompanying figures show plainly, for example, that the genera Cymopolia and Polytrypa may be united; for the typical species thereof offer in every respect the same generic characters, and there is even a difficulty to find for them sufficiently distinct specific characters. Under the denomination of '*Siphoneæ verticillatæ*' I unite (1) Those green-spore bearing algæ arranged by Harvey in the family of the Dasycladeæ; (2) All those fossil gener related to Larvaria, Clypeina, Polytrypa, Acicularia, Dac-

tylopora, and Uteria. This group at present contains over fifty genera, which are for the most part to be met with in the triassic, jurassic, cretaceous, and tertiary strata. In the number of those actually living there is a notable falling off, there being not more than the seven following genera :—Dasycladus, Halicoryne, Cymopolia

FIG. 1.—Transverse section of a morsel of the calcareous tube of *Cymopolia rosarium*, Lamr., showing the canals which receive the whorl of cellules and the central sporangial cavity. FIG. 2.—Transverse section of *Polytrypa elongata*, Defrance, showing the same portions. FIG. 3.—Part of a whorl of cellules of *Cymopolia rosarium*, separated from the calcareous tube by acid. A, wall of central cellule; B, first row of cellules; C, terminal whorl of cellules, in the centre of which is D, the axillary sporangium. FIG. 4.—Exactly the same parts in *Polytrypa elongata*, obtained from a mould.

(with two sub-genera, Polytrypa and Decaisnella,[1] g.n.), Polyphysa, Acetabularia, Neomeris, and Bornetella,[2] g.n." [Doubtless a few more genera of recent forms yet remain to be described. Thus Chloroclados, of Sonder, appears to be a good and distinct genus allied to Dasycladus.]

"The frond in the *Siphoneæ verticillatæ* is simple or dichotomous ; it consists of a central tubular unicellular axis, around which are arranged the radiary and verticellate ramuli, the exact arrangement of which varies according to the genera and to the species. In most of the species carbonate of lime is found deposited in abundance in the outer walls of the main axis and its ramuli, and this forms around the plant a calcareous envelope, in which is reproduced all the details of its organisation. This mineral coating may consist of one or of two calcareous cylinders. The inner cylinder will be formed by the central axis, and the first row of cells which arise therefrom. The outer cylinder is laid down by the most external of the verticels of cells ; these terminate by a splayed-out enlargement, the lateral edges of which become more or less consolidated with the similar enlargements of neighbouring cells, and by thus causing a reciprocal pressure, very regular hexagonal surface markings are produced. The organs of fructification are themselves surrounded by calcareous material, and assist in the formation of the outer cylinder, a fact easily seen in any section of Cymopolia."

The result of such an organisation is that when the organic vegetable matter becomes destroyed there still remains in those fossil species, which laid down a great deal of calcareous material, as well as in those living species—which lay down more or less of it—a skeleton permeated by canals (rays of the ramuli) and chambers (fructification). This arrangement, which permits of an exact classification of the fossil species, being wrongly interpreted, led even some most distinguished authors to see in these morsels of plants the full organisation of a Foraminifer."

Space will not permit of the table of the twenty-two genera and seven families as detailed in the *Comptes Rendus* being here given, but every botanist will look forward with interest to the promised future detailed contributions of the author on this subject. Here it seems desirable to add that his conclusions are in every particular acquiesced in by one in every way thoroughly able to judge of the facts, Dr. Ed. Bornet, and having written this I feel it almost superfluous to say that on a careful study myself of specimens prepared by M. Munier-Chalmas—for which I take this opportunity of thanking him—I cannot conceive his demonstration as admitting of a doubt.

ELECTRICITY AND WATER DROPS [1]

IT has been known for many years that electricity has an extraordinary influence upon the behaviour of fine jets of water ascending in a nearly vertical direction. In its normal state a jet resolves itself into drops, which even before passing the summit, and still more after passing it, are scattered through a considerable width. When a feebly electrified body is brought into its neighbourhood, the jet undergoes a remarkable transformation, and appears to become coherent ; but under more powerful electrical action the scattering becomes even greater than at first. The second effect is readily attributed to the mutual repulsion of the electrified drops, but the action of feeble electricity in producing apparent coherence has been a mystery hitherto.

It has been shown by Beetz that the coherence is apparent only, and that the place where the jet breaks into drops is not perceptibly shifted by the electricity. By screening various parts with metallic plates, Beetz further proved that, contrary to the opinion of earlier observers, the seat of sensitiveness is not at the root of the jet where it leaves the orifice, but at the place of resolution into drops. As in Sir W. Thomson's water-dropping apparatus for atmospheric electricity, the drops carry away with them an electric charge, which may be collected by receiving the water in an insulated vessel.

I have lately succeeded in proving that the normal scattering of a nearly vertical jet is due to the *rebound* of the drops when they come into collision with one another. Such collisions are inevitable in consequence of the different velocities acquired by the drops under the action of the capillary force, as they break away irregularly from the continuous portion of the jet. Even when the resolution is regularised by the action of external vibrations of suitable frequency, as in the beautiful experiments of Savart and Plateau, the drops must still come into contact before they reach the summit of their parabolic path. In the case of a continuous jet the "equation of continuity" shows that as the jet loses velocity in ascending, it must increase in section. When the stream consists of drops following the same path in single file, no such increase of section is possible, and then the constancy of the total stream requires a gradual approximation of the drops, which in the case of a nearly vertical direction of motion cannot stop short of actual contact. Regular vibration has, however, the effect of postponing the collisions and consequent scattering of the drops, and in the case of a direction of motion less nearly vertical may prevent them altogether.

Under moderate electrical influence there is no material change in the resolution into drops, nor in the subsequent motion of the drops up to the moment of collision. The difference begins here. Instead of rebounding after collision, as the unelectrified drops of clean water generally or always do, the electrified drops *coalesce*, and thus the jet is no longer scattered about. When the electrical influence is more powerful, the repulsion between the drops is sufficient to prevent actual contact, and then of course there is no opportunity for amalgamation.

[1] "The Influence of Electricity on Colliding Water Drops." Paper read at the Royal Society by Lord Rayleigh, F.R.S.

These experiments may be repeated with extreme ease and with hardly any apparatus. The diameter of the jet may be about $\frac{1}{20}$ inch, and may be obtained either from a hole in a thin plate or from a drawn-out glass tube. I have generally employed a piece of glass tube fitted at the end with a perforated tin plate, and connected with a tap by india-rubber tubing. The pressure may be such as to cause the jet to rise eighteen or twenty-four inches, or even more. A single passage of a rod of gutta-percha, or of sealing-wax, along the sleeve of the coat is sufficient to produce the effect. The seat of sensitiveness may be investigated by exciting the extreme tip only of a glass rod, which is then held in succession to the root of the jet and to the place of resolution into drops. An effect is observed in the latter but not in the former position. Care must be taken to use an electrification so feeble as to require close proximity for its operation, otherwise the discrimination of the positions will not be distinct.

The behaviour of the colliding drops becomes apparent under instantaneous illumination. I have employed sparks from an inductorium, whose secondary terminals were connected with the coatings of a Leyden jar. The jet should be situated between the sparks and the eye, and the observation is facilitated by a piece of ground glass held a little beyond the jet, so as to diffuse the light; or the *shadow* of the jet may be received on the ground glass, which is then held as close as possible on the side towards the observer.

If the jet be supplied from an insulated vessel, the coalescence of colliding drops continues for a time after the removal of the influencing body. This is a consequence of the electrification of the vessel.* If the electrified body be held for a time pretty close to the jet, and be then gradually withdrawn, a point may be found where the rebound of colliding drops is re-established. A small motion *to* or *from* the jet, or a discharge of the vessel by contact of the finger, again induces coalescence.

Although in these experiments the charges on the colliding drops are undoubtedly of the same name, it appeared to me very improbable that the result of contact of two equal drops, situated in the open, could be affected by any strictly equal electrifications. At the same time an opposite opinion makes the phenomena turn upon the very small *differences* of electrification due either to irregularities in the drops or to differences of situation, and is at first difficult of acceptance in view of the efficiency of such very feeble electric forces. Fortunately I am able to bring forward additional evidence bearing upon this point.

When two horizontal jets issue from neighbouring holes in a thin plate, they come into collision, for a reason that I need not now stop to explain, and after contact they frequently rebound from one another without amalgamation. This observation, which I suppose must have been made before, allowed me to investigate the effect of a passage of electricity across two contiguous water surfaces. The jets that I employed were of about $\frac{1}{15}$ inch in diameter, and issued under a moderate pressure (5 or 6 inches) from a large stoneware vessel. Below the place of rebound, but above that of resolution into drops, was placed a piece of insulated tin plate in connection with a length of gutta-percha-covered wire. The source of electricity was a very feebly excited electrophorus, whose cover was brought into contact with the free end of the insulated wire. When both jets played upon the tin plate the contact of the electrified cover had no effect in determining the union, but when only one jet washed the plate union instantly followed the communication of electricity, and this notwithstanding that the jets were already in communication through the vessel. The quantity of electricity required is so small that the cover would act three or even four times without being re-charged, although no precautions were taken to insulate the reservoir.

In subsequent experiments the colliding jets, about $\frac{8}{100}$ inch in diameter, issued horizontally from similar glass nozzles, formed by drawing out a piece of glass tubing and dividing it with a file at the narrowest part. One jet was supplied from the tap, and the other from the stoneware bottle placed upon an insulating stool. The sensitiveness to electricity was extraordinary. A piece of rubbed gutta-percha brought near the insulated bottle at once determined the coalescence of the jets. The influencing body being held still, it was possible to cause the jets again to rebound from one another, and then a small motion of the influencing body *to* or *from* the bottle again induced coalescence, but a *lateral* motion without effect. If an insulated wire be in connection with the contents of the bottle, similar effects are produced when the electrified body is moved in the neighbourhood of the free end of the wire. With care it is possible to bring the electrified body into the neighbourhood of the free end of the wire so *slowly* that no effect is produced; a sudden movement of withdrawal will then usually determine the coalescence.

Hitherto statical electricity has been spoken of; but the electromotive force of even a single Grove cell is sufficient to produce these phenomena, though not with the same certainty. For this purpose one pole is connected through a contact key with the interior of the stoneware bottle, the other pole being to earth. If the fingers be slightly moistened, the body may be thrown into the circuit, apparently without diminution of effect. This perhaps ought not to surprise us, as in any case the electricity has to traverse several inches of a fine column of water. On the other hand, it appeared that most of the electromotive force of the Grove cell was necessary.

Further experiment showed that even the discharge of a condenser charged by a single Grove cell was sufficient to determine coalescence. Two condensers were used successively; one belonging to an inductorium by Ladd, the other made by Elliott Brothers, and marked "Capacity $\frac{1}{3}$ Farad." Sometimes even the "residual charge" sufficed.

It must be understood that coalescence of the jets would sometimes occur in a capricious manner, without the action of electricity or other apparent cause. I have reason to believe that some, at any rate, of these irregularities depended upon a want of cleanness in the water. The addition to the water of a very small quantity of soap makes the rebound of the jets impossible.

The last observation led me to examine the behaviour of a fine vertical jet of slightly soapy water: and I found, as I had expected, that *no scattering took place.* Under these circumstances the approach of a moderately electrified body is without effect, but a more powerful influence scatters the drop as usual. The apparent coherence of a jet of water when the orifice is oiled was observed by Fuchs, and appears to have been always attributed to a diminution of adhesion between the jet and the walls of the orifice.

Some further details on this subject, and other investigations respecting the phenomena of jets, are reserved for another communication, which I hope soon to be able to present to the Royal Society; but I cannot close without indicating the probable application to meteorology of the facts already mentioned. It is obvious that the formation of rain must depend very materially upon the consequences of encounters between cloud particles. If encounters do not lead to contacts, or if contacts result in rebounds, the particles remain of the same size as before; but, if the issue be coalescence, the bigger drops must rapidly increase in size and be precipitated as rain. Now, from what has appeared above, we have every reason to suppose that the results of an encounter will be different according to the electrical condition of the particles, and we may thus anticipate an explanation of the remarkable but hitherto mysterious connection between rain and electrical manifestations.

A STUDY IN LOCOMOTION[1]

III.

It would be very interesting to pass in review the principal epochs of art and trace out the manner of representing horses in motion in various periods of progress or decadence. But such a study would fail to realise its full value unless carried out by an artist.

Col. Duhousset, who joins the skill of the draughtsman to a perfect acquaintance with the exterior of the horse, has essayed a work of this kind, and in a recent publica-

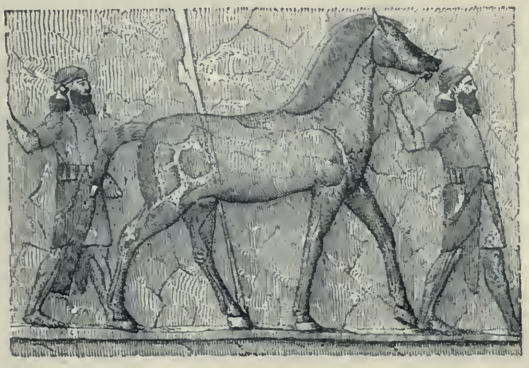

FIG. 20.—Assyrian bas-relief (British Museum). A horse ambling.

tion has pointed out the merits and defects of certain modern artistic performances. M. Duhousset has also gathered together a curious collection of representations of the horse at different epochs of art, and has entrusted to me a few specimens, which I will now exhibit to you. You will see that in a general manner art has progressed, proceeding from simple forms to more masterly delineations.

Figs. 20 and 21 represent horses ambling. Has the artist selected this pace because it was in general use at

FIG. 21.—Egyptian bas-relief (Medinet-Abou). Two horses attached to a chariot, and ambling.

that time? This is scarcely probable; it would seem more likely that he has chosen it because of its extreme simplicity. To seize the moment when the four feet all touch the ground, to repeat in the posterior limbs the attitude of the limbs in front, and, lastly, to represent all the horses harnessed together as keeping exact time in their movements so as to draw them all with a single

FIG. 22.—"The Cavalier and Death," by Albrecht Dürer. Horse at the trot.

profile: this is certainly one way of eluding all the difficulties of the situation.

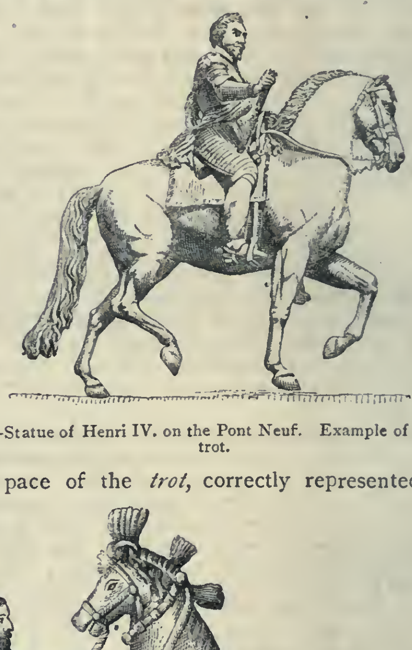

FIG. 23.—Statue of Henri IV. on the Pont Neuf. Example of the correct trot.

The pace of the *trot*, correctly represented in the

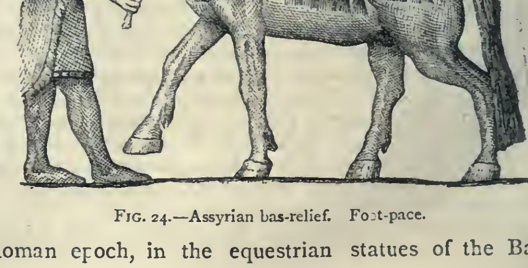

FIG. 24.—Assyrian bas-relief. Foot-pace.

Roman epoch, in the equestrian statues of the Balbi

teenth century in a painting by Albrecht Dürer (Fig. 22,

FIG. 26.—Captain of the Guards riding at a foot-pace. (Column of Trajan.)

"The Cavalier and Death"). The classic statue of

FIG. 27.—Mule laden with baggage, walking at a foot-pace. (Column of Trajan.)

Henri IV. on the Pont Neuf is an example of the correct trot (Fig. 23).

But the representation of the *foot-pace*, more difficult than the preceding, is rarely faithful. Examples, scarcely satisfactory, are found in all the epochs; take, for instances, Figs. 24 and 25.

The foot-pace is correctly represented in the two figures borrowed from the column of Trajan (Figs. 26 and 27). This column also displays oxen and other animals faithfully represented.

These paces, it should be noted, are a little varied with respect to the instant chosen; almost invariably the horse raises only one fore-foot.

The *gallop* is in general the pace of which the representation leaves most to be desired. Without speaking of contemporary art, I will refer only to the paintings of the two or three last centuries. The horses therein deemed to be galloping are represented in a sort of prancing attitude, posed upon the two hind-feet, and raising the two fore-feet to an equal height. We have seen, by the preceding notations, that this synchronous action of the right and left limbs does not exist.

In the grandest epoch of Greek art we find admirable representations of the gallop. Fig. 28 is an example. The attitude chosen is the first step of the gallop as in Fig. 16. The first step has been taken. The diagonal

FIG. 28.—Frieze of the Parthenon. (Bas-relief remaining at Athens.) Right hand gallop.

limbs which make the second step are approaching towards the ground, and the right hand fore-foot which will make the last step is held high in air.

I have already admired the reproduction in plaster of another bas-relief from the same frieze, in which a galloping horse is represented with equal correctness, and I was led to believe that in the age of Phidias, artists were in possession of the science of paces. But subsequently, in examining the reproductions of the entire frieze, I have become convinced that the results were obtained by a happy chance, for the greater part of the horses are represented in false attitudes, which is all the more to be regretted in contemplating the exquisite elegance of their forms.

It is incontestable that at the present day, artists make great efforts to represent the horse with truthfulness, and many among them succeed. But I will not permit myself to criticise the works of my contemporaries. Such, then, is the graphic method, and such are its numerous applications, extremely varied, and often of enormous importance. In this discourse, the length of which you will excuse, I have only shown you a little corner of the subject, but that will suffice, I hope, to give you a desire to study more deeply, and in its entirety, a method which appears to me to be full of promise, and to the development of which I have already consecrated much effort.

GEOGRAPHICAL EVOLUTION[1]

IN the future development of scientific geography one of the main lines of advance will be in the direction of a closer alliance with geology. The descriptions of the various countries of the globe will include an account of how their present outlines came into existence, and how their plants and animals have been introduced and distributed. The principles on which this evolutional geography will be founded have regard to the materials of which the framework of the land consists, to the various ways in which these materials have been built up into the solid crust of the earth, and to the superficial changes to which they have been subsequently exposed. The materials of the land consist mainly of compacted detritus, which, worn from previously existing terrestrial surfaces, has been laid down in the sea. Hence the land, as we now see it, has originated under the sea. But the common belief that over the whole globe land and sea have been continually changing places, and that wide continents may have bloomed even over the site of the most lonely abysses of the ocean, may be shown to be incorrect by a consideration of the character of the sedimentary rocks of the land on the one hand, and of that of the deposits of the sea-floor on the other. The sedimentary rocks, even in the most massive palæozoic formations where they attain depths of several miles, are shallow-water deposits, formed out of the waste of the land and always laid down near land. Nowhere among them, even including the thick organically-derived limestones, such as the chalk, is there any formation which properly deserves to be considered that of a deep sea. Recent researches into the nature of the sea-bottom across the great ocean-basins have likewise shown that the deposits there in progress have no real analogy among the rocks of the land. The conclusion to be drawn from the evidence is that the great ocean-basins have always existed, and that the terrestrial areas have also lain on the whole over those tracts where they still exist.

The way in which the sedimentary rocks have been tilted up and made to lie discordantly on each other shows that the marginal belt of sea-floor near the land has again and again been upraised and worn down. The ocean-basins appear from very early times to have been areas of subsidence, while the continental elevations have been lines of relief from the strain of terrestrial contraction. The land has been subjected to periodic movements of upheaval, sometimes of great violence, whereby not only large areas of sea-bottom were raised into land, but where, as huge earth-waves, lines of mountain-chain were ridged up. During these movements great changes were effected in the structure and arrangement of the rocks in the regions affected, original sedimentary masses being rendered crystalline, and even reduced to such a pasty or fluid condition as to be squeezed into rents of the more solid superincumbent rocks. Volcanic orifices were likewise opened, by which communication was established between the heated interior and the surface. The relative dates of these successive terrestrial disturbances can be satisfactorily determined by stratigraphical and palæontological evidence.

The history of the gradual growth of the European continent furnishes many interesting and instructive illustrations of the principles by which evolutional geography is to be worked out. The earliest European land appears to have existed in the north and north-west, comprising Scandinavia, Finland, and the north-west of the British area, and to have extended thence through boreal and arctic latitudes into North America. Of the height and mass of this primeval land some idea may be formed by considering the enormous bulk of the material derived from its degradation. In the Silurian formations of the British Islands alone there is a mass of rock, worn from that land, which would form a mountain-chain extending from Marseilles to the North Cape (1,800 miles), with a mean breadth of over 33 miles and an average height of 16,000 feet, or higher than Mont Blanc. The Silurian sea which spread across most of Central Europe into Asia suffered great disturbance in some regions towards the close of the Silurian period. It was ridged up into land inclosing vast inland basins, the areas of some of which are still traceable across the British Islands to Scandinavia and the west of Russia. An interesting series of geographical changes can be traced during which the lakes of the Old Red Sandstone were effaced, the sea that gradually overspread most of Europe was finally silted up, and the lagoons and marshes came to be densely crowded with the vegetation to which we owe our coal-seams. Later terrestrial movements led to the formation of a series of bitter lakes across the heart of Europe like those now existing in the south-east of Russia. Successive depressions and elevations brought the open sea again and again across the continent, and gave rise to the accumulation of the rocks of which most of the present surface consists. In these movements the growth of the Alps and other dominant lines of elevation can be more or less distinctly traced. It was at the close of the Eocene period, however, that the great disturbances took place to which the European mountains chiefly owe their present dimensions. In the Alps we see how these movements led to the crumpling up and inversion of vast piles of solid rock, not older in geological position than the soft clay which underlies London. Considerable additional upheaval in Miocene times affected the Alpine ridges, while in still later ages the Italian peninsula was broadened by the uprise of its sub-Apennine ranges. The proofs of successive periods of volcanic activity during this long series of geographical revolutions are many and varied. So too is the evidence for the appearance and disappearance of successive floras and faunas, each no doubt seeming at the time of its existence to possess the same aspect of antiquity and prospect of endurance which we naturally associate with those of our own time. The law of progress has been dominant among plants and animals and not less upon the surface of the planet which they inhabit. It is the province of the biologist to trace the one series of changes; of the geologist to investigate the other. The geographer gathers from both the data which enable him to connect the present aspects of Nature with those out of which they have arisen.

[1] Abstract of an Address given by Prof. Geikie, F.R.S., at the meeting of the Royal Geographical Society on March 24, 1879.

GEOGRAPHICAL NOTES

AT a recent meeting of the Board intrusted by the French Government with the care of granting missions for exploring foreign countries, it was decided that none of the regions proposed offered any special field for exceptional services rendered to science. The funds of the Government will be spent neither in exploring Central Africa nor in seeking the north pole, but in excavating Trojan ruins and examining some of the islands of the Asian Archipelago. It was also complained that no qualified traveller had been sent into civilised parts to study the progress of special arts and sciences. Such excursions as the celebrated "Voyage en Angleterre et en Irlande," accomplished by Baron Dupin in 1820 have rendered immense services to French industry, and the memory of it is not extinguished by the sixty years which elapsed. The sending of regular scientific missions abroad was inaugurated in France by the First Republic, for the purpose, not exclusively for cultivating anthropology, but for introducing into France the progress made by the foreign nations.

M. CHARNAY has recently forwarded to the Minister of Public Instruction at Paris a series of communications on the results of his investigations in Java in the summer of last year. He explored the east and west portions of the island, and he claims to have discovered a close affinity between the remains of the civilisation introduced by Hindu Buddhists and that of the ancient Mexican Empire. He also calls attention to the great density of the population of Java. From this island M. Charnay went on to Melbourne, and when last heard from, was engaged in making natural history collections in Queensland and at Thursday Island in Torres Straits.

THE death of the last chief of the Belgian caravan has not abated the resolution of King Leopold and the members of the International Committee for African Exploration. A third expedition is to be sent out immediately, it is said, under the guidance of Mr. Stanley. It is also stated that a new Belgian expedition led by Capt. Popelin will soon start for Zanzibar, in order to work out the plan of establishing a chain of stations right across Central Africa, viz., from Zanzibar to the Loango coast. The King of the Belgians will grant the means for this important undertaking.

THE last *Bulletin* of the Société de Géographie Commerciale de Bordeaux contains a brief paper by M. Albert Merle, advocating the exploration of Ferlo, Senegambia. This is a tract of country between the Senegal and the Gambia, marked in our latest maps, "desert country, no water;" it extends from 14° to 16° N. lat., and its interior is quite unexplored. Several travellers have passed along the outskirts of the region, and from their accounts and from native reports, it appears to be covered with thick forests containing many kinds of valuable trees; tobacco, indigo, and cotton also grow there in abundance. Those of its products which are at present turned to account, find their way to the Gambia, but M. Merle's desire is to divert the trade to the French settlements on the north.

M. PAUL SOLEILLET, the French traveller who left St. Louis in Senegal with the intention of reaching Algeria through the Sahara, according to the last intelligence received in Paris by telegraph, had reached Segou, the capital of the negro state of the same name, and he was proceeding onwards. This adventurous man received only 6,000 francs from the Governor-General of Senegal. The Paris Society of Geography, as a protest against such indifference, resolved to send him, when possible, all the money disposable from the travelling and exploring funds.

THE latest news from Dr. Rohlfs' expedition to Central Africa states that one of its members, Baron Leopold von Csillagh, has left the expedition, and will return to Europe after paying a short visit to Murzuk. News from Tripolis states that the presents sent by the Emperor of Germany, and destined for the Sultan of Wadai, have at last arrived there. The latest papers sent by Dr. Rohlffs contain a valuable zoological report by Dr. Stöcker, the naturalist accompanying Dr. Rohlffs' expedition, besides a number of astronomical observations.

IN the present demand for accurate information respecting the Zulus and their country, it may not be out of place to call attention to a series of papers which appeared in the *Nautical Magazine* for 1853 and 1854, under the title of the "Loss of the Brig *Mary* at Natal, with Early Recollections of that Settlement." These papers were published anonymously, but were written by Mr. C. R. Maclean, now an official in St. Lucia, who more than fifty years ago spent three years with the famous Chaka, then King of the Zulus, and consequently had the best of opportunities for observing the character of the country and the people.

WE regret to announce the death of Dr. Friedrich Wilhelm Vogler of Lüneberg, well known in Germany as the author of several excellent geographical handbooks. Dr. Vogler was in his eighty-seventh year.

THE King of Portugal has presented to Dr. Oskar Lenz, the well-known African traveller, the knightly cross of the Portuguese Order of Christ.

PROF. BASTIAN, whose severe illness was announced not long ago, is in a fair way of recovery. The indefatigable traveller and ethnographer is at Calcutta and intends soon to start for Batavia.

WE learn from the *Colonies and India* that those who took part in the recent expedition from Wellington, New Zealand, to New Guinea, which proved a failure, intend starting another one. They propose to proceed to Astrolabe Bay, and will take with them two whale boats and a long boat, two horses, some goats, &c. The services of a doctor, geologist, and botanist are to be secured, and a carpenter, gunsmith, and one or two other handicraftsmen are to be invited to join.

NOTES

ON Tuesday morning, in the presence of a small number of his sorrowing friends, the remains of the late Prof. W. K. Clifford were placed in their last resting-place in Highgate Cemetery.

THE following grants have lately been made from the Research Fund of the Chemical Society:—10*l*. to Dr. C. A. Burghardt for an investigation into the constitution of topaz; 20*l*. to Mr. Francis Jones for the investigation of boron hydride; 15*l*. to Mr. F. D. Brown for the study of the theory of fractional distillation; 30*l*. to Dr. Dupré for the estimation of organic carbon in air; and 15*l*. to Prof. T. E. Thorpe for the investigation of albietene, the hydrocarbon of nut-pine.

M. BISCHOFFSHEIM, the well-known French Mæcenas of science, has just returned from Mentone, which he visited with M. Lœwy, the Sub-director of the National Observatory, to examine the practicability of establishing an observatory in his mansion. The site was found to be very convenient in all respects, and M. Bischoffsheim resolved to spend a sum of 900,000 francs for instruments, &c. The work is to begin immediately.

M. ANDRÉ, the well-known eclipse and transit of Venus observer, has inaugurated the publication of meteorological readings taken in the Municipal Observatory established at Tête d'Or, in the vicinity of Lyons. The peculiarity of that establishment is that astronomical and meteorological observations are conducted *pari passu* with the same zeal. It is the only place in France where the schemes organised by Leverrier, at Paris, are practised.

THE Select Committee of the House of Commons appointed to inquire into the subject of the lighting of towns by means of electricity, and to which the Liverpool Lighting Bill was referred, has determined to go into the general question, settle the principle, and then leave the thirty-four private Bills which ask for powers to light by electricity to be dealt with by the regular Committees of the House of Commons. The inquiry will commence on the 31st inst. As the evidence will be lengthy and the committee will probably report late in the Session, it is expected that no powers will be granted this Session for lighting by electricity.

THE Werderman light was tried by M. Becquerel in his lectures on electricity, delivered at the Conservatoire des Arts et Métiers on March 19. This apparatus, which will be tried very shortly in Paris, has been introduced into France by Dr. Cornelius Herz. Six Werderman lights were arranged round the chair of the professor and burned with the utmost regularity every time they were lighted. The opinion of M. Becquerel was very favourable indeed; he insisted upon the presence of a micro-

scopic arc giving an exceptional brilliancy to the flame. He reserved the question of cost in comparison with gas, and confined himself to making a comparison between Werderman and his competitors. M. Jamin has presented to the Academy of Sciences a system of his own, which has been described in the *Comptes rendus*, and will be tried by the Jablochkoff Company. Other systems are said to be preparing so that the partial failure of *bougies* is giving rise to a renewed electric light agitation in Paris. The members of the Municipal Council have determined to give fair play to any rational experiments.

As the result of the experiment of lighting the Holborn Viaduct with the electric light it has been found that the cost is seven and a half times that of gas, while the illuminating power is seven times greater. It has been decided not to continue the experiment.

A VALUABLE contribution to the marine zoology of the coast of the United States is furnished by a paper by Prof. H. E. Webster upon the chætopod annelids of the Virginia coast. This contains the result of several years' observation on the coast of Virginia by Prof. Webster, adding many new species to our hitherto published lists.

THE death of Prof. Yarnell, a much esteemed member of the scientific corps of the United States Naval Observatory, took place in Washington on February 27, at the age of sixty-two. The annual volumes of the Observatory contain a great many important memoirs by Prof. Yarnell, and he had just completed another at the time of his death.

IN the Report for 1878 of the "Observations of Injurious Insects," which has been drawn up by Miss E. A. Ormerod and her fellow-workers, and recently published (London: West, Newman, and Co.), a good many facts interesting alike to the agriculturist, entomologist, and meteorologist are recorded. The thanks of all interested in the preservation of food-crops are due to Miss Ormerod for her persistent efforts to promote a knowledge of, and a means to diminish the ravages caused by insect pests, and to all those who have opportunities to assist, such information if sent to Miss Ormerod, Dunster Lodge, Spring Grove, Isleworth, will be sure to be utilised. For the guidance of fresh observers the points required to be observed are pointed out, those particularly wished for being as follows: "1. With regard to weather; a very few lines as to general state through the year, such as any marked succession of warm or cold days, of great rainfalls, or drought. 2. Any observations as to the spread of common crop-insects from common crop weeds. For instance, with regard to observations of charlock and blackthorn in connection with turnip fly and gooseberry caterpillar. These two plants supply food or shelter for two insects that certainly come under the head of 'pests.' Their presence is either agriculturally bad or of little use, but they keep up the supply of successive insect generations in safety, because little noticed on these worthless growths. 3. Observations as to infested farm stores and seeds might throw much light on the intermittent appearance of some destructive insects. Thus the wheat midge *Cecidomyia tritici* is kept safe in the larval state during winter in neglected chaff-heaps, and the red clover weevil may be seen in legions creeping from the recently-stored clover. The amount of loss from this insect has been observed for more than eighty years, and still *Apion apricans* is at work in the clover as hard as ever." Miss Ormerod further points out that often the larvæ and pupæ are both contained in the seeds, and consequently sown with them, and she further remarks that we shall probably find the key to great devastations in what were originally small appearances. "Each note of information," we are reminded, "even if incomplete in itself, will or may probably join on to those of other observers, and thus the circumstances which give rise to insect ravage be gradually more and more clearly made out, till we may hope, if not entirely to check the evil, at least to mitigate it greatly." The special points of interest in the report under consideration are: 1. The spread of the turnip fly in localities where charlock was most prevalent, and attention is drawn to the desirability of eradicating, as far as possible, this food-plant of the insect. 2. The effect of rain or dew in diminishing the spread of the pest by reducing its powers of locomotion; and 3. The observations regarding the destruction of insects by birds. One observer mentions that in the neighbourhood of Plymouth migratory insectivorous birds were very abundant, especially starlings, who congregated in such enormous quantities that the flocks coming in from all quarters to roost in the evenings so completely filled the roosting-trees as to constitute quite a sight. The report altogether is one of much value, and its circulation will, we doubt not, create that interest in the subject which the promoters desire.

MISS E. A. ORMEROD, who has done so much in the field of economic entomology, has recently contributed a brief but interesting paper, entitled "Notes on Economic Entomology," to the Watford Natural History Society. This paper may well be taken as a companion to the "Notes of Observations of Injurious Insects" for 1878.

THE *Chemist and Druggist* gives the following account of an experiment in opium-smoking, made by Dr. Miclucho Maclay upon himself during his stay in Hong Kong:—The experiment was made at the Chinese Club, where every convenience for smoking opium is to be found. Dr. Clouth, of Hong Kong, took the necessary observations, and his notes are recorded below. These may be summarised as follows:—Herr Maclay was in normal health, and had fasted eighteen hours before commencing the experiment. He had never smoked tobacco. Twenty-seven pipes, equivalent to 107 grains of the opium, used by the Chinese, were smoked in two and three-quarter hours, at tolerably regular intervals. The third removed the feeling of hunger caused by his long fast, and his pulse rose from 72 to 80. The fourth and fifth caused slight heaviness and desire for sleep, but there was no hesitation in giving correct answers, though he could not guide himself about the room. After the seventh pipe the pulse fell to 70. The twelfth pipe was followed by singing in the ears, and after the thirteenth he laughed heartily, though without any cause that he can remember. Questions asked at this time were answered only after a pause, and not always correctly. He had for some time ceased to be conscious of his actions. After the twenty-fifth pipe questions asked in a loud tone were not answered. After the last pipe had been smoked he remarked, "I do not hear well." Forty minutes later there was a slight return of consciousness and he said, "I am quite bewildered. May I smoke some more? Is the man with the pipe gone already?" Fifteen minutes later (4.55 P.M.) he was able to go home, and then retired to bed. He woke the next morning at 3 A.M., and made a hearty meal, after his fast of thirty-three hours. During the next day he felt as if he had bees in a great hollow in his head, as well as a slight headache. The organs of locomotion were first affected, next came sight and hearing, but Herr Maclay is very positive that there were no dreams, hallucinations, or visions of any sort whatever.

IT is well known from the equable temperature of the Fiji Islands and the favourable nature of the soil of many parts that the colony is well adapted to the cultivation of various useful plants that require only to be introduced to thrive. These matters have recently been discussed in a little pamphlet published at Levuka, on the agricultural prospects of Fiji. That the productive powers of these islands is very great is here fully exemplified. It is shown that tropical produce of all kinds is capable of being grown on an extensive scale, so that the resources

of the islands might be made highly remunerative. Sugar-cane, coffee, tea, cinchona, and cocoa are the principal staples advocated. Sugar is looked upon in a most favourable light; some parts of the islands, both in richness of soil and climate, as well as in extent, are spoken of as extremely favourable for growing and maturing the cane; so much so as to make all well-wishers of Fiji look for the time when sugar will be made in the islands and "exported by the hundred thousand tons and to the value of millions of pounds sterling." Regarding coffee we learn that the Government have sent large supplies of seed into the interior of Viti Levu to form coffee gardens for the natives. The plants are described as having an extremely healthy appearance. Tea and cinchona could both be grown successfully in Viti Levu over an extent of country roughly estimated at about one hundred square miles. Though many valuable timber trees exist in the islands it is suggested that several well-known Indian trees such as teak, saul, sissoo, toon, and ebony, as well as mahogany, rosewood, and others should be introduced. It is to be hoped that as the resources of Fiji, including those of the forests, become developed, no undue sacrifice of timber will be effected, but on the contrary the trees will be carefully preserved or replanted as others are cut down.

THE class of substances whose fluorescence does not follow Stokes's law, and so which do not emit rays of less refrangibility than the existing rays, has lately been enlarged by Prof. Lommel by addition of one of two new fluorescing substances. That is anthracene blue, an etheric solution of which fluoresces olive green very strongly; it is excited extremely weakly by the blue and the greater part of the violet rays, but very strongly by the orange-green and yellow-green. The second new fluorescing substance is bisulphobichloranthracenic acid, the etheric solution of which gives superficially a beautiful blue, and the interior a greenish fluorescence. It obeys Stokes's law.

THE French Minister of Public Works has not yet answered the inquiries made by M. Giffard as to the probability of the Cour de Tuileries being at his disposal up to the end of September, in order to organise a new series of captive ascents. But M. Giffard, willing to give the preference to his native city, has rejected the advantageous offers made by the German company offering to work his captive balloon, and to pay him a royalty of 33 per cent. on the gross receipts.

AT 12.35 A.M. on the 22nd inst. an earthquake traversed Northern Persia, taking a direction from Tabreez to Zendjan and Mianeh, and shocks continued with more or less severity until Sunday, the 23rd. Several strongly-built houses were thrown down at Mianeh, and in others large rents were made in the walls. The most serious damage, however, appears to have been occasioned in two villages off the road, about four farsachs from Mianeh, named respectively Tark and Manan. These were totally destroyed, and of the 500 inhabitants in the one case and the 600 inhabitants in the other, only a few are reported to have been saved. Mianeh is situated in north lat. 37° 27′, east long. 47° 43′.

IN a report from the Philippine Islands we learn that in the towns of Molo and Javo, both situated close to each other, and distant about three miles from Yloilo, it is very rare to enter a house that has not its loom at work, so large a trade is done in weaving not only in the towns themselves but all over the province. The principal fibre used is that of the pine-apple, and some of the articles manufactured, such as shirts and dresses, are of considerable merit and sell at high prices. In weaving China silk in colours is intermixed with the pine-apple fibre, for the purpose of giving stripes to the dresses and shirts. The value of the Chinese silk so imported varies at from 200,000 dol. to 400,000 dol. (£40,000 to £80,000) per annum.

THE Teplitz thermal question may be considered as being solved in the most satisfactory manner. The Spring Committee established by the Austrian Government declared that the quantity of recovered water is 2,224 cubic feet per hour, which is sufficient for supplying all the thermal establishments in existence before the catastrophe. The temperature has not been altered in any sensible manner. It appears that altogether the catastrophe may be considered as having been in some respects useful. The actual quantity is one-third more than the sum of the several sources which were used before the catastrophe.

WE have received the first number of a new American journal —*Useful Arts*—edited by Mr. J. A. Whitney. It contains a great deal of miscellaneous industrial information, mostly referring to patents.

Gardening Illustrated is the title of a new cheap "weekly journal for town and country."

A METEOROLOGICAL work, entitled "Ergebnisse fünfzigjähriger Beobachtungen der Witterung zu Dresden," with an introduction on meteorology, the atmosphere, meteorological instruments and observations, has just been published by Dr. Adolf Drechsler, the director of the Royal Physico-Mathematical Institution at Dresden.

THE additions to the Zoological Society's Gardens during the past week include a Mona Monkey (*Cercopithecus mona*) from West Africa, presented by Miss Sandford; a Bonnet Monkey (*Macacus radiatus*) from India, presented by Mr. George Eggar; a Chinchilla (*Chinchilla lanigera*) from South America, presented by Sir Chas. Smith; a Greater-spotted Woodpecker (*Picus major*) European, presented by Mr. H. Laver; a Sumatran Rhinoceros (*Rhinoceros sumatrensis*) from Sumatra, a Tabuan Parrakeet (*Pyrrhulopsis tabuensis*), a Stair's Dove (*Phlogœnas stairi*) from the Fiji Islands, deposited; a Pied Wagtail (*Motacilla yarrelli*), a Reed Bunting (*Emberiza schœniclus*) European, purchased.

SPECULATIONS ON THE SOURCE OF METEORITES[1]

I HAVE recently read M. G. Tschermak's most interesting memoir, "Die Bildung der Meteoriten und der Vulcanismus."[2] I am not competent to offer any opinion on the mineralogical questions involved in his discussion, but the numerous arguments he has adduced appear to me to justify his conclusion that "the meteorites have had a volcanic source on some celestial body." These arguments are briefly as follows:—

Meteorites are always angular fragments even before they come into the air.

Most meteoric irons have a crystalline structure which, according to Haidinger, requires a very long period of formation at a nearly constant temperature. This condition could only have been fulfilled in a large mass.

Many meteoric stones show flutings resembling those seen on terrestrial rocks and which are due to the rubbing of adjacent masses.

Other meteoric stones show a joining together of several fragments analogous to breccia.

Many meteoric stones are composed of very small particles analogous to volcanic tufas.

After glancing at the old theory of the volcanoes in the moon and rejecting as untenable the supposition that meteorites have any connection with ordinary shooting stars, Tschermak concludes—"We may suppose that many celestial bodies of considerable dimensions are still small enough to admit of the possibility that projectiles driven from them in volcanoes shall not return by gravity. These would really be the sources of meteorites." Similar views having been put forward by Mr. J. Lawrence Smith and other authorities it is not unreasonable to discuss the following problem.

[1] Read at the Royal Irish Academy, January 13.

[2] "Sitzungsberichte der mathematisch-naturwissenschaftlichen Classe der kaiserlichen Akademie der Wissenschaften," Wien, 1875. Band lxxi., Abtheilung 2, pp. 661–674.

If meteorites have been projected from volcanoes, on what body or bodies in the universe must those volcanoes have been located?

Let us first take up a few of the principal celestial bodies *seriatim* and consider their claims to the parentage of the meteorites. We begin with the sun. It has been abundantly shown that there exists upon the sun tremendous explosive energy. It is not at all unlikely that that energy would be sufficiently great under certain circumstances actually to drive a body from the sun never to return. We might therefore find upon the sun adequate explosive power for the volcano, but the projectiles are here the difficulty. There are a number of circumstances (notably the breccia-like appearance of some meteorites) which show conclusively that the meteorites have beeen torn from rocks which were already nearly, if not quite, solid, and as it seems in the highest degree improbable that rocks of this nature should exist in the sun, we may conclude that the sun has not been the source of the meteorites.

Can the meteorites have come from the moon? Owing to the small mass of the moon the explosive energy required to carry a body away from the moon is comparatively small. Can such a body fall upon the earth? *To simplify questions of this kind we shall suppose various disturbing influences absent.* We shall suppose that the projectile is discharged from a volcano on the moon with sufficient velocity to carry it therefrom. We shall then omit all account of the disturbing influence both of the sun and moon on the projectile, and we shall suppose that the projectile is really revolving round the earth as a satellite. This projectile will fall upon the earth if its distance from the earth's centre when in perigee be less than the radius of the earth (augmented, perhaps, by the thickness of the earth's atmosphere). It should however be observed that *if the projectile once escaped the earth it would never fall thereon*, hence the question as to whether the moon can be the source of the meteorites now falling appears to be connected with the question as to whether the lunar volcanoes are *now* active. But it is generally believed that the lunar volcanoes are not now active to any appreciable extent (even if the suspected indications of recent change were thoroughly established). It follows that even if the moon has been a source of meteorites in ancient times, we no longer receive a supply from that quarter. There is of course just a possibility that projectiles from the moon which have been revolving round the earth as satellites in elliptic orbits ever since their ejection may, under the influence of *the disturbing causes previously excepted*, gradually change their orbits until they become entangled in the atmosphere and descend as meteorites. It therefore appears to be not quite impossible that even still a meteorite which had its origin in the moon in past ages may occasionally tumble on the earth.

Passing from the sun and the moon let us now bring under review some of the other celestial bodies and see how far they will fulfil the conditions of the question. Is it possible that the meteorites can have been projected from the surface of a planet? In order to get over the difficulties of the great initial velocity which would be necessary to overcome the gravitation of a large planet, it seems natural to inquire if a volcano placed upon one of the small planets could accomplish the task.

It is clearly impossible that a projectile should ever fall on the earth unless the orbit of the projectile cuts the plane of the ecliptic in a point which lies in the narrow ring between 8,000 and 9,000 miles wide which the earth traces out on the ecliptic, but if a meteorite with an elliptic orbit intersect this ring, then, in the lapse of time, it may happen that the earth and the meteorite meet at the intersection of their orbits, in which case of course the long travels of the meteorite will come to an end.

We shall therefore consider the circumstances under which it would be possible to discharge a projectile from the surface of a planet (say Ceres), so that the projectile shall intersect the ecliptic in the ring we have just referred to. The planet being small the initial velocity that would be required to carry a projectile from its surface presents no difficulty; perhaps an ordinary cannon would be sufficient *so far as the mere gravitation to the planet is concerned.* But when we consider the necessity that the projectile must be driven through the ring we have been considering, a vastly more powerful instrument would be required.

Ceres is moving in an orbit (supposed circular and in the ecliptic) with a velocity of about eleven miles per second. A projectile discharged from Ceres will have an actual velocity which is compounded of the velocity of Ceres, with the velocity which is imparted by the volcano. But simple dynamical considerations show that if the projectile have an initial velocity *perpendicular to the radius vector*, differing from about eight miles per second, it can never intersect the ring, no matter in what direction it be discharged.[1] The volcano on Ceres must therefore be adequate to the abatement of the velocity perpendicular to the radius vector from eleven miles per second to eight miles per second, *i.e., the volcano must be at the very least adequate to producing an initial velocity of three miles per second.* As this is quite independent of the additional volcanic power requisite to carry the projectile away from the attraction of Ceres, it is obvious that after all there may be but little difference between the volcano which would be required on Ceres, and that (of six mile power) which would project a body away from the surface of the earth for ever.

Admitting, however, that a volcano of sufficient power were placed upon Ceres, would it be likely that a projectile driven therefrom would ever cross the earth's track? This is a question in the theory of probabilities, and it is not easy to state the problem very definitely. If the *total* velocity with which the projectile leaves the orbit of Ceres be less than eight miles per second, then the projectile will fall short of the earth's track; on the other hand, if the *total* initial velocity exceeds sixteen miles per second, the orbit in which the projectile moves will be hyperbolic, and though it may cross the earth's track once, it will never do so again. Taking a mean between these extreme velocities we may investigate the following problem:—Suppose that a projectile is discharged from a point in the orbit of Ceres in a *random* direction with the *total* initial velocity of twelve miles per second, determine the probability that the orbit of the projectile shall cross the earth's track. When this problem is solved in accordance with the calculus of probabilities it is found that the chances against the occurrence are about 50,000 to 1, *i.e.*, out of every 50,000 projectiles discharged at random from a point in the orbit of Ceres, only a single one can be expected to cross the earth's track.

It is thus evident that there are two objections to Ceres (and the same may be said of the other minor planets) as a possible source of the meteorites. Firstly, that notwithstanding the small mass of Ceres, a very powerful volcano would be required; and secondly, that we are obliged to assume that for each meteorite which could ever fall upon the earth, at least 50,000 must have been ejected.

It thus appears that if the meteorites have been originally driven from any planet of the solar system, large or small, the volcano must from one cause or another be a very powerful one.

There is, however, one planet of the solar system which has a special claim to consideration. On that planet it is true that a volcano would be required which was capable of giving an initial velocity of at least six miles per second; but *every* projectile launched from that volcano into space would, after accomplishing an elliptic orbit round the sun, dash through the track of the earth, and again pass through the same point at every subsequent revolution. It is not here a case of one solitary projectile out of 50,000 crossing the earth's track, but every one of the 50,000 possesses the same property. The planet of which we are speaking is, of course, the earth itself. If in ancient times there were colossal volcanoes on the surface of the earth which had sufficient explosive energy to drive missiles upwards with a velocity sufficient to carry them away from the earth's surface, after making allowance for the resistance of the air, these missiles would then continue to move in *orbits round the sun*, crossing at each revolution the point of the earth's track from which they were originally discharged. If this were the case, then doubtless there are now myriads of these projectiles moving through the solar system, the only common feature of their orbits being that they all intersect the earth's track. It will, of course, now and then happen that the earth and the projectile meet at the point of crossing, and then we have the phenomenon of the descent of a meteorite. This theory, that the meteorites have originated in the earth, was so far as I know first put forward by Dr. Phipson. Mr. J. Lawrence Smith in a letter I received from him some months ago inclines to the same view as at all events one of the probable sources.

It is well to note here the great difference between the lunar theory of meteorites and the terrestrial theory. For the lunar theory to be true it would probably be necessary that the lunar volcanoes should be *still* active. In the terrestrial theory it is only necessary to suppose that the volcanoes on the earth *once*

[1] Disregarding an obvious exception.

possessed sufficient explosive energy. No one supposes that the volcanoes on the earth at present eject the fragments which will constitute future meteorites, but it seems probable that the earth may be now slowly gathering back in these quiet times the fragments she ejected *in an early stage of her history*.

Assuming, therefore, that the meteorites have had a quasi-volcanic origin on some considerable celestial body, I am led to agree with those who believe that most probably that body is the earth.

ROBERT S. BALL

RECENT RESEARCHES ON ABSORPTION SPECTRA

THE numerous absorption spectra of soluble substances which have been described hitherto, have referred as a rule to the solutions of the substances, and but rarely to the solid substances themselves. It is true that certain differences were remarked between the spectra of certain solutions, those of uranium and didymium salts, for instance, and the spectra of the solid salts; yet, on the whole, these differences were so slight that it was generally believed that the spectra were essentially the same. On the other hand experiments had shown that the spectra of solutions differed according to the dissolving medium; indeed Herr Kundt established the fact that the absorption band of a substance in solution lies the nearer to the red end of the spectrum the stronger the dispersion of the dissolving medium. In these experiments the fact seems to have been overlooked that when changing the dissolving medium often the whole character of the spectrum is changed, so that comparison with the former one becomes extremely difficult. Close investigation of these differences was therefore an important desideratum, both for the theory of absorption spectra as well as for practical absorption spectrum analysis.

In the Monthly Report of the Berlin Academy of Sciences, Herr Vogel has recently published the results of such investigations, to which he was led by the remarkable differences between the spectra of solid and those of dissolved substances which he had observed in the case of certain pigments.

For the examination of these absorption spectra Herr Vogel used instruments of but moderate dispersion, which allow of an easier survey of the whole spectrum, and consequent judgment of its general character, than is the case with strongly dispersing spectroscopes. The absorption spectra of solid salts and pigments were obtained from thin layers of these substances, prepared upon glass plates, through evaporation of a few drops of solution. Herr Vogel reproduces the spectra he observed on two plates, which at once show not only *the differences in the spectra of one and the same solid substance and its solution*, but frequently an *extraordinary coincidence in the position of the absorption bands belonging to totally different substances* (for instance, in nitrate of uranium and permanganate of potash). Of several substances, such as iodine, hyponitric acid, and indigo, the spectrum of the vapour is also given for comparison, and in most cases the aqueous, alcoholic, and some other solution of each substance has been examined.

Without entering into the highly interesting details for which we must refer our readers to the original paper, we confine ourselves to stating the results of Herr Vogel's researches, which are the following: 1. Considerable differences exist between the spectra which a substance gives in the solid, liquid, or dissolved and gaseous state. Characteristic bands which are shown in the spectrum of one state are either not reproduced in that of the other (this is the case with chrome alum, chloride of cobalt, iodine, bromine, naphtaline red, fuchsine, indigo, cyanine, aniline blue, methyl violet, eosine, carmine, purpurine, alizarine, santaline), or they reappear in a different position, or different intensity (examples: nitrate of uranium, permanganate of potash, hyponitric acid, alcanna red). Sulphate of copper and chlorophyll show the same absorption both in the dissolved and in the solid state.

2. The spectra given by the same substance when dissolved in different media are the same in some cases (purpurine in alcohol or sulphide of carbon, aldehyde green in water or alcohol, methyl violet and indigo-sulphuric acid in water or amylic alcohol); in other cases they differ only in the position of bands (chloride of cobalt, fuchsine, coralline, eosine and iodine green in aqueous or alcoholic solutions); and again in others their character is totally different, so that no point of coincidence remains (iodine in sulphide of carbon or alcohol, naphtaline, aniline blue, purpurine, hæmatoxyline, brasiline in water or alcohol).

3. The rule established by Kundt, viz., that the absorption bands of a body in solution lie the nearer towards the red end of the spectrum the greater the dispersion of the dissolving medium is in the region of the bands, is not confirmed in many cases; on the contrary, in some instances the absorption bands move towards the blue in a solution of greater dispersion (nitrate of uranium and blue chloride of cobalt in water and alcohol); in other cases their position remains unaltered for various media (hyponitric acid in air and benzol, indigo-sulphuric acid and methyl violet in water and amylic alcohol, aldehyde green in water and alcohol, purpurine in sulphide of carbon and alcohol). In some cases a great difference in the sense of Kundt's rule becomes apparent, while in others for the same spectral region but a very trifling one appears, according to the nature of the pigment (coralline and fuchsine). Indeed it happens sometimes that certain bands are in the same position with different dissolving media, while others which are *simultaneously* visible are displaced (nitrate of uranium in water and alcohol, oxide of cobalt in glass and in water, protonitrate of uranium in neutral solution and in a solution of oxalic acid, chlorophyll in alcohol and ether).

4. The position of absorption bands in the spectra of solid and dissolved bodies may be only exceptionally deemed characteristic for any certain body. Totally different bodies show absorption bands in exactly the same position (solid nitrate of uranium and permanganate of potash in the blue; naphtaline red and coralline in the yellow; indigo, aniline blue, and cyanine in the orange; aldehyde green and malachite green in the orange). Closely related substances sometimes show remarkable differences in the position of their bands under prefectly equal conditions (solid uranium salts).

5. The rule set up for absorption spectra, "each body has its own spectrum," can be admitted only with great restrictions. The great number of polychromatic substances show different colours and different spectra in the solid state, according to the direction in which they are observed. Most other bodies show different spectra in the solid state from those of their solutions, and in the latter case again different ones according to the dissolving medium, and the question arises which of all these spectra is the body's "*own*" spectrum.

The most important difference of the spectra of elements in a state of incandescent vapour, the position of the spectral lines, ceases to be characteristic in the case of absorption spectra of liquid and solid bodies. In the latter spectra, however, the characteristic differences shown by the spectra of incandescent vapours cannot be expected. It is known that metals, which give such remarkably different spectra in the state of incandescent vapours, all give qualitatively the same spectrum as incandescent liquids or solids, viz., a continuous one; for this reason the absorption spectra of these bodies cannot show any remarkable characteristic differences, whatever quantitative differences may become apparent with regard to the absorbed colours. If these well-known facts show that already with regard to elements the laws applying to the spectra of gases do not apply to those of liquids and solids, then Herr Vogel's investigations prove that in the case of compound bodies simple relations between the spectra of their different aggregate states are still less frequent and occur only exceptionally.

The analysis of absorption spectra therefore is based not so much upon the recognition of the position of the absorption bands of a substance, as upon the *changes in the spectra* of the same body which take place under the influence of various dissolving media and reagents. Thus cyanine and aniline blue dissolved in alcohol give a very similar spectrum, dissolved in water a totally different one. The absorption bands of oxyhæmoglobine disappear with reducing agents; those of carmine, which are in a similar position, do not; the band of brasiline disappears when acetic acid is added to the solution, that of fuchsine does not, &c., &c.

The position of bands becomes more characteristic for the recognition of a body, if the latter shows *several* absorption bands. But even here we should go too far if from the accidental coincidence in the position of bands of two different bodies we were to draw conclusions regarding any similarity or chemical identity between them (this has indeed been done in certain cases, particularly with blood and chlorophyll). A conclusion regarding such similarity or identity is only justified if *the same bands show equal intensities and analogous changes under the influence of the same reagents*.

INTELLECT IN BRUTES

We have received so many letters on this subject that we are compelled to content ourselves with giving the following extracts :—

The Rev. George Henslow comments as follows on some of the cases already adduced :—

I would not assert that what I call "practical reasoning"—that is, reasoning applied to objective facts directly apprehended by the senses—is fundamentally different from "abstract," *i.e.*, with no objective fact immediately present to consciousness; but they certainly do represent two stages in our own mental development.

E. H. Pringle's account of "Bully" shows nothing beyond what is common to dogs in practical cunning (*i.e.* reasoning) with objective things, (1) his "lady" friend, (2) best road to take so as not to be seen, (3) the person to be avoided, (4) E. H. Pringle's eye to be eluded. In the only point where abstract reflection was really required Bully failed, just as a child would, *viz.*, in shamming sleep. For, it is not enough *to lie down* and *shut one's eyes*. This is all a child is told to do, or is conscious of doing on going to sleep. The relaxation of every muscle follows spontaneously. Hence, as children do not think of this when pretending (since it requires reflection) they can so easily be detected by some rigidity of the muscles in the face or in breathing which at once betrays them. I have known a child overdo it by screwing up its eyes in order to appear *very fast asleep!* Exactly so, too, Bully was totally unable to think of the importance of putting his ears in repose.

Dr. Rae's dog only strengthens my case, for it clearly associated the bell with a *particular* maid, whereas a reasoning human being would have *generalised* that since the maid was in the room, the bell could be rung for some one else. Hence the dog proved its impotency in all power of generalisation, which is a pure form of abstract reasoning.

Dr. Muirhead's donkey was solely concerned with immediate sense-objects, the gate and the cows, and required no abstract reflection. That horses and donkeys can discover how to open gates is by no means uncommon.

Lastly C.M.'s cat and Mr. Belsham's kitten are the only cases I have yet seen which show a *primâ facie* evidence against the distinction I propose to draw. But, that a half-grown kitten could go through such a process of reflection analogous to what I gave for a hypothetical untaught dog ringing a bell, would be so astounding, that all possible explanations must be eliminated first, before it is credited.

Is it not far more probable that the cat and the kitten discovered by accident that the door was opened when a knock was made, and that this discovery arose from the common habit of cats to play with anything suspended within their reach? That animals discover facts, and then use them, will not be disputed, like the dog that, on discovering a stream carried him down too far on swimming across it, ran a mile up stream ever afterwards to allow for the current. Again, that animals mimic, as do parrots and apes, is common enough, but they do not know why they do it. A monkey might knock at a door after seeing a man do it, but, I believe, could have no similar motive as the man, until (like the kitten) it should accidentally discover for itself what the real use was, or else unless it be taught to do it.

In re rats gnawing pipes. I have just heard of a mouse gnawing through a gas-pipe. May it not be accounted for by the fact that, although the upper incisors of a rodent, by working on the lower, keep the chisel-like ends in order; yet this may be assisted by gnawing wood, lead, or other hard substances? Does not this account for rabbits, though well fed on cabbage and bran, &c., still persisting in gnawing their hutches?

I will, in conclusion, give another case to illustrate the want of abstract reflection: this time in a lady (aged thirty), whose mental powers were curiously arrested. Looking at the picture of a shark in the sea, with a pig in its mouth, in "Masterman Ready," and knowing that the pig had been dropped from the wreck to see if it would swim to shore, she *naïvely* asked, "Is the shark carrying the pig to the shore?" The idea of the shark eating the pig would only arise from the abstract reflection on the habits of sharks, which was not suggested by the story; the single objective fact present to her mind was that "the pig had to get to the shore."

Mr. Arthur Nicols writes :—

I cannot understand practical *reasoning*, but a practical result of reasoning upon either simple or abstract ideas is intelligible. Can we conceive any human being reasoning more correctly than a dog did in the following instance?—Towards the evening of a long day's snipe-shooting on Dartmoor, the party was walking down the bank of the Dart, when my retriever flushed a widgeon which fell to my gun in the river, and of course instantly dived. I said no word to the dog. He did not plunge in after the widgeon *there*, but galloped *down* stream about fifty or sixty yards, and then entered the water, and dashed from side to side —it was about twenty or thirty feet wide—working up stream, and making a great commotion in the water, until he came to the place where we stood. Then he landed and shook himself, and carefully hunted the near bank a considerable distance down, crossed to the opposite side, and diligently explored that bank. Two or three minutes had elapsed, and the party was for moving on, when I called their attention to a sudden change in the dog's demeanour. His "flag" was now up, and going from side to side in that energetic manner which, as every sportsman knows, betokens a hot scent. I then knew that the bird was as safe as if it was already in my bag. Away through the heather went the waving tail, until, twenty or thirty yards from the bank opposite to that on which we were standing, there was a momentary scuffle; the bird just rose from the ground above the heather, the dog sprang into the air, caught it, came away at full gallop, dashed across the stream, and delivered it into my hand. Need I interpret all this for the experienced sportsman? The dog had learned from long experience in Australia and the narrow cañadas in the La Plata that a wounded duck goes down stream—if winged, his maimed wing sticks out, and renders it impossible for him to go up—and will invariably land, and try to hide away from the bank. But if the dog enters at the place where the bird fell, the latter will go on with the stream for an indefinite distance, rising now and then for breath, and give infinite trouble. My dog had found out all this long since, and had proved the correctness of his knowledge times out of number, and by his actions had *taught me* the whole art and mystery of retrieving duck. His object—I say, without a doubt, because I had had numberless opportunities of observing it—was to flurry the bird and force it to land by cutting it off lower down the stream. Then assuming, as his experience justified him, that the bird had landed, he hunted each bank in succession for the trail, which he knew must betray the fugitive.

Mr. A. Petrie writes :—In my own family we had a tabby cat, who, when turned out, would let herself in at another door by climbing up some list nailed round it, then pushing up the click-latch, pushing the door, with herself hanging on it, *away* from the post, so as to prevent the latch falling back into its place, and then dropping down and walking back to the fire. I knew a Skye terrier, who, being told to carry a fishing-rod, carefully experimented along its length, to find its centre of gravity, then carried it on till his master came to a narrow path through a wood. Here Skye considered, dropped the rod, took it by the end, and dragged it under him lengthwise, till the open road was gained, when he took the rod by the centre of gravity again, and went on. This could not be a copy of human actions, but the result of original reasoning.

Mr. Henry Cecil gives the following on the authority of the late Mr. Dawes the astronomer :—

Being busy in his garden, and having a large bunch of keys in his hand, he gave it to a retriever to hold for him till he was at liberty. Going into the house soon after he forgot to reclaim the keys. The remembrance of what he had done with them only returned to him when he required to use them in the evening. He then recalled that he had given them to the dog, and forgotten to take them again. Calling him, and looking impressively in his face, he said, "My keys! fetch me my keys." The dog looked wistful and puzzled for a moment, and then bounded off to the garden, his master following. He went straight to the root of an apple-tree, scratched up the keys, and brought them. May we not fairly put into words the dog's train of reasoning thus: "My master has given me these keys to hold; he has forgotten them; I cannot carry them all day; but I must put them in safety where I can find them again?"

Mr. W. S. Chamberlayne writes that many years ago, taking an afternoon ride through a wood in the Bahamas, he came to a gate which was kept closed by a small iron hoop hung over a post and the end of the gate. To open the gate he leant over his horse's neck and lifted up the hoop, shutting the gate

and replacing the hoop when he had passed through. On returning from his ride the gate was still shut, when, to his surprise, his horse, without any hesitation, took the hoop in his mouth and tried to lift it off the gate. He, however, was not successful in his efforts, and Mr. Chamberlayne had to finish the operation for him, but the exhibition of memory was certainly remarkable.

Mr. T. B. Groves, of Weymouth, sends the following account given to him by a relative, a gentleman well known in the district, and who would be everywhere accepted as a trustworthy and competent observer:—

In the wine-cellar two vessels, one an open earthen jar containing hazel-nuts, the other a wooden sieve, tub, or something of the kind, full of wine-corks, stood side by side. It was observed that the nuts were gradually diminishing, owing to the depredations of mice; but after a time this seemed to have altogether ceased, and it was inferred that the difficulty of egress had caused the mice to abandon the enterprise as soon as the level of the nuts had reached a certain depth from the mouth of the jar. Matters so remained for some little time; but afterwards, on visiting the cellar, it was found, to the owner's great surprise, that his nuts had now entirely disappeared, and in their place were discovered the corks! The only explanation that could be suggested was this: that the mice, *reflecting* on the difficulty of making their exit from the partially-emptied jar, had *conceived* and carried out the plan of providing for their escape by dropping into the jar from time to time sufficient corks to enable them to make a safe retreat with their plunder.

Mr. R. Howson sends us the story of a terrier-like dog of no particular breed, named Uglymug, who had a poodle for companion. Whenever Uglymug saw signs of a family meal being laid out, he inveigled the poodle into a labyrinthine shrubbery under pretence of seeking for rats, and when the latter was fairly intent on its game, Uglymug sneaked back to enjoy all by himself what he could get from the family table.

V. I. writes:—The following instance will show that in the case of the mule intelligence has a limit. We had a mule who could take the staple out of a gate and open it (he never shut it). This mule used to go to the water-butt, turn the brass tap, and drink, but never turned the water off. Common sense would have forbidden a human being neglecting such a precaution.

Mr. E. Parfitt, of the Devon and Exeter Institution, writes of a favourite cat:—She would frequently come and sit near the door opening into the library of the institution. The door only divides my house from the library; puss would place herself here mostly at dinner-time, and, as I am informed, not before; she would wait here until she heard my footsteps down the library; she would then proceed directly to the kitchen, and inform the servant, either by mewing or looking up into her face. She would then come to me and tell me in her way that she had ordered dinner. I have seen her scores of times trotting along the passage to the kitchen, when I have opened the library door, to inform the servant that I was coming. How Topsy ascertained the time to proceed to the door I do not know, except that she saw that dinner was preparing; but how did she know the time it would be ready and the time that I was expected to come in?

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

The Association for promoting the Higher Education of Women in Oxford is to open two halls in Oxford in October for the reception of lady students. One of these is to be an "Academical house on the principles of the Church of England," and in the other, "Somerville Hall" (after Mrs. Somerville), care will be taken that members of different religious denominations are placed on the same footing. The charges in the latter will be considerably lower than in the former.

Two Combe Exhibitions of 35*l.* each will be open for competition in May next at Trinity College, Oxford. Candidates will be at liberty to offer classics, mathematics, chemistry, and physics, a period of history, or any two or more of these branches of study. There is no fixed limit of age. The examination, which will be combined with the ordinary Matriculation examination, will commence on Tuesday, May 20, at 9 A.M. Names, with subjects offered and testimonials of good conduct, to be sent to the president not later than May 12.

The Astronomer-Royal continues to give evidence of his intense desire for the promotion of sound mathematical training, and has published to the Cambridge Senate his views as to the papers set in the Smith's Prize examinations of recent years, classifying the questions set, and showing that several subjects, more valuable, in his opinion, to men of science and to students, than all the others together, have had no questions set upon them. Among these are attractions, higher dynamics, perturbations, figure of the earth, thermodynamics, waves and tides, sound, physical optics, &c. He says very pertinently: "The use of an examination is to test the power of a candidate to command the application of mathematics when required. The use of publication of examination is to guide students in the subjects recommended for their study. The guidance which too many of these subjects intimate is this: that clever and abstruse algebra, without any reference to its benefit as an application of a tool to other purposes, is the *summum bonum*." He believes this guidance is against the instincts of many residents at Cambridge and the desires of undergraduates.

Progress is evident at Cambridge in response to the memorial we recently referred to against the compulsory study of Greek by all undergraduates. Very few votes prevented reform years ago; no doubt the claims of science students and of liberty for all will now be more fairly listened to. The syndicate on the subject includes Dr. Humphry, Professors Liveing and James Stuart, and Mr. Todhunter, and thus the real interests of mathematics, physics, biology, and medicine, as regards the education of students, as well as the progress of science, will be sure of recognition.

The examiners in the Cambridge natural sciences tripos this year are Dr. Humphry, Prof. Bonney, Mr. J. F. Walker, (Lecturer on Chemistry at Sidney Sussex College), and Mr. Yule, of Magdalen, Oxford, the foregoing being re-appointments, and Prof. Liveing, the Rev. J. W. Hicks (University Demonstrator of Chemistry, and Lecturer on Botany at Sidney Sussex College), Mr. W. Garnett, Demonstrator of Experimental Physics, and Mr. F. M. Balfour; the latter three are fresh nominations.

In the last Cambridge Local Examinations (December, 1878), among 626 senior boys there were 92 candidates for the chemistry paper and 44 for practical chemistry; of 997 senior girls, 29 took the paper and only 4 the practical examination; 21 boys and no girls entered for experimental statics and dynamics, &c., 38 boys and 24 girls for heat, 30 boys and 4 girls for electricity. The result is that only 3 boys, 2 from the Liverpool Institute and 1 from Newton College, Devon, obtained the mark of distinction in the section "natural philosophy," in which all these subjects are included; and no girls. It should be added that a pass may be attained on two of these subjects, and only three in all may be taken by any candidate. Is it possible to show more strongly the lack of attention to and interest in the elementary forces of nature in English schools and by English parents? These are boys and girls between sixteen and eighteen years of age, most of them supposed to be ready, or almost ready, to leave school and take part in the battle of life. Among 3,329 junior boys and 1,483 junior girls, 423 boys and 13 girls took the chemistry paper, 169 boys and 1 girl the practical chemistry, 76 boys and no girls statics, &c., 178 boys and 12 girls heat. Seven boys, the majority from Liverpool College, and no girls, obtained distinction. We do not become further consoled by finding that 15 senior boys and 79 senior girls took zoology, 11 boys and 177 girls botany, 24 boys and 150 girls geology; for girls have no *more* right to a scientific training than boys. Most likely, however, boys and their teachers will seek to know more of the life and the past history of the globe when they find that girls can really hold their own in and enjoy these studies, and look with amazement on men for being so unwilling to learn or teach them. Among the juniors, 75 boys and 148 girls took zoology, 45 boys and 238 girls botany. These numbers, however, represent no great attainments as yet, for the standard of passing is very low; severity would only kill the tender growth. But evidently there is in secondary schools little belief in the educative and attractive power of the study of nature. Why is it not considered that *mathematicians* are fostered by neglect and hindrance? It appears to be thought capital training to produce physicists and naturalists. Really, conservatism and unwillingness to take a little trouble are the enemies.

A REVISED schedule of subjects in natural science for the *ordinary* B.A. degree at Cambridge has just been issued. This is for the third or final examination, and a pass in one subject is sufficient to give a degree. Is it supposed at Cambridge that a year is to be fully employed in dealing with botany in an *elementary* manner? The schedule says the questions (all elementary) will include the description and classification of plants; the form, structure, and development of stem, root, leaf, flower, and fruit; inflorescence, cross-fertilisation, germination, and nutrition. Twenty-one "natural orders" are specified for special attention, including one cryptogamic group, Filices. This seems a vague syllabus, not likely to encourage the study of botany. How much and how little knowledge of physiology and histology will satisfy such terms as "nutrition," "structure"? No doubt the present is better than the old in omitting to insist on technical terms, some of them antiquated. But cannot more definite requirements be suggested for ensuring some practical insight into vegetable life on the part of the man who is to be stamped as an elementary botanist? Surely the best way is to let the knowledge be good, and sound, and practical, as far as it goes, giving some training in scientific method, and capable of further development in after life. We believe many would welcome a change giving the ordinary B.A. for a lower standard of attainment in the first part of the natural science tripos, thus doing away with the recognition of *dilettante* work in a single subject as a sufficient basis for a B.A. degree. A very satisfactory schedule is presented for zoology, requiring a knowledge of the anatomy of certain selected principal types, as well as the characters of orders, and the comparative anatomy and functions of the systems and organs as exemplified in the animal kingdom. Further, the general development of the embryo chick, the leading facts and conclusions respecting the geographical distribution of animals are included in the subjects. The schedule is to be discussed next Saturday.

THE Cambridge Council of the Senate has framed a draft statute to carry out the grace passed in December last in favour of the appointment of a general Board of Studies, representative in character, to report upon the proposals of each special board of studies as they arise, and so aid in holding the balance among the various interests concerned. The draft statute provides that the new Board shall consist partly of persons appointed on the nomination of the Boards of Studies, but abundant freedom is left to the senate to add other members and to vary from time to time the composition, mode of appointment, and duties of the new board.

AT the next meeting of the Governors of Addenbrooke's Hospital Mr. J. W. Cooper will propose: That a memorial be presented to Her Majesty's Commissioners for the University of Cambridge, under the seal of the Governors, representing that Addenbrooke's Hospital is extensively used as a place of study by the Medical Students of the University; that it is essential in the interests of the Medical School that it should not cease to be a recognised place of medical study; and, further, that as large endowments have been left to various colleges for the promotion of medical study, some adequate endowment should be made for Addenbrooke's Hospital out of the funds at the disposal of the Commissioners. There cannot be much chance of success for such a proposal unless it be made more definite. The hospital can only properly benefit by educational endowments by being the locus of the study and appliances of research in therapeutics, sanitation, and pathology.

GEOLOGICAL students at Cambridge will have plenty of work provided for next term. Prof. Hughes will give one course on the geology of the neighbourhood of Cambridge, and another stratigraphical course, beginning with the Permian, and ascending. Prof. Bonney will continue his lectures on elementary physiography, and will give weekly demonstrations on microscopic lithology. Mr. Tawney will be demonstrating the principal genera of fossil invertebrata; and both he and Dr. R. D. Roberts will give practical instruction in petrology. Lectures begin April 25. The first geological excursion of the term is fixed for Saturday, May 3.

MR. THOMAS W. BRIDGE, B.A., of Trinity College, Cambridge, and Demonstrator of Comparative Anatomy in the University of Cambridge, has been appointed to the Professorship of Zoology at the Royal College of Science at Dublin, vacant by the resignation of Dr. Leith Adams, F.R.S.

SOCIETIES AND ACADEMIES

LONDON

Royal Society, March 13.—"The Contact Theory of Voltaic Action," No. III. By Professors W. E. Ayrton and John Perry. Communicated by Dr. C. W. Siemens, F.R.S.

The authors commence by referring to the experiments that had been made prior to 1876, on the difference of potentials of a solid in contact with a liquid, and of two liquids in contact with one another, and they point out that :—

1. The earlier experiments were not carried out with apparatus susceptible of giving accurate results.

2. Owing to the incompleteness of the apparatus assumptions had to be made not justified by the experiments.

3. *No direct* experiments had been performed to determine the difference of potential of two liquids in contact, with the exception of a few by Kohlrausch, using a method which appeared to the authors quite inadmissible as regards accuracy of result.

In consequence of this great vagueness existed as to whether the contact difference of potentials between two substances, when one or both were liquids, was a constant depending only on the substances and the temperature, or whether it was a variable dependent upon what other substance was in contact with either. Some authorities regarded it as a variable, Gerland considered he had proved it to be a constant, but first, the agreement of the value of the electromotive force of each of his cells with the algebraical sum of the separate differences of potential at the various surfaces of separation, and which was the test of the accuracy of his theory, was so striking, and so much greater than polarisation, &c., usually allows one to obtain in experiments of such delicacy, that one could not help feeling doubtful regarding his conclusions; secondly, his apparatus did not allow of his experimenting with two liquids in contact, consequently he could not legitimately draw any conclusion in this latter case. And although Kohlrausch had made some few experiments on the difference of potentials of liquids in contact, still since he employed moist blotting-paper surfaces instead of the surfaces of the liquids themselves, the authors considered for that reason alone, if for no other, that his results did not carry the conviction the distinguished position of the experimenter might have led them to anticipate.

They therefore designed a method and an apparatus for carrying it out, by means of which they could measure the difference of potentials, in volts, at each separate contact of dissimilar substances in the ordinary galvanic cells, from which they could ascertain whether the algebraical sum of all the contact differences of potential was, or was not, equal to the electromotive force of the particular cell in question. From the results they obtained, and which are given in Papers Nos. I. and II., *Proc.* Roy. Soc., No. 186, 1878, they concluded within the limits of their experiments that if $\overline{AB}$, $\overline{BC}$, $\overline{CD}$, &c., were the contact differences of potential measured *separately* of the substances A in contact with B, and neither in contact with any other conductor, B in contact with C, &c., then, any one or more of the substances being solid or *liquid*, if any number $A, B, C \cdots\cdots K$ were joined together, and the electromotive force of the combination $\overline{AK}$, measured, the following equation was found true :—

$$\overline{AK} = \overline{AB} + \overline{BC} + \overline{CD} + \cdots\cdots + \overline{JK},$$

which proved that each surface of separation produced its effect independently of any other.

Their method, by which any single contact difference of potentials was measured, was as follows :—Let 3 and 4 be two insulated gilt brass plates connected with the electrodes of a delicate quadrant electrometer. Let 1 under 3, and 2 under 4 be the surfaces whose contact difference of potential is to be measured; 3 and 4 are first connected together and then insulated, but remain connected with their respective electrometer quadrants. Now 1 and 2 are made to change places with one another, 1 being now under 4 and 2 under 3, then the deflection of the electrometer needle will give a measure of the difference of potentials between 1 and 2.

The apparatus employed by the authors in the present investigation is then explained in detail, and it is shown how, by improving on their earlier form, they have removed a difficulty which formerly existed, and which prevented their previously experimenting on pairs of substances having very different weights, such as a vessel of mercury and a sheet of metal.

The authors explain that the results they have obtained in this investigation have divided themselves into three groups :—

1. The contact difference of potentials of metals and liquids at the same temperature.

2. The contact difference of potentials of metals and liquids when one of the substances is at a different temperature from the other in contact with it—for example, mercury at 20° C. in contact with mercury at 40° C.

3. The contact difference of potentials of carbon and platinum with water, and with weak and with strong sulphuric acid.

They mention, however, that they give only the results under head No. 1 in the present communication, reserving those they have obtained under heads Nos. 2 and 3 for a future occasion.

Then follow arranged in the order in which they were obtained from January to May, 1878, some 150 results of experiments (each result given being on the average the mean of ten observations), representing the contact differences of potential of nine solids and twenty-one liquids. The authors explain that many of the results they obtained are not mentioned in the paper, having been rejected on account of inaccuracies arising from the great delicacy of the experiments. These remarks especially apply to the authors' attempts to measure the contact difference of potentials between a liquid and a paste—for example, mercury and mercurous sulphate paste, great difficulty being introduced by the extremely thin layer of water on the surface of the paste acting inductively instead of the paste itself. They mention that this difficulty is a very good example of the inaccuracies that must have been introduced by former experimenters using a moist blotting-paper surface instead of the surface of the liquid itself.

A large number of discordant results were obtained in March, 1878, and their explanation led to the interesting result that the apparent contact difference of potentials between a metal and mercury, as measured inductively, varied much with small additions of temperature. The investigation of this apparent change of contact difference of potentials with temperature led to a consideration of the contact difference of temperature of mercury with air, since, of course, in all these inductive experiments two air contacts are included in the result.

It has usually been thought that the differences of potential of liquids in contact with one another were so small as to be almost inappreciable in comparison with the differences of potential of metals in contact; but the authors have ascertained, among other results, that strong sulphuric acid in contact with distilled water, solutions of alum, copper sulphate, and zinc sulphate, has a measured difference of potentials of 1·3 to 1·7 volts, or an electromotive force more than twice as high as that of zinc and copper in contact. And hence the great importance of an apparatus that can directly measure the difference of potentials of two liquids in contact.

Zoological Society, March 18.—Prof. St. George Mivart, F.R.S., vice-president, in the chair.—The Secretary called the attention of the meeting to the herd of Japanese Deer (*Cervus sika*) in the park of Viscount Powerscourt, at Powerscourt, in Ireland, now about eighty in number, and gave an account of their introduction and history, from particulars supplied to him by Lord Powerscourt.—A communication was read from Dr. G. Hartlaub, containing the description of a new species of Barn Owl, from the island of Viti-levu, which he proposed to call *Strix oustaleti*.—Mr. Edward R. Alston read a paper on female deer with antlers, showing that these weapons are not unfrequently abnormally developed in fertile females of certain species of *Capreolis* and *Cariacus*, and giving reasons for believing that in the ancestral forms of deer they were probably common to both sexes.—Mr. Sclater made remarks on some of the rarer parrots living in the Society's Gardens. The whole series of this group in the Society's collection was stated to consist of 170 individuals belonging to ninety-eight species.—A communication was read from Prof. Garrod, F.R.S., containing notes on the visceral anatomy of the Tupaia of Burmah (*Tupaia belangeri*). The cæcum coli in this animal was stated to be small, whilst in a specimen of *T. tana* it was ascertained to be wholly wanting.—A second communication from Prof. Garrod contained notes on the anatomy of *Helictis subaurantiaca*, in the course of which he showed that the hippocampal gyrus of the brain is partly superficial in this animal, which is not the case in any other carnivorous animal yet recorded.

Linnean Society, March 20.—William Carruthers, F.R.S., vice-president, in the chair.—The Rev. G. E. Commesford Casey was elected a Fellow of the Society.—A paper by Mr. Fred. Smith, on new aculeate hymenoptera from the Sandwich Islands, collected by the Rev. T. Blackburn, was read. The author states the general aspect of the series is certainly North American, with mixture of a few South American forms. The ants are most diverse in character, some being cosmopolitan in range. The house ant of Madeira is common, and the little European ant (*Ponera contracta*) unexpectedly turns up here.—Some observations on the reproduction of ferns, by Mr. T. R. Sim, were also read by the Secretary in the absence of the author. Among the great collection of living ferns at Kew a marked feature is the large number of species that regularly bear adventitious buds. Of a thousand species there grown barely fifty are ever found without buds, and some forms produce them regularly, though the normal forms do not. The above number seems very high when compared with Phanerogams, where adventitious buds, with some few exceptions, may be said never to be normal. Among viviparous ferns the contrary obtains, and the buds are always on the same part of the plant in all the individuals of a species. *Polystichum angulare*, for example, bears a bud on the rachis in the axil of almost every pinna on the lower part of the frond, in some all up the rachis. Some Aspleniums produce them on the veins of the upper surface of frond, but never directly through from a sorus. Great variety in position, however, is manifested in different genera and species where budding occurs, various examples of which the author gives. Where buds become detached, considerable difference obtains as to size and stage of separation, whereof many instances are pointed out and other curious instances of deviations related by the author. In commenting on the subject, Sir J. D. Hooker stated his belief that ferns at Kew were more bulbiferous than in their natural state, possibly from more constant nutrition and warmth.—The fifth contribution to the ornithology of New Guinea, namely, recent collections from the neighbourhood of Port Moresby, was read by the author, Mr. R. Bowdler Sharpe. The interesting series dwelt on were obtained by Mr. Kendal Broadbent, and usefully compare with those got by Signor Albertis from the Fly River. A parrot of the genus *Aprosmictus* closely resembles one from the Fly River, but nevertheless is specifically distinct, offering thus a parallel case to the crowned pigeons, *Goura albertisi*, inhabiting Port Moresby, and *G. sclateri*, the Fly River. At present the affinities of the South-Eastern species seem to be with those of Australia, a few to those of the Aru Islands.—Mr. W. T. Thiselton Dyer exhibited *Helichrysum vestitum*, a perennial everlasting, from the Cape of Good Hope.

Anthropological Institute, March 11.—Mr. E. Burnett Tylor, D.C.L., F.R.S., president, in the chair.—The president read a paper entitled "The Geographical Distribution of Games," in which attention was called to the games of Polynesia and America as proving that a drift of civilisation from Asia reached these regions before they were known to Europeans. The draughts played in the Sandwich Islands and New Zealand were not our modern game, but apparently some variety related to the ancient classical game (which is alive in Egypt to this day). It may have reached the South Sea Islands from Eastern Asia, together with kite-flying, at which they were experts, and which they perhaps had before the comparatively modern time when it reached England.

Royal Microscopical Society, March 12.—Dr. Beale, F.R.S., president, in the chair.—The following papers were read:—Contribution to the knowledge of the British Oribatidæ, by A. D. Michael, F.R.M.S.—The development and retrogression of fat cells, by G. and F. E. Hoggan.—Microscope with swinging sub-stage and improved motions, by J. Beck, F.R.M.S.—The use of osmic acid in microscopical preparations, by T. J. Parker, F.R.M.S.—Other papers by Prof. Keith, Mr. Tolles, and Mr. Crisp were taken as read, or postponed in consequence of want of time.—The new $\frac{1}{18}$ oil immersion objective by Zeiss was exhibited, with remarks by Prof. Abbe on the Stephenson homogeneous immersion system.—A large number of objects were exhibited illustrative of the papers read and otherwise, together with microscopes and apparatus by Mr. Crisp.—Lord Justice Bramwell and six other gentlemen were elected Fellows.

Photographic Society, March 11.—James Glashier, F.R.S., in the chair.—Papers were read: On coloured glass suitable for the developing-room, and on the employment of quinine as a substitute, by Capt. Abney, R.E., F.R.S., who, in illustration of his paper, exhibited photographs of the solar spectrum taken through various stained glasses, and stated that a combination of cobalt and stained red glasses secures immunity from the actinic action of light, and that collodion-films on both sides of a glass, stained with either magenta, aurine, or chrysoidine,

practically are also non-actinic. Quinine, he found, cuts off the ultra-violet rays, and no others.—Mr. C. Bennett, on the gelatine emulsion process, enforced the fact that the extreme sensitiveness of his process was produced by the long time he allowed the gelatine and salts to emulsify or ripen before eliminating the bromide and silver not taken up.—Mr. W. Wainwright, jun., note on Bennett's gelatine emulsion process; also, Mr. Howard Grubb exhibited some new forms of stereoscopes, one designed to exhibit pictures of a much larger size than ordinary.

Institution of Civil Engineers, March 11.—Mr. Bateman, president, in the chair.—The paper read was on movable bridges, by Mr. James Price, M. Inst. C.E.

PARIS

Academy of Sciences, March 17.—M. Daubrée in the chair.—The following papers were read:—On an electric burner and blowpipe, by M. Jamin. Two carbons are supported vertically abreast, hinged below, and drawn together at the top by a spring. A current is sent up one (A), down the other (B), then round a rectangular circuit inclosing the two, and passing first round A; by current attraction the carbons are drawn apart, and the arc appears at the top and descends gradually, consuming one or both carbons. When the action of the rectangle is sufficient, the arc driven beyond the points is like a gas flame, and M. Jamin receives it on a piece of lime, magnesium, or zirconium, getting intense light. It is also so hot as to fuse the lime, and the author recommends it as a blowpipe to chemists and physicists.—On a meteorite belonging to the group of eukrites, which fell on July 14, 1845, in the Commune of Teilleul (Manche), by M. Failli.—M. Larrey communicated a letter from M. Tholozan, Persia, on the plague, which he shows to have sprung up and died out in certain localities in the absence of restrictive measures. The French Government have sent Dr. Zuber to Astrakhan to study the disease.—On a new type of anomalous stems, by M. Cornu. This relates to supplementary cortical ligneous bodies anastomosed together, in certain *Sempervivum* and *Crassula*; their *rôle* seems to be to strengthen the fragile stems when they have to bear a large inflorescence.—On the amyloid granules of the yolk of eggs, by M. Dareste. He urges reasons for thinking the granules starch, and not lethicine (as has been affirmed). They are difficult to study.—On the correspondence between Chladni's acoustic figures and liquid systems produced on vibrating circular plates, by M. Decharme. It was stated that the Italian Society of Natural Sciences had formed a service of antiphylloxeric vedettes, to survey vineyards, and report the first suspicions of the disease.—On a new catadioptric telescope, by MM. Paul and Prosper Henry. The tube of a reflecting telescope is hermetically sealed by means of a thin crown glass lens of the same size as the mirror, very slightly concave, and not detracting from the optical power of the instrument. The instrument has given remarkable results.—Demonstration of the convergence of a double series met with by Lamé in his researches in mathematical physics, by M. Escary.—On the integration of a differential equation, by M. Halphen.—On the determination of the imaginary roots of algebraic equations (concluded), by M. Farcas.—On a system of light signals permitting the determination of differences of longitude between different stations not connected electrically, of a triangulation of parallel or meridian, by M. Liais. This system has been adopted in Brazil. M. Liais shows the advantage of making rhythmic signals commanded by a clock, and received at the other station by a chronographic inscription. In this way there is no variable personal equation to be concerned about. The point is to make a screen, with aperture, beat seconds (*e.g.*, by a clock commanding an electro-magnet) so as to give an instantaneous appearance of light each second. The receiving-station may either register with a chronograph or (better) compare directly the clocks of the two stations by the method of coincidences; a screen, with aperture, passing before the objective of the telescope, and the light seen only when the two clocks are in coincidence.—On the distribution of heat on the sun's surface; results of the first series of observations at the Imperial Observatory of Rio de Janeiro, by MM. Cruls and Caille. These researches fully confirm the results got by Secchi, though there are some differences as to absolute value of radiations. The absolute radiation of the whole disk was estimated at $\frac{22}{100}$, the absorption, $\frac{78}{100}$.—Determination of the approximate value of a coefficient relative to the viscosity of water, by M. Geoffroy.—New experiments on telephones without a diaphragm, by M Ader. He gets better results than with an ordinary telephone from a thin piece of wire (with small helix round it) fixed at one end in a wooden board (a microphonic speaker being used), better if the two ends are in contact with metallic masses. Voice is reproduced, too, from a mere bobbin without core, if the windings are very free. He supports M. du Moncel's view that the sounds in the telephone are from contractions and elongations of the magnetic rod.—M. Du Moncel described some observations in the same sense.—M. Resis presented a note on a hydro-electric telephone, in which the variations in intensity of the current are reproduced by variations in resistance of a liquid column, which serves as receiver (without any electro-magnetic organ).—On new combinations of hydrochloric acid with ammonia, by M. Troost. The two specified are the tetra and hepta-ammoniacal chlorhydrates.—Combinations of phosphuretted hydrogen with cuprous chloride, and its determination in gaseous mixtures, by M. Ribau.—On the crystalline form of combinations of stannmethyls and their homologues, by M. Hiertdahl.—On a new process of treatment, by the dry way, of iron and copper pyrites, by M. Simonin. This relates to Mr. Holloway's method.—On the state in which precious metals are found in some of their combinations; ores, rocks, products of art, by MM. Cumenge and Fuchs.—On the constitution of coal, by M. Guignet. He treated powdered coal with phenol, nitric acid, &c. With the latter he obtained, *inter alia, trinitroresorcine* (oyxpicric acid), probably from resinous or waxy matters retained in the coal. No resorcine was found.—On alcoholic fermentation, by MM. Schutzenberger and Destrem. Yeast prevented from developing and multiplying still retains its power of decomposing sugar; and yeast acting on sugar deassimilates more nitrogen than that kept in presence of water, but without sugar and oxygen.—On the determination of glucose in the blood, by M. Cazeneuve. He criticises Bernard's method (by cupropotassic liquor) as inexact, and thinks the study of glycæmia should be taken up again when a more precise method is acquired.—On the derivatives of normal methyloxybutyric acid, by M. Duvillier.—Analysis of some fodders, and observations on damage done to Italian beans by weevils, by M. Grosjean.—Comparative evolution of the male and female genital glands in the embryos of mammalia, by M. Rouget.—On the non-excitability of the grey cortical substance of the brain, by M. Couty.—Note on the history of peduncular expansions, by M. Bitot.—On the nature of the albumen of hydrocele, by M. Bechamp.—Experimental researches on a leptothrix found during life in the blood of a woman attacked with grave puerperal fever, by M. Feltz.—On the modifications of the physical properties of starch, by M. Musculus.—On ferruginous particles observed in dust brought by a blast of sirocco to various parts of Italy, by M. Tacchini. This was in February. He thinks the phenomenon of so-called *meteoric* spherules must in many cases be attributed to this phenomenon.—Morphology of the dental follicle in vertebrates, by MM. Legros and Magitot.—Pathogeny and treatment of intermittent convergent strabism, without operation, by use of mydriatics and myosics, in children, by M. Boucheron.

COLOUR IN NATURE

The Colour Sense: its Origin and Development. An Essay in Comparative Psychology. By Grant Allen, B.A. (London: Trübner and Co., 1879.)

THIS interesting and suggestive work deals with the whole question of colour in nature, and more especially with its manifestations in the organic world and the complex colour reactions between plants and animals. It traces the origin of the colour sense in insects to their visits to primeval flowers in order to feed upon the pollen, and in birds to their seeking for fruits, whose seeds they dispersed and whose colours were developed to attract them. It thus attempts to show that the very existence of most of the brilliant colours of the organic world is due to the influence of the colour sense in animals. The author adopts, with some reservations, Mr. Darwin's theory of sexual selection to account for the colours of most animals, and he endeavours to show that only those groups display beautiful colours in which a taste for colour has been aroused by the influence of flowers, fruits, or brilliant insects, their habitual food. All these subjects are treated in a very thorough manner, with a wealth of illustration, a clearness of style, and a cogency of reasoning, which make up a most attractive volume; and though we may not agree with all the author's conclusions, and may even doubt the accuracy of some of his facts, we cannot but admit that he has placed the whole subject before us in a way that must engage the attention both of the man of science and the general reader. We will now proceed to give an outline of the whole work, dwelling here and there on the more interesting points, and especially on those where we venture to differ from the conclusions arrived at.

After an introductory chapter, the contents of which are above indicated, an excellent account is given of the nature of light, and of those peculiarities of the æther-waves which produce in us the sensations of light and colour. The third chapter deals with the organ of vision, giving an account of its earliest appearance and progressive complexity in the animal kingdom, and of the structure of the eyes of the higher animals, and the relation of their parts to the perception of light and of differences of colour. One of the most important facts here brought out is, that the complex mechanism required to produce vision has been several times independently evolved—the eye of the bee, of the cuttle-fish, and of the eagle have each apparently been separately developed from unlike remote sightless ancestors.

The next chapter is a long and very interesting one, on "Insects and Flowers." It deals with the origin and development of these two classes of organisms and their actions and reactions on each other. It is full of interesting facts; and the discussion of the mode of origin of the colours of flowers by a reference to the conditions under which colour appears normally in living plants is especially instructive; the generalisation being arrived at that the leaves which create or store up energy for the plant are green, while whenever leaves lose this function and become expenders of energy they lose the green tint and acquire various other colours; growing shoots, young leaves, buds, stamens and stigmas, and their protecting scales, are almost always variously coloured. The rudiments of colour being thus always ready in the floral organs, it is not surprising that flowers have been separately developed in monocotyledons and dicotyledons, and also probably many times over in each of these divisions.

In this part of his work the author exhibits his tendency to trust far too much to negative evidence, especially to that afforded by geology. He speaks of the carboniferous epoch as presenting a green jungle of ferns and club-moss, "in which there is no trace of bee or moth or joyous butterfly;" while "scarlet berry and crimson blossom, gorgeous bird, and painted insect were all equally absent from the unvaried panorama of green overhead and brown beneath." As the flora preserved to us in the coal-measures was almost certainly that of swamps only, we cannot possibly tell what existed on the uplands and mountains of that period. The enormous differentiation of flowering plants, and the comparatively little change they seem to have undergone during the whole tertiary period would lead to the inference that they may have already existed in some variety during the carboniferous epoch; while the actual discovery of a butterfly in the lower oolite, and of a well preserved wing of what appears to be a large moth in the carboniferous shales of Belgium,[1] renders it quite possible that coloured flowers and gay butterflies *were* then in existence. The statements as to the time when the different orders of insects first came into being (quoted at p. 68) are quite worthless when we consider how rare must be the conditions leading to the preservation of winged insects, and they are already contradicted by well-known palæontological facts. Another statement that seems equally open to doubt is, that even in early tertiary times there were no orchids (p. 97), a statement founded on the generalisation that entomophilous monocotyledons are later productions than entomophilous dicotyledons, because the perianth of the former is usually less specialised. But surely in orchids the perianth is more highly specialised than in any existing flowers whatever; and if we take into account the world-wide distribution of these plants, their immense richness in genera and species, and their wonderful complexity of structure, we must consider them as among the most ancient instead of the most recent of flowers. They are also exceptions to the general rule of the size of the flower being in inverse proportion to its special adaptation to insect fertilisation; of which the large but simple lilies and tulips as contrasted with the small but complex labiates, are quoted as examples.

The next chapter, on the colour sense in insects, sets forth both the direct and the indirect evidence on this question; such as Sir John Lubbock's experiments on bees and wasps, the mimicking insects which deceive other insects, the clear relation of coloured flowers to the visits of insects, the fact of insects often visiting hundreds of the same species of flower in succession, &c. This chapter concludes with a striking picture of the vast effect which has been produced on the appearance of external nature by insect agency, "which has turned the

[1] *Breyeria borinensis*, "Annales de la Société Entomologique de Belgique," t. xviii. Pl. v. (Photograph).

whole surface of the earth into a boundless flower-garden," supplying insects from year to year with pollen or honey, and itself gaining in return a renewal of life by means of the baits that it offers for their allurement. "If," adds Mr. Allen, "any man can seriously doubt that these changes are really due to a colour sense in the little creatures which live upon the beautiful flowers; if he can imagine that the plant has produced its gorgeous petals for no other purpose than that of suicidal wastefulness; that the *Mantis* has grown into the perfect semblance of a leaf from pure wanton causeless mimicry; that the lurid red of fly-fertilised blossoms bears its likeness to the mangled flesh of animals by a simple freak of creative power; then the whole science and philosophy of the last hundred years have been thrown away upon him, and he may return at leisure to the blind and hopeless chance of the eighteenth century atheists."

The relation of birds and mammals to fruits is next discussed, and this is shown to be in many respects parallel to that of insects and flowers, only those fruits being conspicuously coloured which are edible, and the dispersal of whose seeds is effected by the birds or other animals which eat them. The whole of this subject is very well treated, but the evidence that fruits in general have been modified both in edibility and attractiveness in relation to the animals which feed upon them, is by no means so clear as in the case of flowers. With regard to small and hard-seeded fruits, such as our strawberries, currants, and raspberries, our hips and haws, our yews and cranberries, this is no doubt the case, since they are carried away by birds and vegetate after passing through their bodies. It is also the case with such fruits as the nutmeg, whose bulky seeds pass undigested through the stomachs of the great fruit pigeons, but whether the same rule applies to most of the larger fruits may be doubted except when they have hard, stony seed-coverings, as in the case of plums and apricots, which evidently protect the seeds from being eaten, or, if eaten, from being digested. But the majority of the larger fruits are eaten by mammals, and it is doubtful whether their seeds can survive the process. Such are oranges and shaddocks, and gourds of various kinds, while many large bright-coloured fruits of the tropics do not seem to be eaten at all. Many of these are very round and smooth, and may get dispersed by mere rolling down hill, as occurred with the mango in Jamaica,[1] or by being accidentally disturbed by the feet of animals. It is to be observed, too, that the fruits of trees are usually so abundant that, if eatable, there is no danger of their not being eaten even if uncoloured, as in the case of our acorns, beech-nuts, and chestnuts. An immense number of the tropical fruits eaten by monkeys and parrots are not coloured, and the half-developed seeds are often alone eaten; while in others, as the jack-fruit, bread-fruit, and durian, the large seeds are as eatable as the pulpy mass, and the edible nature of the fruit must be injurious rather than otherwise as leading to the destruction of seeds. This need be no difficulty when we consider that with forest trees, which live for several centuries, there is only vacant space for young trees at long intervals, and thus no rigid selection of seeds takes place tending to secure them from being destroyed as food for animals.

[1] See Sir Joseph Hooker's lecture at the Royal Institution on "The Distribution of the North American Flora."

On account of the fondness of most birds and other animals for the very same fruits which we like best, Mr. Allen maintains the general community of taste in all animals. I have, however, usually found monkeys eating fruits which were very disagreeable to me, and the theory is hardly consistent with the fact that many nauseous fruits are bright-coloured. Thus the *Citrullus colocynthus* of Palestine has a beautiful fruit of the size and colour of an orange, but, according to Canon Tristram, "nauseous beyond description to the taste,"—while the *Solanum sanctum*, generally called the "Dead Sea apple," is almost equally disagreeable, but is of a brilliant red colour. Now if these fruits are eaten by any animals their taste must be very different from ours, while if they are not, these fruits have become strikingly attractive from other causes than to induce animals to eat and disperse them. This latter view is supported by another fruit, also found in Palestine, the *Calotropis procera*, which is as large as an apple and bright yellow, but is full of thin flat seeds winged with exquisitely fine silky filaments. Here, then, the seeds having special powers of dispersal by the wind do not need the aid of animals, yet the fruit is most attractively coloured. This is one of the Apocynaceæ, which are usually poisonous, and I have observed brilliantly coloured fruits of the same order in the tropics, but some of these are known to be eatable. Taking into consideration all the facts, it seems probable that attractive fruits are more abundant among the smaller trees and shrubs of temperate lands than in the forests of the tropics, and that their colours are largely due to those adventitious causes which our author has himself so well elucidated. When their distribution has been aided by birds their colours, their edibility, and the non-digestibility of their seeds would all be increased by natural selection. The dry fruits of herbaceous plants, in which the struggle for existence is probably more severe, have no doubt often been prevented from acquiring bright colours by natural selection in order to protect their seeds, just as so many insects and birds have acquired brown or green protective tints.

A curious point in relation to this question, and one that has not been noticed by our author, is the very different characteristic colours of fruits and flowers. I have tabulated the colours of these, under four heads, taken from two books of manageable size—Hooker's "British Flora" and Mongredien's "Trees and Shrubs for English Plantations." The colours of the two classes I find to be as follows, dividing the purples between the red and blue to the best of my judgment, and taking black among fruits as corresponding to blue in flowers.

Flowers.	White.	Yellow.	Red.	Blue.
British Flora	292	228	168	123
Trees and Shrubs ...	160	73	62	37
Totals	452	301	230	160
Fruits.				
British Flora	2	3	33	24
Trees and Shrubs ...	5	11	35	21
Totals	7	14	68	45

Here we see that white and yellow which immensely preponderate in flowers are very scarce among fruits, among which red and blue (or black) predominate, the two colours which are far less common in flowers. We must

conclude, either that there is not a community of taste in colour between insects and birds, or, that what may be termed the normal colours of both have been more or less intensified and utilised by natural selection in order to attract insects and birds respectively.

The next chapter, on the colour-sense in vertebrates, clearly establishes the fact of the possession of this sense by all vertebrate animals, but more especially by birds and reptiles. The evidence of such a sense in mammalia generally is very scanty, though it undoubtedly exists in monkeys; while there are good reasons for believing that it is more acute in birds than even in ourselves. Birds on the whole need to perceive colour more than any other animals, both because the insects and fruits and buds on which so many of them feed are small variously-coloured objects, and because from their habits they require to see and recognise these objects from a considerable distance. It is therefore a remarkable confirmation of the modern theory—that the cones of the retina are colour organs while the rods are only light organs, that in birds the cones are three times as numerous as the rods, while in mammals they are less numerous. Nocturnal birds, such as owls, however, have very few cones, while nocturnal mammals have none. The *macula lutea*, a central yellow spot consisting largely of cones, is found in man and monkeys only, while it exists in all diurnal birds, and these in addition have their cones furnished with variously-coloured globules, which are supposed to give a still more perfect perception of colour. The eye of the chameleon is as perfect as that of a bird, and this accords with its capacity of colour change, and the extreme accuracy with which it detects and captures insects. Mammals, on the other hand, even the insectivorous and frugivorous kinds, have very little occasion for a refined colour sense, since the great mass of creeping insects are of obscure colours, while the squirrels and allies feed on brown nuts rather than on coloured fruits. The evidence seems to show, therefore, that a tolerably perfect colour-sense has only been attained, among mammalia, in the monkeys and man, while even in these it is probably very inferior to that of birds. It seems probable, therefore, that the prevalence of colour-blindness is really an indication of the colour sense in man having been a comparatively recent development, instead of being, as Mr. Allen thinks, a disease of civilisation. An acute colour sense is certainly not of the first importance to savages; and though our author has adduced valuable evidence that most savages distinguish colours just as well as we do, it is very important to ascertain whether colour-blindness exists among uncivilised peoples to a greater or a less extent than among Europeans.

The next chapter, on the direct action of the colour sense upon the animal integuments, deals with the theory of sexual selection as advanced by Mr Darwin, and endeavours to support it by a variety of general considerations. Many of these arguments are very weak, and are often founded on insufficient or erroneous facts, some of which I shall endeavour to point out. The great aim of this chapter is to prove that the colours of animals are intimately associated with the colours of the objects they feed upon. Butterflies and moths being the most beautifully coloured of all insects and feeding on flowers, is held to be the first great fact in support of this view; and this is backed up by the remark that "the colours of caterpillars are mostly protective, being due to natural selection alone, while those of butterflies are mostly attractive, being largely due to sexual selection." To this we must altogether demur, as slurring over what is really a stupendous difficulty in the way of the theory. So far from the colours of caterpillars being "mostly protective" every entomologist knows that a large number of caterpillars in every part of the world are conspicuously coloured, and what is more to the point that their colours are as brilliant and varied as those of butterflies themselves, if we take into account the nature of their integument, the small amount of surface, and the uniform cylindrical form of their bodies. The caterpillar of *Papilio dissimilis*, for instance, on a bluish green ground has a series of broad irregular longitudinal bands of the richest orange yellow, and between these there are a number of round red spots; while those of many of the Euplæas are adorned with exquisite pink and yellow markings, and with a number of long fleshy processes of equally brilliant colours. Owing to caterpillars being so difficult to preserve, and being rarely collected and figured in their native countries, comparatively few of them are known, but it is certain that they often exhibit the most brilliant hues and the most exquisite patterns; and as they may be said to feed invariably on green leaves, while sexual selection cannot affect them, the natural inference is that the same general laws which produce colour in them are quite sufficient for the production of even more varied hues in the perfect insects, whose expanded wing surfaces, ever varying in size, form, and neuration, offer a field so much better fitted for its development.

In beetles the appearance of colour is also attempted to be correlated with their flower-haunting habits by means of equally doubtful facts. The magnificent Buprestidæ and Longicorns are, as far as my experience goes, almost wholly wood-feeders, frequenting the bark of dead trees, and very rarely found on flowers; the Cleridæ and Silphidæ feeding on dead animal matter, are often brilliantly coloured; and generally in beetles, the absence of colour may be traced to the need of concealment and protection, while whenever a special mode of protection exists, whether by nauseous secretions, hard integuments, rapid flight, or facilities for concealment, then colour appears in infinitely various phases; and this law generally prevails throughout the whole insect-world. In his argument in favour of bright hues being attractive to the opposite sexes of insects, Mr. Allen seems always to forget that it is the male that is attracted to the female, and not *vice versâ*; and when he says (p. 158) that he "cannot see why Mr. Wallace, who allows the attractive nature of colouring in flowers, should deny its attractive nature in the question of sex," I reply, that in flowers colour enables the insect to recognise the species, but no one has ever asserted that insects improve and alter the colour of flowers by their preference for certain varieties of colour irrespective of the honey or pollen produced; and in like manner I maintain that the colour of an insect is a guide to easy recognition by its mate, but that there is not one single particle of evidence to show that minute differences in the colour of the same species are observed by insects, still less that such differences are so important

to them as to lead to the rejection of a healthy and well-organised mate; yet unless this is the case, the whole theory of sexual selection falls to the ground.

Again, the general connection between coloured flowers and coloured insects is by no means so general and constant as Mr. Allen supposes. Perhaps the richest displays of gay flowers in the world are to be found in temperate Australia, in South Africa, and in the South European Alps, yet in all these countries the butterflies are very inferior to those of tropical forests, where flowers are comparatively rare. In the forests of Para, for instance, gay flowers are very scarce, as noticed by Mr. Bates as well as by myself, yet the butterflies are endless in their variety of lovely hues. Of course there *are* bright flowers in the tropics, and as travellers notice these whenever they see them and also notice the handsome butterflies, it is easy to infer, as is here done, that the two invariably go together. We may also remark that the sexual allurement of a peculiar odour given out by special patches of scales on butterflies' wings has been discovered by Fritz Müller in the genera *Mechanitis*, *Dircenna*, and *Thecla*, all very brilliantly coloured groups, a clear indication that colour is not a sexual allurement, or we should find it most developed, not in conjunction with, but in the absence of, the attraction of odour.

We must now pass on to the vertebrates, and we here find very good evidence adduced of the existence of a colour-sense in fishes, reptiles, and birds, as we should expect from the known structure of their eyes; while in the case of mammals it is far less decisive. The attempt to associate the brilliant colours of these animals with their food and surroundings, acting through sexual selection, is, however, what we have now to consider; and though many alleged facts are adduced in support of it, several of them are as doubtful and inconclusive as in the case of insects. We shall confine our attention to the birds, which are the stronghold of the theory, and are so much more completely known than the less highly-organised fishes and reptiles. Mr. Allen claims the parrots as fruit-eaters, but they are really seed-eaters, their bills being specially formed to crack the shells and extract and grind up the kernels of nuts and other fruits. They do not therefore aid in the disposal of seeds, as they feed on brown nuts or unripe green fruits from which they extract the seeds, much more frequently than on coloured ripe fruits. The general green colour of parrots is undoubtedly protective, and this green colour is lost, and vivid tints appear just in proportion as, owing to various conditions, the need of concealment diminishes. This is especially the case in countries where mammals are few and a low type of organisation prevails, as in the Australian region, in Madagascar, and in South America; while in Africa and Asia, where a higher type of organisation prevails, the colours of parrots are more sober and protective. A little further on we find the Australian honey-suckers noted for their magnificent coloration; the fact being that they are decidedly a dull-coloured group, hardly superior to our thrushes, and not equal to our finches. Yet they are as universally flower-feeders as the humming-birds themselves; and the total absence of brilliant colour from these birds, which are *the* characteristic family of Australia, and have been developed in correlation with the brilliant Australian flora, absolutely negatives the idea of colour in birds being dependent on the amount of colour in the food and surroundings of certain groups. Again, the ground-feeding pheasant family are passed over as containing only one brilliant bird, the peacock, whereas it abounds in species of the most gorgeous colour. Such are the Impeyan pheasant of the Himalayas, whose metallic plumage is that of a gigantic sun-bird; the golden pheasant, the silver pheasant, and Reeves' pheasant of China, all unsurpassed for gay and conspicuous colouring; the glorious crimson and white-spotted tragopans, the elegant peacock-pheasants, and the intensely brilliant fire-backed pheasants of the Malay countries—together composing a group of birds whose colours are unsurpassed for beauty and splendour, and thus are directly opposed to the general gloom and absence of colour in their habitual surroundings.

In treating of mammals we find an equal want of discrimination in estimating comparative colour and conspicuousness. The tigers, the zebras, the beautifully marked antelopes, and the spotted deer and giraffes, which are really among the most brightly-coloured of all mammals, are passed over as less beautifully coloured than the squirrels and monkeys, in order to support the theory that arboreal mammals feeding on fruits should be (though unfortunately for the theory they are not) the most brightly coloured. Monkeys, as a rule, are very dingy brown or black, about one or two per cent. of the species having patches of bright colour on the bare skin of various parts of their bodies, while the nut-eating squirrels as a whole are certainly not superior to the grazing antelopes. In the summary of facts given at pages 184 and 185 there are many errors. *Scissirostrum Pagei* does not "belong to a family generally dull," while it is itself decidedly dull-coloured; the "pretty cigana" is a very plain coloured bird; Santarem, of which it is said "the pastures are destitute of flowers, and also of animal life, with the exception of a few small plain-coloured birds," is one of the richest localities for flowering shrubs in South America, and one of the few places where I remember the conspicuously coloured fruits on many of these shrubs, while the butterflies in the adjacent forests are gorgeous in the extreme; and lastly, the "gay-coloured squirrel," for which I myself am made responsible, is one of the dullest of the group, pretty indeed as are all squirrels, owing to its brown and yellowish ringed tail, but in no sense whatever "gay," while I certainly say not a word about its feeding on "bright-coloured fruits."

Such mistakes as these pervade this portion of the work, and are made the foundation for repeated argument and illustration; and they serve to show how impossible it is even for the most earnest and enthusiastic student to make a few months' labour suffice for a correct appreciation of the bearing of the overwhelming mass of facts presented by the countless species of the animal and vegetable world. I have marked a number of other passages to which I altogether demur, but many of them involve arguments which would extend far beyond the limits of an article. For the same reason I can only briefly refer to the concluding chapters on the "Colour Sense in Man," in which the theory of Mr. Gladstone and the German philologists is disproved in a manner which is absolutely conclusive.

In the summary and recapitulation we find all the facts

and arguments we have referred to marshalled in an imposing array, and finally summed up in the following condensed formula :—

"Insects produce flowers. Flowers produce the colour-sense in insects. The colour-sense produces a taste for colour. The taste for colour produces butterflies and brilliant beetles. Birds and mammals produce fruits. Fruits produce a taste for colour in birds and mammals. The taste for colour produces the external hues of humming-birds, parrots, and monkeys. Man's frugivorous ancestry produces in him a similar taste; and that taste produces the final result of human chromatic arts."

Although I totally differ from Mr. Allen's conclusions as to the production of the varied colours of the animal world, I must express the extreme pleasure with which I have read his book, which I most cordially recommend to all who love colour, and can enjoy a thoroughly well-written volume on a most interesting but difficult subject.

ALFRED R. WALLACE

GEODESY

Die geodätischen Hauptpunkte und ihre Coordinaten. Von G. Zachariæ. (Berlin: Oppenheim, 1878.)

THE science of geodesy, though far from a popular one, exercises something like a fascination over its own devotees. It is not a standstill science; how to devise instruments—theodolites, altazimuths—which shall excel their predecessors; how to use these instruments so as to eliminate the sources of possible error they individually present; how, having got the observations, to eliminate in the use of them, their own errors as far as possible; and finally, how, after obtaining final results, to express the degree of reliance to be placed on them: these are all ever-fresh questions, capable, many of them, of engaging—as one may, for instance, see in the works of the late Prof. Hansen—considerable mathematical ability. The work before us is of Danish origin, and it is clear that the Danish meridian arc and the geodetic operations connected therewith have been executed in a thoroughly scientific manner. To those who are employed in geodetic operations, this treatise will be most welcome. In an introductory chapter we have the definitions of the mathematical surface of the earth, expressions for the radius of curvature and various lines connected with the spheroid, and remarks on the deviation of the actual surface from that of a true spheroid. The first section treats of the method of laying out a triangulation, of the measurement of angles, and of the measurement of base lines, together with the calculation of the probable errors of results. The second section deals with the calculation of triangles: after giving Legendre's theorem, the writer shows how spheroidal triangles may be computed as spherical, and gives the expressions for the differences between the angles of a spherical triangle and a spheroidal triangle having sides of the same length, with any position in azimuth. Then the method of calculating a triangulation by least squares is entered into. The third section deals with the subsequent expression of the results in the form of co-ordinates—of the method of calculating differences of latitude and longitude. Throughout the work, in all formulæ which are approximative, the nature or order of the terms omitted is expressed by a neat notation which is very useful. The fourth section is devoted to the measurement of heights, and levelling operations and calculations; the subject is gone into thoroughly, including the investigation of the coefficient of terrestrial refraction and the errors which may accumulate from various sources. The last part of the section is devoted to the consideration of the "Schlussfehler," or "error of close" in levelling. This error may arise from mountain attraction, or may exist even without it. We know that at the surface of the spheroidal earth the equipotential surfaces—take any two of them a few hundreds or thousands of feet apart—are not parallel, but the distance between them at any point is inversely proportional to gravity there. If P, Q be two points on the higher of two equipotential surfaces, p, q, their projections on the lower, then levelling from p to Q, if we in imagination take the path, $p\,P, P\,Q$, we have $p\,P$ as the height of Q above p; then continuing the levelling from Q by the path $Q\,q$, $q\,p$, to p, it is clear there will be an error in the close of the levelling of the amount $Q\,q - P\,p$. Practically, of course, this is very small. An error of close of levelling may occur in working over a mountain; the attraction of the mountain deflects the vertical, and too small a height is the result; of course if the hill is symmetrically shaped, the same amount of error is involved on both sides, and there would be no discrepancy in results obtained by levelling over and round or through the hill. But generally the error on the two sides is not the same. In the work before us the case is supposed of levelling being carried over a mountain-chain of uniform triangular section. In the triangular section $A\,B\,C$, C being the ridge and $A\,B$ the base, suppose levelling to be started from A the foot of one slope, along a level surface *through* the mountain, or, which is the same, along a level surface round it, to B, a point on the *same* level-surface as A; then up the slope from B to C, then down the other slope from C to the starting-point A. Then the error of close, or the "Schlussfehler," is a certain multiple of the integral of the difference between the horizontal component of the attraction of the hill at any point as P on the slope and the horizontal component of the attraction at p, which is the projection of P on the level surface $A\,B$, multiplied by the element of horizontal distance, and taken from A to B. So that if we do not misunderstand the writer, the numerical examples of "Schlussfehler," given at p. 290, are very much too large. In fact the before-mentioned multiple of the difference of potential at A and B, when added to the right-hand member of the equation (3) on the page referred to, very nearly cancels that term.

The fifth and last section of the work treats of the influence of small alterations of the spheroid of reference on the reduced triangulation, and of the determination of the elements of that particular spheroid which is most in accord with the results of the triangulation under consideration. The formulæ throughout the work are very neatly developed and the typography is admirable.

OUR BOOK SHELF

A History of the Birds of Ceylon. By Capt. W. Vincent Legge, R.A. Part I. Imp. 4to. Pp. 1–345. (London: Published by the Author, 1878.)

THE many interesting papers on Ceylonese birds published during the last few years by Capt. Legge in the

Ibis and in the Indian journal *Stray Feathers*, will have prepared his readers for an excellent account of the habits of the birds of that island. The avifauna of Ceylon did not attract the attention of the naturalist to any great extent after the year 1854, when Mr. E. L. Layard published his valuable notes in the *Annals of Natural History*, and brought to light a number of new and interesting forms, until in 1872 Mr. E. W. H. Holdsworth presented to the Zoological Society an excellent memoir, embodying not only all that was known on the subject, but adding greatly to our knowledge from the results of his five years' residence in the island. Ornithologists, however, could hardly have expected from the published accounts that so much would remain for Capt. Legge to do in a field often supposed to be tolerably well exhausted by the labours of the two naturalists mentioned above, and it is impossible to speak in too high terms of the volume which our author has now presented to the public, and which, in our opinion, is one of the best ornithological works ever yet produced. Not only does Capt. Legge excel in his descriptions of the habits of the Ceylonese birds, which he has himself studied in the jungle during his seven years residence in Ceylon, devoting his whole leisure time to the pursuit of ornithology, but on the return of his regiment to England he at once sets to work to complete the scientific history of the birds with whose life-history he is already so well acquainted. The result of the patient labour which he has devoted to both branches of the subject is apparent on every page, and from the peculiar relations of the avifauna of Ceylon this task has been by no means an easy one. Possessing only a limited number of peculiar forms, the birds of Ceylon indicate affinities on the one hand to those of Southern India, and on the other to those of the Malayan Peninsula, while in the higher ranges a decided Himalayan element crops up. Sometimes the differences between the forms of birds inhabiting these regions and Ceylon are found to be of specific importance, but more often the variation does not extend beyond the recognition of a climatic race or sub-species. Not one of these difficult questions is shirked by the author, who diligently compares the subject of every article with the allied forms of surrounding countries, so that many of his descriptions amount to monographic revisions of genera and species of the highest importance to the student of Indian ornithology.

Commenced originally with the idea of providing a handbook to the birds of Ceylon, for the use of the numerous planters and civil servants interested in the study of birds (and Capt. Legge's work shows that these are already a goodly company), this production not only fulfils the author's original purpose, but forms a most valuable addition to the series of similar works, such as Buller's "Birds of New Zealand," Dresser's "Birds of Europe," &c. We regret to see that the great length of the articles, which the conscientious researches of the author have obliged him to write, has already forced him to give to the one part now published no less than 340 pages, which was as much as the entire book was expected to occupy. Involving as this does a serious pecuniary loss, we feel bound to call attention to the fact, as evidencing the self-sacrificing enthusiasm with which Capt. Legge regards his subject, and when we state that the coloured plates, which give illustrations of every peculiar Ceylonese species, are in Mr. Keuleman's very best style, we can add nothing more to recommend the work to the attention of the scientific public. R. BOWDLER SHARPE

Sur la Structure et les Modes de Fécondation des Fleurs. Par L. Errera et G. Gevaert. 1e partie. (Bruxelles, Mayolez, 1879.)

IF the value of a work is to be judged by the extent of the original research to which it has given birth, then surely few have been published possessing so high a value as those of Mr. Darwin. The little volume before us is a direct outcome of attention directed by Darwin's writings to the subject of the fertilisation of flowers. Without pretending to any novel discovery, it gives a clear and succinct *résumé* of our present state of knowledge of the subject, the writers themselves confirming Darwin's observations on some important points. Appended is an interesting morphological study and comparison of two species of *Pentstemon*, *P. hartwegi* and *gentianoides*, of which the authors consider the latter to be a derivative from the former. They regard the natural order Scrophulariaceæ as being the offspring of certain forms belonging to the Solanaceæ.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

Deltaic Growth

THERE can be no doubt that there are conditions very favourable to the rapid deposition of sediment brought down by the Irrawaddy, Sittang, and Salween rivers, in the Gulf of Martaban—as a reference to the map will show—but the amount can hardly be as great as that afforded by the following results, which, I anticipate, may be of some interest to your readers.

While proceeding northwards towards Rangoon from Penang, in the s.s. *Fitzpatrick*, Commander Humphries, I observed, shortly after we entered, discoloured or muddy water in the open sea, lat. 15° 15′ N.; the soundings taken were only from fifteen to sixteen fathoms in places where the Admiralty charts showed from thirty-two to thirty-four fathoms, just *double*, or a difference of 100 feet.

The chart was based on surveys originally made by Captains Ross and Crawford, probably thirty years back, and lately issued in an amended form, supposed to have been "corrected to date." PAT. DOYLE

Jordan's Hotel, Rangoon, February 27

Atmospheric Pressure

DANS le No. de la NATURE de 6 courant, p. 420, àpropos d'une appréciation des observations météorologiques de *l'Hydrographic Office* à Pola, on lit le suivant :—

"The amount of this third maximum is very small, and the evidence yet adduced is not sufficient to determine whether it is a real increase of atmospheric pressure or merely an apparent increase due to undetected instrumental errors."

Nous avons remarqué ce maximum secondaire du baromètre dans une recherche sur les variations diurnes de la pression à Lisbonne, avant de savoir qui M. Ricatscheff avait fait une mémoire sur ce sujet, et nous pouvons affirmer que le dit maximum n'est dû à des erreurs de l'instrument :—

La recherche que nous avons fait a été dans une série de 12 années d'observations horaires, déduites du barographe (système photographique) et nous avons constaté le suivant :

1. Pas une seule des 12 courbes de la pression atmospherique, correspondantes aux 12 mois de décembre ou aux 12 mois de janvier, a laissé d'exhiber le dit maximum secondaire entre les 13 et 15 heures.

2. Les valeurs des erreurs probables des pressions moyennes dans les heures (13, 14, 15) sont encore inférieures aux erreurs probables des autres heures du jour.

3. En groupant les pressions horaires des jours sereins et calmes des mois de janvier et de décembre, pendant toute la série de 12 années, le maximum en question est ressorti plus régulier et beaucoup plus developpé que dans les courbes des pressions moyennes de les mêmes mois. Il me semble donc démontré l'existence de ce maximum secondaire, très difficile à expliquer, et que rendra plus obscure l'explication de la double oscillation diurne du baromètre. JOAO CAPELLO

Observatorio do Infante D. Luiz, Lisbonne, 14 mars

On the Pupation of the Nymphalidæ

IN NATURE, vol. xvi. p. 502, I called attention to some observations and experiments of mine on the pupation of several species of *Nymphalidæ* and *Pieridæ*, the results of which were: (1) That, in the species referred to, a connection (larvo-pupal ligament) exists between the larva-skin and the chrysalis which is the sole support of the suspensus chrysalis during the final process of pupation, namely, during the extraction of its tail from the larval skin and fastening the anal hooks in the supporting silk; (2) That this ligament is not confined to the *Suspensi*, but exists also in species of the *Succincti* where it has not the same function to perform; and (3) That nevertheless, in these latter cases, when other support is withdrawn by cutting the girdle before pupation, this ligament is capable, in the majority of cases, of fulfilling the same office as it does in the *Suspensi*.

These views have recently received important confirmation and extension at the hands of Mr. W. H. Edwards, of West Virginia. I refer in the first place to a paper of his in the *Canadian Entomologist* for December, 1878, which is reprinted in the *Entomological Monthly Magazine* for the present month. Here Mr. Edwards describes the ligament as found by him in *Grapta interrogationis* and *Danais archippus*. In the latter it is black. Of the former Mr. Edwards writes: "When I lifted the flap of skin entirely clear of the struggling segments, and cut it off a little below the tail, the bendings and contortions were not interrupted by my interference, nor was the effort to reach the silk in the least abated. Held firm by the stretched ligament, which was in plain view, the body rose, and the tail, which had got well outside the padded skin and was, before complete extrication, bent backward, now bent forward, and by the upward swing, was brought exactly to the silk. Several times as I was lifting, the skin and chrysalis together were dislodged, and fell into my hand. Then by drawing the skin back the ligament was exposed, and it was distinctly seen that it was attached to the chrysalis by the pointed ends of the ridges before mentioned and that there was no other connection between skin and chrysalis." As regards the second and third points mentioned above, Mr. Edwards writes to me as follows:—"I experimented on *Papilio ajax* and *P. asterias*, also following your illustration with Pieris, and was successful in discovering the membrane in both species. *Ajax* has the terminal part of the chrysalis remarkably short, but although I cut the band and let the larva hang, the chrysalis generally succeeded in reaching the button of silk. So with *Asterias*, in which the terminal joint is longer. I have no doubt all the Papilionidæ possess this membrane, and probably the Satyridæ."

We have now the existence of the ligament demonstrated in three species of *Suspensi*, viz., *V. urticæ*, *G. interrogationis*, and *D. archippus;* and in three or four *Succincti*, namely, *Pieris brassicæ*, *Papilio ajax*, and *P. asterias*, and probably also in *A. cardamines;* all of which latter also pupate more or less successfully when artificially converted into suspensi by cutting the loop. To the case of *A. cardamines*, which, when pupating as an artificial suspensus, does not remove the tail of the chrysalis from the pocket of the old larva skin, there is a parallel in *Pyrarga egeria*, and perhaps also in *Epinephele janira*, in regard to the former of which Mr. Newman states ("British Butterflies," p. 85):—"The skin of the caterpillar always remains attached to the anal extremity [of the chrysalis], even after the butterfly has escaped." In reference to *Janira* he writes (*op. cit.*, p. 92):—"Three of my specimens changed to chrysalids," &c.; "in two instances the skin of the caterpillar remained, enveloping the anal extremity, so that the chrysalis could not be suspended; in the third it hung for a time from a blade of grass, the skin still enveloping the anal extremity, but attached by its anal hooks to silken threads on the grass."

Mr. Edwards promises further researches during the coming season, for which he has favourable opportunities in his locality, and I think we may confidently look for interesting and perhaps important results. The question of rank in the diurnal lepidoptera is one that has been much contested (see Wallace's essay on "The Malayan Papilionidæ," &c., "Contributions to the Theory of Natural Selection," p. 133), and will probably be decided differently, according to the standard of perfection set up; but the question of *derivation* is probably more capable of definite solution, and on this point the suspensory ligament seems well calculated to afford important guidance. In the meantime more extensive observations and experiments are wanted, and will no doubt be afforded by those interested in the subject when their attention has been once directed to the matter.

Milford, Letterkenny, March 26 J. A. OSBORNE

Tides at Chepstow

I AM unable to find any certain record of "exceptionally high tides" at Chepstow. They must be of rarer occurrence than is commonly supposed. A very high one is mentioned as having flooded the lowest parts of the town January 29, 1846; and a very low neap tide is noted in a wharfinger's books, on March 19, 1876. Measurements of these cannot be obtained; but the highest known rise of the tide at Chepstow since the erection of the iron passenger bridge in 1816, has not exceeded fifty feet; and probably has never attained such an elevation even with the conjunction of much fresh water inland, and a stiff S.S.W. breeze.

Fair proof of the accuracy of this statement is afforded in the elevation of the railway bridge that spans the Wye about two miles and a half from its mouth. By the requirements of the Admiralty, a clear headway of fifty feet had to be left above the highest known tide. Besides attention to these requirements, the contractors had to provide approaches to the roadway of the bridge, involving, on the Gloucestershire side, a long and deep cutting through limestone rock, and on the Monmouthshire side a lofty embankment. A very large outlay of money depended on the determination of the "highest known tide," for it regulated the point of suspension for the bridge, and the level of the approaches. Yet, as may be seen in the official report appended to these notes, *forty-four feet* only were allowed for the "rise of the tide." The readers of NATURE may refer for a drawing of the bridge, plans, and a detailed report, to the *Illustrated London News* of July 24, 1852, to satisfy themselves.

Through the kindness of Mr. Henry Gillam, and of Messrs. Miller, the lessees of the salmon fisheries in the Severn and in the Wye, I have received measurements of this day's tidal range in both rivers, taken personally by those gentlemen. Amongst well-known points I cite the height at Portskewitt landing stage, New Passage, on the Severn, 39 feet 3 inches; at Chepstow railway bridge, 39 feet; at Chepstow Passenger bridge, about a quarter of a mile higher up the river, 35 feet.

In the geographical part of Knight's Cyclopædia, article "Chepstow," the rise of water at Chepstow Bridge at high tide is given as "fifty feet, being the greatest tidal rise in Europe."

The highest reliable measurements that I have met with for the tidal rise in the Severn are 47 feet 6 inches, marked on the Portskewitt landing-stage.

For accidental phenomena affecting the tidal levels, I refer to the following extract from the Bristol Tide Book:—

By a careful comparison of the differences of the predicted and observed heights of tide at Bristol with the contemporaneous heights of the barometer, Mr. Bunt found that a depression of one inch in the mercurial column is accompanied by an elevation of fourteen inches, nearly, in the height of the tide. Hence, by observing the state of the barometer a few hours before high water, we obtain the following correction of the height predicted in the tide table:—

When the barometer stands at	Inches.		Inches.
	28 6	Add to the predicted height	20
	29 0		14
	29 4		8
	29 8		3
	30 0		0
	30 4	Deduct from the predicted height	6
	30 8		11

Our highest tides for 1879 are marked in the table as occurring Monday, March 10, and Tuesday, April 8. JOHN YEATS

Chepstow, March 24

P.S.—Through the kindness of the four brothers Miller, I am this morning in possession of measurements of yesterday's tide in the Severn and Wye, taken, by the request of the firm, at distant stations. I enclose one, at Tintern Abbey, taken by Wm. Bowen, a regular correspondent of the Meteorological Department.

March 25

Tintern Abbey, near Chepstow, March 24

MR. ALEXANDER MILLER

DEAR SIR,—As requested, I have taken the height of the flow of tide this morning and find it 15 feet 1 inch above present level

of river, which is about 2 feet 9 inches above summer low-water level.

Yours truly,
WILLIAM BOWEN

The pier master (W. Mants) at Clevedon, near Weston-super-Mare, reports that he timed the rise of the tide there on March 10 from two hours flood, and found that it flowed thirty feet perpendicular in two hours and forty-five minutes. On March 24 the tide rose thirty-eight feet at the Clevedon Pier Head.

J. Y.

Ice Pearls

A PHENOMENON of singular beauty presented itself on the morning of March 24. A patch of meadow land, several acres in extent, had been inundated so far as to leave, pretty regularly distributed throughout, stalks of last year's grass projecting several inches above the surface of the pond. During the preceding night the temperature had been below freezing-point, but the wind which rippled its surface prevented the pool from freezing, while it alternately raised and depressed the stalks of grass. The water thus collected by the bending and rising grass-heads formed into large shining beads of ice which lay at the point of junction of the stalk and the pool. The effect was as if each projecting stalk had unfolded a white flower floating on the water, and when a gleam of sunshine smote the surface of the pool, the effect was resplendent.

J. SHAW

Tynron, Dumfriesshire

Unscientific Art

MR. COPPOCK's explanation (NATURE, vol. xix. p. 484) has occurred also to me; but may I be allowed to remind him that in consequence of the internal construction of the marine barometer (the pipette and the contraction in the tube), when it is sloped the mercury rises and falls very slowly. As it naturally rises and falls at a decreasing rate, if the barometer be sloped for a few seconds it takes a comparatively long time for the mercury to resume its original position. I have just sloped one of Adie's marine barometers at 30° from the vertical, and I find it takes more than ten minutes to recover itself. I do not know what may be the actual practice on board ship, but I cannot but think that a plan which renders a barometer useless for ten minutes to another or the same observer must be an unusual one.

JOHN W. BUCK

New Kingswood, Bath, March 28

SCIENCE AND WAR—SIGNALLING BY SUNSHINE

THE use of the heliostat in the field adds one more to the many applications of science made by our soldiers and sailors. Signals by sunshine may be no novelty, but the present Afghan campaign and the Zulu war will henceforth be cited as the first in which the heliostat was employed as an implement of warfare. There can be little question as to its value to the soldier, for it affords at once a ready and far-reaching mode of signalling; but sunshine is an obvious *sine quâ non* to its use. In this country, where the Astronomer-Royal tells us the number of hours of sunshine in the week sometimes does not go beyond the units, the heliostat would furnish but an irregular means of telegraphing, and interruptions in the service would be both frequent and prolonged. But in India, on the other hand, at special seasons, at any rate, sunshine is the rule rather than the exception, and consequently the heliostat furnishes an excellent means of communication which our scientific soldiers have done well to make use of.

Heliostat stations are established at this moment throughout the Khyber Pass, and General Sir Sam. Browne, at Jellalabad, has his orders passed up to him by flashes of light from Peshawur and Ali Musjid. Lord Chelmsford has of late also been furnished with heliostats, in order to provide him with better means of commuication along the Tugela. The plan of working is very simple. The mirror of the heliostat is placed so as to reflect the sun's image to a distant station, and when the instrument has once been set the clockwork arrangement, it need not be said, suffices to maintain the mirror in its proper position. In this way the distant station in question always sees the dazzling ray reflected from the mirror, except when the latter is purposely obscured. The appearance and disappearance of the bright spot or flash constitute the signals. There is no need for any superintendence when once the apparatus has been put in working order, and a trained signalman suffices for the duty. The ordinary Morse alphabet supplies an intelligible code, and no one out of the line of signals can read or understand the message. As a substitute for the dot and dash, which go to make up the ordinary written Morse code, the light is shown for short and long intervals; thus the light shown for a short period followed by a long period signifies A, while B is represented by a long period followed by three short ones; in the case of C, long, short, long, short signals are made in turn; and to form E, the letter most frequently used, the light is permitted to shine for one single short period only.

The intensity of these sunshine signals can scarcely be imagined by any one who has not seen the heliostat in working order, and the distance to which they might be made to travel, could suitable stations be provided, is practically unlimited. But everybody has noticed at one time or another, just before sunset, the light striking vividly against the windows of a house. In this case the burning spot may be seen for miles away, and forms the most striking object in the whole landscape. The heliostat signal is obviously brighter still than this, and the appearance and non-appearance of the light is to be appreciated at ten or twenty miles distant without the aid of telescope or binocular.

Signalling by the aid of a mirror is among the earliest experiments of telegraphy, nor, if we are to believe travellers, is the use of a reflecting surface in this way new in warfare; it is only the heliostat, indeed, which we can claim to have been the first to employ in the field. Several instances are on record of polished metal surfaces being used in this manner by savage nations, and it is but two years ago that the United States forces captured a tribe of Indians to whom the use of the mirror was not unknown. These were the Nez Percés Indians, and, according to latest accounts, they were still confined by the American Government in a camp near Fort Leavensworth, where, however, they were left pretty well to their own devices. According to the *New York Daily Graphic* their chief carried with him a looking-glass, "used to direct military manœuvres in battle, by means of reflected rays of light. Their various significations, however, have never yet been found out by the white man," we are told. These are not likely to have been very complicated. The difficulty, in fact, is not so much in reading light-signals of this kind as to reflect the rays in precisely that direction in which the party for whom they are intended happens to be located. How the chief of the Nez Percés managed to do this with his hand-mirror is rather what "the white man" would like to understand.

One other incident in the history of light-signals deserves to be mentioned. When Admiral Sheriff was stationed at Gibraltar in 1835, he made a series of experiments with a view to employing light as a means of telegraphy. His signals were made by an ordinary toilet looking-glass from his bedroom window, that looked out upon the Mediterranean, and by the aid of this simple apparatus he was enabled to communicate with a friend at Tangiers. His light-signals travelled from "the Rock" right across to the African mainland, a distance of something like twenty miles, and were read and answered without difficulty by his colleague on the opposite shore.

Besides the heliostat, our troops in the field are provided with flags and lamps for signalling by day and night. The flags are made four feet square, so as to be

visible at some distance, and they are white or black, to be used according to circumstances; moreover, the signalmen are furnished both with binoculars and telescopes to enable them to read the signals from remote stations. At night either a bright colza light is made use of, or a spirit flame, into which is blown from to time a mixture of powdered magnesium and resin. A short puff or a long puff constitutes short and long signals, which are displayed, as before, in accordance to the Morse code. Every battalion of infantry and regiment of cavalry in the British army has a proportion of its men trained as signallers, so that these can act at once on taking the field. Their duty is to communicate between outlying pickets and the fighting column, and to do duty where there is no telegraph. For let the field telegraph of an army be ever so well ordered, there is always plenty to do for the army signaller; and he will doubtless find in the heliostat a means of fulfilling these duties with increased efficiency. H. BADEN PRITCHARD

FLOODING THE SAHARA

THE French scheme of turning part of the Algerian Sahara into an inland sea continues to attract considerable attention in France, and scarcely a week passes without some allusion being made to it in the Paris Academy. At a recent sitting M. de Lesseps read a letter from Capt. Roudaire in which the latter gave some details of the results of his sounding of the soil at various points, sands and marls being the beds most commonly met with. At one place, four metres below the surface, plenty of potable water was met with, which will be a great saving in carrying on the work.

At the same sitting MM. Ch. Martens and Ed. Desor presented several considerations against carrying out the plan, their opposition to it being shared by several other French men of science. They have themselves examined part of the ground which it is proposed to put under water, so that their opinions ought to have some weight. While giving every credit to M. Roudaire for the accuracy of the survey which he is carrying out, they, however, point out the difficulty of perfect accuracy, which in this case is all important, in the classic country of mirage, where the surface of the ground is constantly altered and deformed by reflection and refraction. Moreover, they point out that to the south of the projected sea is the Wed-Souf, where are ripened the dates known as Tunis dates, the culture of which is a very special one. The least error in surveying, it is shown, might lead to the destruction of this culture, by allowing the waters of the Mediterranean to penetrate the soil where the date-trees are grown, and thus destroy them. The authors do not attempt to touch the argument that even in historical times part of the Sahara now being surveyed was really a great lake; but they point out that there are proofs that in prehistoric times there must have existed an interior sea, at an epoch when the hydrographical conditions of Europe were very different from what they are now. In 1863, when exploring the region between the oases of Guemar and the south extremity of the Shott Mebrir, they found the gypsum beds of the plateaux ended in regular lines like sedimentary beds, and from the soil they collected the *débris* of shells, truly marine, such as *Buccinum giberrulum*, Lam., and *Balanus miser*, L. Above these shells, in the sand, they found *Cardium edule*, better preserved than they had ever seen it. Thus they found fossils characteristic of salt water, and of those which are a mixture of salt and sweet. The retirement of the waters from the Sahara the authors attribute to the elevation of the land, which is even yet below the level of the Mediterranean, and is to a great extent a network of salt lagoons.

It has been said that the creation of an interior sea, of 13,280 square kilometres, would change the pluviometric condition of the country, and even that of the whole of Algeria. This MM. Martens and Desor regard as a great illusion. Although the laws of the general atmospherical movements are little known, yet it is admitted that the Atlantic is the great reservoir from which come the vapours which are resolved into rain over the European continent. They believe that this is also the case for Africa. The Mediterranean is really only a Gulf of the Atlantic, and they do not believe that an addition of 13,000 kilometres will add anything to its climatic influence. Long calculations have been made as to the quantity of water that would be evaporated by the new sea; but the authors point out that the predominating wind in the region is north, and that if it were rendered either too cold or too moist it would injuriously affect the date-culture carried on in the south. The surroundings of interior seas, like the Caspian and Aral, are steppes noted for their aridity; the shores of the Mediterranean suffer in the same way when, as last year, the rains of the north do not extend to the south. For these reasons MM. Martens and Desor think it would be a mistake to insist on the creation of the interior Saharan Sea.

In a subsequent sitting, however, it should be said, M. Favé endeavoured to show that their fears were groundless, especially with regard to the accuracy of the survey; he thinks that the work in connection with the Suez Canal showed that perfect confidence may be placed in the methods of surveying adopted.

THE LONGEST TUNNEL IN THE WORLD

SCHEMNITZ, the principal mining city of Hungary, has celebrated the opening of the Joseph II. Mining Adit, the deepest gallery of efflux of that place, and the longest subterranean work of this kind in the world.

Its excavation was commenced in the year 1782, during the reign of the Emperor Joseph II., whose name it bears, and has been continued since that time, but with varied energy. The most rapid progress was made within the last five years, so that its completion on September 5th, 1878, was a kind of surprise, and was saluted by guns, which caused a great joy in the city, because it announced a new era for the mining operations of the whole district.

Works of such importance deserve to be installed with solemnity, and a festival was arranged for the purpose on October 20-22, 1878. Prof. Szabó, one of the guests from Budapest, delivered a report to the Royal Hungarian Society of Naturalists, as a representative of that body, and we shall not hesitate to communicate an extract of this.

As the mining operations were progressing in depth, there was at the same time a well regulated system of sinking shafts and driving tunnels employed. The Joseph II. Adit is the eleventh of that kind; it lies 200 metres deeper than the Francis Adit, which was until now the principal gallery of efflux for the mines of Schemnitz. This was excavated between the years 1494 and 1637 to a length of 1,968 metres; but a greater extension was given to it by continuing the works from 1747 till 1765. After this period the mines of Schemnitz proved to be so lucrative, that the idea of undertaking some greater work for securing the future prosperity of the mines was conceived, and so the plan was fixed of driving a tunnel at the deepest possible level, which could convey the waters to the valley of Gran, the lowest point indeed which could be obtained within a practicable distance.

They commenced boring the tunnel west from Schemnitz, near the village of Voznitz, on the left bank of the Gran. The height of it is three metres, the width 1·6 metres. About the lower third is destined to convey off the waters, while the upper two-thirds are separated from this by a platform, and adapted for transporting the ores.

According to the original plan it could have been finished in thirty years at the cost of 1,215,000 florins

The cost per metre would thus have been 87fl. 86kr., and indeed such was the case in the first eleven years; but after the French revolution the value of money was greatly changed, and the prices became so high, that in the next thirty-three years very little was done, the yearly progress not being more than 61·4 metres, and the cost per metre 371fl. 52kr.

From 1826 the works were carried on with greater energy at the cost of 260fl. 40kr. per metre till 1835, when the progress again became slow, and remained so for the next eighteen years, only seventy-two metres being worked yearly, at the cost of 313fl. 45kr. per metre.

But after the middle of the present century the sense of the decline of the mines from their former state of prosperity was so prevalent, that the director of the district, M. Russegger, well known on account of his scientific travels in Europe, Asia, and Africa, proposed that they should again devote greater energy to the works in question, as most of the mines were under water, and the raising of this by machines caused an outlay which the mines were not able to bear. For the next twelve years the yearly progress was 293·2 metres, at the cost of 237fl. 63kr. per metre. During the next five years after Russegger's time only 141·1 metres were worked out yearly.

The Hungarian government has through the last ten years again developed greater activity in this work, and the parliament has at its request granted the yearly sum of 100,000 florins for the purpose.

In the year 1874 there were still 2,326 metres to be worked out, which would under ordinary circumstances have been a task of eleven years; but in 1873 experiments were made in boring with machines, which method was tried for the first time in the Mont Cenis tunnel, with surprising success, then in the St. Gothard railway tunnel, and lastly in the "Sutro" gallery (Nevada). After many trials they succeeded in finding out the most convenient arrangement, and the whole work was done in three and a half years. With this method the entire tunnel could have been finished in 27 years.

The length of the	Mont Cenis tunnel is ...	12,233 metres.
" "	St. Gothard is	14,920 metres.
" "	Sutro gallery of mines is	6,147 metres.
" "	Joseph II. Adit is ...	16,538 metres.

The total cost amounts to 4,599,000 florins.

The importance of this tunnel is very great, firstly as regards *geology*. The geological and orographical literature of that country is very old; Schemnitz has been repeatedly visited by distinguished men of science from all quarters of Europe, but the difficulties and complications of its geological structure are so great that there is still much to be done. One of the greatest obstacles in the way of investigation is that the surface is very seldom well exposed; dense forests and products of decomposition of the rocks cover many of the slopes. The tunnel furnishes a section more than ten miles in length, and gives not only valuable information as to the downward prolongation of the lodes known in the upper levels, but some new ones have been traversed, and the entire series of rocks, with their mutual limits as well as modifications and occasional transitions is to be seen without interruption.

It is important secondly as regards *mining*. A new region has been made accessible, and the master-lodes can now be worked to their full extent, while in past years all activity was absorbed by the unlucrative Adit itself. Now the works again promise a long continuance. All the machines used in raising the waters are put away, and thence an outlay of more than 100,000 florins is saved yearly.

The last and not least advantage consists in enriching the miner with new means of working. The application of mechanical boring may be considered as forming for him a new era, just as did the introduction of gunpowder; he will now much more easily undertake the driving of adit-levels, whenever this is feasible, and so, it is to be hoped, that the neighbouring old mining cities will successively have their galleries of efflux too, which is the essential condition of the restoration of their prosperity in mining.

OUR ASTRONOMICAL COLUMN

BRORSEN'S COMET.—From an observation at Kremsmunster by Prof. Strasser on March 14, it appears that this comet has passed its perihelion several hours later than the time calculated by Dr. Schulze of Dobeln, the corrections to the ephemeris on that date being – 31s. in right ascension and – 3′·5 in declination; yet observations at Rome on February 17 and at Arcetri, Florence, on March 10, give different corrections. For the present, as the ephemeris is sufficiently near for finding the comet, the following positions and distances may be extracted from it:—

oh. Berlin M.T.	Right Ascension. h. m. s.	Declination North. ° ′	Log. distance from Earth.	Log. distance from Sun.
April 4	2 55 29	25 44	9·9789	9·7767
„ 5	2 59 16	26 59		
„ 6	3 3 5	28 15	9·9663	9·7824
„ 7	3 6 58	29 32		
„ 8	3 10 55	30 49	9·9538	9·7898
„ 9	3 14 56	32 7		
„ 10	3 19 2	33 25	9·9415	9·7986
„ 11	3 23 13	34 44

On March 10 Dr. Tempel estimated the comet brighter than a star of the eighth magnitude, the theoretical intensity of light at the time being 1·18; the maximum value attained this year is 3·33 on April 14, and during the latter half of April and the whole of May the comet will no doubt be well observed; from April 14 to June 10 it will be constantly above the horizon of Greenwich. At its next return in 1884, its apparent track in the heavens is not likely to be a favourable one for observation, and as long a course of observation as is practicable at the present appearance will be desirable for carrying forward the elements of the orbit to 1890.

MIRA CETI.—In 1879 and 1880 the minima of this variable occur at times when the star will be too near the sun to be observable, but the maxima, according to Argelander's formula of sines, take place under very favourable circumstances for accurate determination, in 1879 on September 11, and in 1880 on August 11. From the observations of Dr. Julius Schmidt at Athens, it appears that this formula, which had given the epochs of maximum in 1876 and 1877 (two) earlier than the observed times by 17·7, 16·8, and 19·4 days respectively, was only in error in this direction four days in 1878.

Among variable stars now favourably situated for observation, may be mentioned Lalande 23617 and 23726, the former has been rated from 6m. to 9m., and the latter from 5m. to 8m. Also Lalande 26211, which has been noted as high as 6m. and as low as 9m.; the variation, however, appears less decided in this case, though Bessel estimated the star 8m.; Lalande's 9m. may perhaps be considered a misprint, as there are known to be similar cases in the "Histoire Céleste."

THE MINOR PLANET HILDA.—A new determination of the orbit of this, the most distant member of the minor planet group, by Kühnert, of Vienna, assigns a period of revolution of 2,861 days, or 7·832 years, and an aphelion distance of 4·52; at this point of its orbit the planet is distant from the orbit of Jupiter only 0·85, so that considerable perturbations are possible. The search for Hilda at the present opposition, so far as we know, has been unsuccessful.

EXPERIMENTAL RESEARCHES ON THE REPULSION RESULTING FROM RADIATION

IN previous papers[1] I have described my earlier experiments with the radiometer, and I then showed that the movement of this instrument was due to the presence of residual gas. I have since examined the repulsion exerted by a standard flame shining on pith and mica disks, coated with various powders, chemical precipitates, &c., and suspended *in vacuo* in a torsion apparatus, and I propose in this and succeeding papers to give an account of these experiments, and of the concluding researches on the repulsion resulting from radiation.

The apparatus I used to get quantitative measurements of the repulsion produced by radiation on various kinds of disks, and coated with different substances, is similar to one I have already described, but in order that the experiments may be better understood, it is shown in Fig. 1. I append the following description:—

ab is a horizontal glass tube containing the beam,

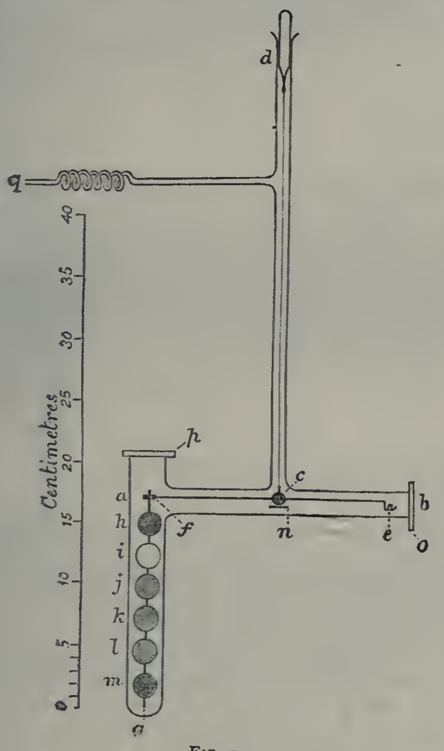

FIG. 1.

which, in this case, is made of straw, so as to secure lightness with absence of flexure under the comparatively heavy weights it sometimes has to bear; *cd* is a fine torsion fibre drawn from flint glass, to which the beam is suspended; it is cemented at *d* to a well-ground stopper, so as to admit of adjustment. When in position, cement, made by fusing together eight parts by weight of resin, and three parts of bees' wax, is run round the stopper. At *c*, the point of junction between the torsion-fibre and the straw beam, is a silvered glass mirror. At the end *e* of the beam, is a small pan to hold the weights counterpoising the disks, which are suspended to the other end. A flat stirrup of aluminium at *f* fits stiffly on the straw beam, and carries a flat glass fibre, *f g*, cemented to it so as to allow of no play, the straw beam, the aluminium hook, and the glass fibre being perfectly rigid. The experimental disks are fixed on the glass fibre by means of a touch of cement at the back. The vertical tube is arranged to hold six disks, the top one, *h*, being always the same standard lamp-blacked pith; the others, *i*, *j*, *k*, *l*, and *m*, being changed each time. A small magnet, *n*, attached to the central mirror, and controlled by a bar-magnet outside, gives the power of bringing the beam to zero, should it happen to get out of adjustment, without having to melt the cement and alter the angle of the torsion fibre by turning the stopper *d*. Plate glass caps at *o* and *p*, cemented to the ground edges of the tubes, give access to the interior; *o* allows the counterpoises to be adjusted in the pan, and *p* allows the aluminium stirrup to be unhooked, and the whole of the disks to be lifted out together. The apparatus is connected to the mercury pump by the arm and spiral *q*. The weights and dimensions of the various parts of the apparatus are as follows:—

Weight of straw beam, mirror, magnetic needle, aluminium stirrup, and flat glass fibre, &c.	7·25 grains.
Average weight of six plain mica disks ...	2·40 ,,
Average weight of six plain pith disks ...	0·59 ,,
Length of straw beam, from centre of counterpoising pan to centre of disks	17·0 centimetres.
Length of arm from centre of suspension to centre of pan	7·6 ,,
Length of arm from centre of suspension to centre of disks...	9·4 ,,
Glass torsion fibre—Length	23·0 ,,
,, ,, Thickness	0·0013 inch.
Torsion with a glass weight hanging from it	½ oscillation in 15·75 seconds.

Fig. 2 shows the apparatus fitted up for experimentation. The disks are shown in position at *a*; a brick wall, *b c*, has holes pierced through it in two places, as shown, one hole, *d*, being opposite the centre mirror, and the other, *e*, opposite the disks. The aperture *d* is lined with card, lampblacked inside, and the interstices between it and the bricks are well plugged with cotton wool. A water cell at *d* prevents radiant heat from the lamp getting to the apparatus. Through the hole *e* pass six card tubes, lampblacked internally, 20 millims. diameter, and 23 centims. long. The tubes are firmly cemented to the wall, so that each shall be exactly central with its corresponding disk, and the outer end of each is closed with a cork. The space between the tubes and wall is well stuffed with cotton wool. The apparatus, being once fixed in position, is surrounded on all sides, as well as above and below, with cotton wool. Outside this is a row of glass bottles filled with water, and in front of all is a wooden screen. When protected in this manner, the inside of the apparatus is found to be free from disturbances caused by changes of temperature. When the disks have to be changed, air having been let in through the pump, access is easily obtained to the glass cap *p* (Fig. 1), and the cement being softened by heat, and the cap removed, the disks are lifted out together by seizing the aluminium stirrup with forceps. A fresh set of disks being introduced, the apparatus is again packed up and re-exhausted.

A lamp at *f* throws a narrow beam of light on the mirror of the apparatus, through the aperture *d*. The ray is reflected to the scale *g*, where its deflection from zero shows the angular movement of the torsion beam when one of the disks is repelled by radiation. The scale is 1½ metre from the reflecting mirror.

A standard candle (the kind employed in gas photometry, and defined by Act of Parliament as a "sperm candle of six to the pound, burning at the rate of 120 grs. per hour") is supported on a heavy stand, *h*, and can be raised or lowered by means of the sliding piece, *i*. Another sliding piece, *j*, carries a pointed wire projecting from it. The upright rod of the stand is graduated and numbered, so that when the sliding piece *j* is at mark 1,

[1] NATURE, vol. xv. pp. 224, 299.

the point of the wire is on the prolongation of the axis of tube and disk No. 1, and so on. Then, by sliding the candle up till the most luminous part of the flame is level with the point of the wire, it is known that the light will shine full on the disk under experiment. A half cylinder, *k*, covered with black velvet, protects the candle from draughts. The candle-stand *h* slides along a straight edge, *lm*, screwed to the bench, so graduated that by bringing a mark on the sliding stand to one of the divisions, it indicates the number of millimetres separating the surface of the experimental disk from the centre of the candle flame. The experimental powders are laid on one surface of mica or pith disks as a water paint, no cement being used to promote adhesion. Disks of mica or thin metal were punched, while other materials were cut or filed into the shape of disks 17·25 mm. in diameter.

The exhaustion, which had to be effected after each change of the experimental disks, was carefully brought to the same degree both by actual measurement on a McLeod gauge, and by getting the same repulsion on the standard black disk. In this way all the different results were fairly comparable one with the other. The presence of aqueous vapour was specially guarded against by means of tubes containing phosphoric anhydride.

To show the effect of residual gas intending to equalise the amount of repulsion on variously coloured surfaces, I devised an experiment with pith disks, one being lampblacked and the other retaining its natural white surface, the standard candle being at the same distance in each case. When the exhaustion is good enough to cause a fair repulsion, the ratio between the amplitude of swing when the black is exposed, and that when the white is exposed, is as 100 : 55·5 ; at a little higher exhaustion the ratio is, Black : White : : 100 : 42·5 ; at a still better exhaustion the ratio is, Black : White : : 100 : 35. The results of the quantitative examination of the repulsion resulting from radiation when falling on about 100 different substances I have arranged in fourteen tables, for details of which I must refer to the Bakerian Lecture for 1878. The repulsion is measured, first when no screen is interposed, and secondly, when a cell of water is inserted in the path of the rays. In comparing the two results it must be remembered that the actual amount of repulsion on the standard lampblacked disk, when the water screen is interposed, is only one-twelfth of the amount obtained when no screen is in the way, the distance of candle and

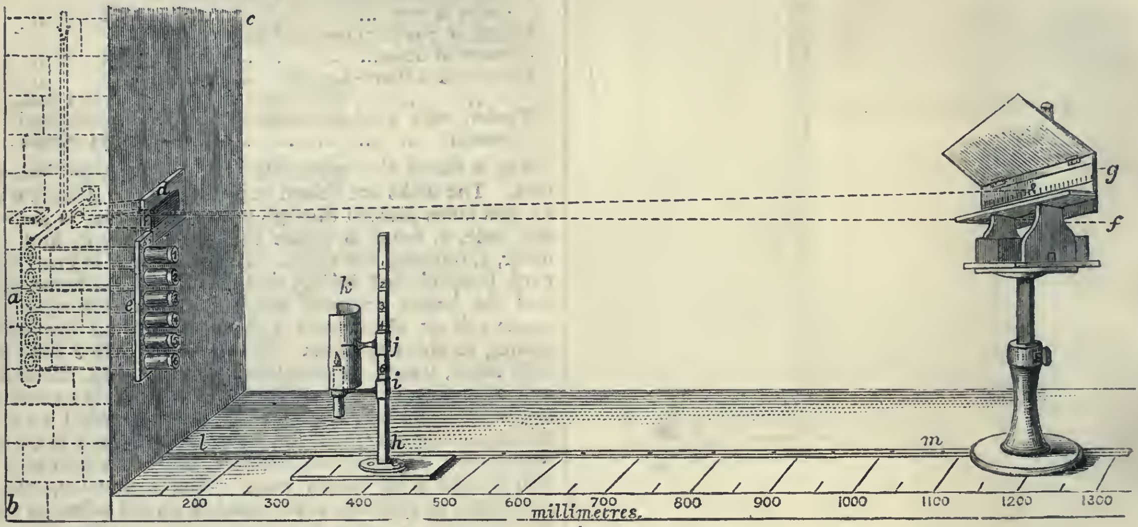

FIG. 2.

other things being equal. In order therefore to compare one with the other the result behind water must be divided by 12.

TABLE I.—*Results of the Examination of Black Powders*

Compared with lampblack = 100 these have an average value of 92·2, which becomes 99·1 by the interposition of water.

TABLE II.—*White Powders*

These have an average value of 33·5, which is reduced to 8·3 behind water. The powerful absorption for the invisible heat rays which white powders exercise is somewhat remarkable. Assuming that the ultra red rays from a candle are almost entirely cut off by a water screen, the comparatively strong action (33·5) produced by the naked flame must be mainly due to the absorption of the invisible heat-rays ; and when these are cut off by water, the action is diminished nearly fifty times. With black powders the water only diminishes the action about eleven times.

TABLE III.—*Red Powders*

Amongst these precipitated selenium is noteworthy. To the naked flame its value is 35·8, but when a water screen is interposed, the action becomes 69·5, in comparison with standard lampblack = 100. Omitting selenium, the mean action on red powders without a water screen is 32·2, and with a water screen, 24·9.

TABLE IV.—*Brown Powders*

Amongst these, peroxide of thallium is remarkable as being repelled under the influence of radiation to a greater extent than any other body hitherto examined, its value being 121·7, in comparison to lampblack = 100. Brown powders behave most like black, the averages of the columns *without* and *with* a water screen being 92·7 and 94·5.

TABLE V.—*Yellow Powders*

Among these, anhydrous tungstic acid resembles scarlet selenium in its anomalous action, the figures being, *without* water, 50·8, and *with* water, 72·2. The averages of the other yellow powders are 35·7, and behind water, 13·8.

TABLE VI.—*Green Powders*

These show some discrepancies, which will be referred to farther on.

TABLE VII.—*Blue Powders*

These show a much stronger proportionate action behind a water screen than with no screen, the averages being 55·8 and 65·2.

TABLE VIII.—*Dyes and Colouring Matters of Organic Origin*

Among these may be noticed saffranin, and a product of the decomposition of chlorophyll, which show an increased ratio or action when the heat-rays are cut off by water. Leaving out these, the mean actions of the other substances are, with no screen, 44·5, with a water-screen interposed, 28·1.

TABLE IX.—*Metals prepared in different Ways and coated with Lampblack, Mica, &c.*

Curious results are shown with iron and with gold, the former metal chiefly absorbing the invisible heat rays, whilst the latter metal is principally acted on by the luminous rays.

TABLES X. AND XA.—*Various Silver Salts*

The chloride, bromide, and iodide of silver in their different states were exposed to the standard candle after being submitted to the action of magnesium light, sunlight, and daylight. The results show how readily a change in the state of the surface is detected by an increased amount of repulsion under the influence of radiation.

TABLE XI.—*Selenium—Crystalline and Vitreous*

The former is in the state most sensitive to light action. With the crystalline disk results have been obtained which seem to show that the impact of light on its surface produces a superficial disturbance there and in the adjacent gaseous molecules, which takes some time to subside. This is connected with the change in electric conducting power of crystalline selenium—a change which, when the element is transferred from light to darkness, also takes some time to subside.

TABLE XII.—*Miscellaneous Substances—Pith, Mica, Charcoal, Glass*

The complicated nature of these actions was well shown in the results I obtained with three pith disks, the first being plain white, the second lampblacked on the front, and the third lamblacked on the back. The first was repelled with a power of 17·7, the second, which was the standard, with a power of 100, whilst the third was not moved at all. The repulsion exerted on the white surface must have been the same in each case, but the pressure *behind* the pith caused a radiation of heat from the back surface, which produced molecular pressure just sufficient to neutralise the pressure in front.

To show that physical condition has more effect in causing repulsion than chemical composition, I experimented with various kinds of charcoal. I found that the repulsion suffered by cocoa-nut shell charcoal is much less than that of white pith, being only 11·6 against 17·7. At the same time a radiometer made of cocoa-nut shell charcoal, lampblacked on one side, was only moderately sensitive, instead of being superior to one made of pith lampblacked on one side. The low figure shown by the charcoal was caused by its density enabling it to conduct heat from one surface to the other. Molecular pressure is therefore generated on both the back and front surfaces, and the figure I obtained is simply the difference between the two opposing actions.

I used other screens, besides water, to filter the radiation of the candle before it fell on the disk. I, however, preferred water. It is almost perfectly opaque to the invisible heat rays, and therefore its employment allows easy discrimination between actions due to heat and to heat and light combined; secondly, it is colourless, and having no selective action on any visible ray of light, it can be used in conjunction with any coloured powder without complicating the results. Alum acts in a similar manner to water; coloured solutions act as water with a super-added action due to their colour. Very thick plates of glass have less action on the invisible heat rays than a thin layer of water. Sulphate of copper, in a solution so weak as to appear only slightly green, has a very strong action when artificial light is used, as it cuts off the lowest visible red rays as well as the ultra red.

I found that the substances I had experimented on might be divided into two classes.

1. *Negative*, those in which the repulsion behind water is *greater* in proportion to the standard than when no screen is present.

2. *Positive*, those in which the repulsion in proportion to the standard is *less* behind water than when no screen is present.

Amongst Class 1 may be mentioned copper tungstate, saffranin, scarlet selenium, and copper oxalate; these are more affected by light than by invisible heat. Amongst Class 2 I may mention pale green chromic oxide, persulphocyanogen, hydrated zinc oxide, barium sulphate, and calcium carbonate; these substances are more acted on by the ultra-red rays than by the luminous rays. To render these differences of action more comparable, I divided the averages obtained by the water

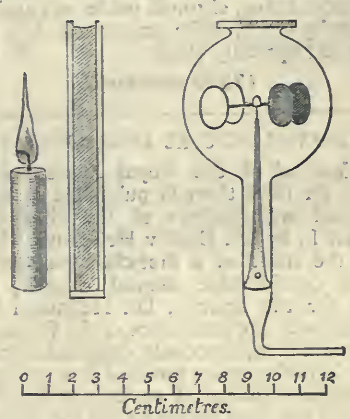

FIG. 3.

screen by twelve. Uniting the two classes together, the figures then became as follows:—

	No screen.	Water screen interposed (5 millims.)
Lampblack (*standard disk*) ...	100·0 ...	8·3
Chromic oxide, pale green ...	71·5 ...	1·7
Copper tungstate	51·2 ...	6·4
Persulpho-cyanogen	43·9 ...	1·0
Saffranin	41·0 ...	4·3
Hydrated zinc oxide	40·5 ...	1·2
Barium sulphate...	37·4 ...	0·3
Selenium, precipitated	35·8 ...	5·8
Copper oxalate	30·1 ...	3·3
Calcium carbonate	28·5 ...	0·3

An examination of this table shows that the results can be proved by balancing one powder against another in a radiometer. A bulb was therefore blown on the end of a wide tube, as shown at Fig. 3. The top of the bulb was opened and turned over to form a lip; this was ground smooth and polished, so as to be readily closed by cementing on it a piece of plate glass. A glass stem supports a fine needle in the centre of the bulb, and on this rests a glass cap, to which is attached four radial arms of aluminium. To these arms disks of mica or pith can be fastened so as to form the movable fly of a radiometer. The disks can be changed by uncementing the glass top, and lifting the fly

out with tweezers. The lower part of the tube is drawn out for connection with the mercury pump. The powders used for experiment were carefully painted on the opposite sides of pith or mica disks, only water or alcohol being used.

Disks coated on alternate sides with chromic oxide and precipitated selenium move in one direction to the naked flame of a candle, and in the other direction when a water screen is interposed. With saffranin and hydrated zinc oxide the instrument does not move at all when exposed to the naked flame, but revolves when a water screen is interposed. With thallic oxide and Magnus's green platinum salt, the instrument moves strongly when no screen is interposed, but is stopped with a water screen. These results are all in conformity with the figures.

A pith radiometer coated with precipitated selenium and chromic oxide was exposed to the radiation from a colourless gas flame from a Bunsen burner, coloured intensely green by thallium. To the eye, by this light, the chromic oxide looked nearly white, and the selenium black. The rotation due to the repulsion of the chromic oxide was, however, apparently as strong as when the non-luminous flame was used. This experiment proves that certain substances have an opposite absorptive action on rays of dark heat to what they have on light, and that an optically white body may be thermically black, and *vice versâ*. In this case, for instance, chromic oxide was optically green, and thermically black, while scarlet selenium was thermically white and optically black. W. CROOKES

(*To be continued*)

METEOROLOGICAL ORGANISATIONS

IN the *Journal* of the Royal Statistical Bureau of Prussia for 1878, there is published a report on the meteorological organisations of the chief countries of Europe, Part I., by Dr. Gustav Hellmann, who is rapidly coming to the front as a first-class meteorologist. In addition to considerable mental capacity and much enthusiasm for the science, Dr. Hellmann has, at the instance, and with the assistance of the Prussian Minister of Public Instruction, especially qualified himself for the work by undertaking tours more or less prolonged, in the countries the meteorological systems of which he reports on. These in the Part before us are the various systems in France, Great Britain, Belgium, and Holland. With the aid of a renewed grant he sets out on a second tour, this time through northern Europe, especially Russia, for the purpose of presenting similar reports on the meteorology of these countries. This action on the part of the Prussian Government has been taken, in view of a contemplated reorganisation of its meteorological system, so that when the time comes, the system may be established, not at haphazard, but on a sure basis, founded on the fullest knowledge of the requirements of the science, and on the best means to be adopted for its healthy development.

The Weather Telegraph systems of France, Great Britain, Belgium, and Holland, are fully detailed, very special attention being given to the weather warnings of France, carried out for the benefit of agriculture and horticulture. This system of weather warnings, which is so peculiarly adapted to the wants of Germany, was, as our readers are aware, the last gift to meteorology of the great Leverrier, to whom, in its practical bearings, meteorology stands so deeply indebted.

As regards France, meteorology would appear to have a most hopeful future before it, as evidenced by the mental activity brought to bear on the science, the fertility of resource in devising new methods and subjects of observation, the breadth of view shown in making the study of weather and climate subserve great public interests, and withal by the pecuniary assistance liberally and heartily given by Government and other bodies intrusted with the public funds, to the observatories, societies, and associations in various parts of France that are doing its meteorological work. Among the more special work France is doing may be noticed the application of the electric thermometer to the observation of the temperature of the air at great heights and of the soil at great depths; the establishment of several stations in Paris for the investigation of the chemistry and micrography of the atmosphere in their relations to the health of the city; and the establishment of high-level stations, which has been done largely through assistance given from the public purse.

We note with the liveliest satisfaction the great increase of meteorological stations over these four countries, the introduction of instruments for continuous observations in regions where they were much required, and a more adequate observation of the rainfall, particularly in the British Isles, where about 2,100 rain-gauges are at work, and in the river-basins of France, where the rainfall is noted at 1,111 stations.

Forcible attention is directed to the fact that in some cases the reduction of the observations and publication of the results are not carried out, or carried out very imperfectly, so that no little difficulty is experienced when conducting climatological inquiries, in obtaining the data from considerable portions of Western Europe. This defect ought to be rectified without delay.

Reference is made to international stations, or stations at which observations are made for purposes of international meteorology. But on looking at the diverse hours of observation adopted by the different European systems, it is evident that the attempt recently made to found an international meteorology must be regarded as a failure, since the prime and most elementary condition of uniformity as regards hours of observation has been neglected, the just views on this vital point propounded by Humboldt and the meteorologists of his time being at present, if appreciated, entirely set aside.

MYCOLOGY[1]

IT is perhaps not generally known how very numerous are the specimens comprised under the branch Mycology. The mycological herbarium which is in the course of transmission to Kew consists of at least 10,000 species, of which 7,500, comprising the Hymenomycetes and Ascomycetes, have already been forwarded. But not only are many species very beautiful in form and colour, but the subject is one of great interest both in a physiological and economical point of view, apart from mere distinction of species and nomenclature, and, therefore, while especial journals are devoted to entomology, malacology, algology, and other branches of natural history, it is quite right that we should have one devoted to fungi. M. Roumeguère ought, however, to have mentioned that England already possesses one in Grevillea quite equal to the French journal, which has appeared with great regularity ever since 1872, and is monthly instead of trimestrial, of the existence of which he could scarcely be ignorant, as it is referred to more than once in the number before us.

The Journal before us commences with a paper on the much-vexed question of the real nature of lichens, in which the author is altogether opposed to Schwendener's theory of their parasitic growth on Algæ. There are two points which ought to be noticed: that the growth of Gonidia from Hyphæ was observed by Mr. Berkeley, as recorded in the "Introduction to Cryptogamic Botany,"[2] while the stem of the curious

1 "Revue Mycologique: Recueil trimestriel consacré à l'Étude des Champignons." Par M. C. Roumeguère. (Paris: J. B. Baillière et Fils.)

2 "Int. Crypt. Bot.," p. 373, Fig. 78*a*.

3 "Int. Crypt. Bot.," p. 341, Fig. 76.

genus, *Emericella*,[3] a Lycoperdoid, is composed of bodies which closely resemble *Palmella botryoides*, Grev. The fungus was found on the leaves of *Euphorbia neriifolia*, in the hot country of Secunderabad, a very unlikely locality for a *Palmella*. Though the observations in the paper are not absolutely convincing, they are highly worthy of consideration, and may induce the advocates of the theory of Schwendener to reconsider the matter and make fresh experiments.

The other papers in the number do not require any especial consideration, though it may at once be allowed that they contain much matter of interest, scarcely, however, so much as regards physiology as might have been wished, for that, after all, is the point which is most likely to engage general interest. It is very unfortunate that the Tulasnes, after doing so much for mycology, have of late retired almost entirely from their former line of study. It is impossible to give too much credit to the result of their researches, or the admirable drawings with which they are abundantly illustrated. There are, however, other labourers in the field who are carrying on their work, amongst whom it is impossible to neglect De Bary, even when such observations as those on the development of *Ascobolus* may require confirmation. They are too curious and important to be set aside without fresh examination, and whatever views may prevail as to the nature of lichens, it is so certain that they are essentially fungals, that the origin of the fructification must be the same, or at least analogous. Much remains to be done as to the impregnation of the English fungi, for Mr. W. Smith's ingenious paper on the fructification of *Agaricus lacrymabundus* cannot at present be received as more than a mere speculation. De Bary's observations on the supposed occurrence of asci in *Agaricus melleus* are confessedly due to the presence of a parasitic Hypomyces. M. Cornu, however, is attending to this as to many other objects of interest; while van Tieghem is adding daily to our knowledge of the different kinds of *Mucedines*, and Drs. Cunningham and Lewis are working effectively in India. It is to be regretted that Mr. Renny has never published the numerous new genera he has figured in this department, which vie, for beauty and singularity, with anything which has been recorded by van Tieghem. Mr. Abbay has lately made some curious observations on the germination of the spores of *Hemileia*, which is so destructive in the coffee plantations of Ceylon. He does not, however, seem to be aware, that Mr. Thwaites had already observed that the species in germinating always produce a Penicillium, though Mr. Abbay has much extended his observations.

Brefeld and Rees have made many valuable observations with respect to the production of asci with sporidia in yeast. Rees, however, states that under the most advantageous conditions he has never been able to induce the globules to send out threads of mycelium. This was, however, done by Mr. Hoffman, of Margate, the account of whose observations, in company with the author of the present notice, are recorded in the article "Yeast," in the "Cyclopædia of Agriculture," the same manipulation showing that the Sclerotium of onions is a condition of a minute Mucor. Their success depended upon having the disk of water in which a very limited number of yeast globules were inclosed, being surrounded in a sealed cell with an atmosphere of air.

These observations should not be closed without a notice of Woronin's very complete observations on the disease commonly known as the club in cabbages. He not only succeeded in discovering the fungus to which it is due, but was enabled to complete his experiments by its actual cultivation. The figures which accompany his memoir are beyond all praise. We may expect more from his hand on these obscure productions. The genus *Protomyces* will probably afford some unexpected results, and we may yet hope for something more satisfactory on the nature of the bodies which are so common on the roots of Leguminosæ.

Finally, M. Cornu's researches in the Saprolegniæ have increased our knowledge of these curious organisms, most authorities being now of opinion that they are aquatic fungi; while many other valuable communications, of almost equal interest, are necessarily omitted.

M. J. BERKELEY

GEOGRAPHICAL NOTES

THE April number of the Geographical Society's new periodical contains Mr. Comber's paper on his explorations inland from Mount Cameroons, and his journey through Congo to Makuta, the late Capt. Patterson's notes on the Bamangwate country, South Africa, and Gen. Kaye's paper on the mountain passes leading to the Valley of Bamian, all of which were read at recent meetings. These are followed by some remarks on the colouring of maps, by Prof. Cayley, the Council's memorial respecting professorships of geography, &c. The geographical notes contain several items of interest. In one are some useful explanatory remarks respecting Major Pinto's reported "solution of the Cubango mystery," while another fixes the locality of Lake Chaia (not marked on any of our maps) near which Lieut. Wauthier died and Mr. Penrose was murdered. There are also same particulars respecting Japanese colonisation in the Island of Yesso, and Mr. Alex. Forrest's expedition to explore and survey the unknown tract of country between the De Grey and Victoria rivers in North-western Australia. The present number is illustrated by two maps, the one of Mount Cameroons and the neighbouring country, from a drawing by Mr. Comber, and the other of the Bamangwate country, also from new material.

THE *Globe* gives the following as the official programme that has been drawn up for the "Imperial Expedition" to Central Asia, under the command of the Grand Duke Nicholas Constantinovitch. The staff of the expedition will be an engineer from the Ministry of Railways, an officer of the Baltic fleet, a surveyor, a naturalist, an archæologist, a geologist, a painter, a correspondent, and a topographer. The aim of the expedition is to select the route of the Central Asian Railway, to examine the navigability of the Oxus, and to decide the possibility of diverting it into the Caspian. The route will be from the River Ural to Karasugai, on the Syr Daria, thence *viâ* Tashkend and Samarcand to the Oxus at Kunduz (Afghanistan); afterwards along the river to Khiva, and across the Kara Kum to Krasnovodsk. The work of the expedition will be: 1. To collect information as to the cost of the railway, the ability to obtain materials for its construction, whether fuel exists on the route, and the amount of labour obtainable. 2. To investigate the speed of the Oxus, the height of its banks, the population of the nearest towns and settlements, and the existing commerce on the river. 3. To examine the Khiva oasis, the floods of Sari Kamish, and the ancient bed of the Oxus, commonly known as the Uzboc. 4. To carry out astronomical observations all the way along the route, to make military plans, to sketch the features of the country, to collect objects of mineralogical, zoological, geological, and archæological interest, and to keep a journal of daily events. Finally, in collecting information respecting the ancient course of the Oxus, to decide whether it can be diverted afresh into the Caspian without detriment to the Khivan oasis. It seems possible, however, that in case of certain Eastern complications the expedition may develop into a military one against Merv.

FURTHER news has been received from Dr. Crevaux, the explorer of French Guiana. He returned to Guiana about the middle of last year for the purpose of exploring

the Oyapok, the second river of the colony, the basin of which was comparatively unknown. On August 21 Dr. Crevaux was at the mouth of the river. Crossing a second time the Tumuc-Humac range, which separates the waters of the Oyapok and Maroni from those of the Amazon, he descended the Kou, an affluent of the Yari, the course of which was unknown. Arrived at the Yari, which on a former occasion he had ascended only as far as Yacouman, he followed its course to its sources, which he reached on October 24 last, after a journey of about 170 miles on that river. On that date he wrote a note in pencil to Paris, announcing the result of that part of his journey, but predicting for the remainder of his exploration considerable difficulties, which, however, he has succeeded in surmounting. A short letter just received by *La Nature* intimates the return of Dr. Crevaux to Sainte Marie de Belem on January 9 last, and contains a topographical sketch of the region explored. After having crossed the secondary chain which separates on the west the Yari from the Parou, another almost unknown affluent of the Amazon, Dr. Crevaux completely explored this considerable watercourse, and afterwards, descending the river, he re-explored the lower course of the Yari.

A TELEGRAM addressed by Gordon Pasha from Abu-jerad, on the White Nile, to the president of the Italian Geographical Society, announces that Signor Matteucci, the leader of the Italian scientific expedition, having received permission to enter Abyssinia, had started from Adowa and landed at Massowah.

THE French traveller, M. le Comte de Semellé, arrived at Fernando Po on February 13 from the Upper Niger and Binué. He started on his expedition in May of last year, and had been engaged in pursuing his researches up to the time he returned to Fernando Po. He has forwarded to England and France an account of some of his discoveries.

THERE seems every likelihood that an attempt will be made to train African elephants as bearers of burdens, and indeed it is stated that an association has been formed for the opening up of African trade by this means. This seems to us a much more sensible and practicable plan than the construction of a railway, which has been so prematurely proposed in some quarters. With the aid at first of Indian trainers we see no reason why the African elephant should not be made as useful as his Indian brother.

THE intended laying of a telegraphic line from Aden to Zanzibar, and from Zanzibar to Port Natal *viâ* Mozambique and Delagoa Bay has promoted a project for connecting the Mascarene Islands either with Zanzibar by the Comoros or with Delagoa Bay through Madagascar by a special line. It is said that the general council of Reunion will take the lead. The aggregate population of the Mauritius and Reunion is more than half a million, and the trade of these two islands with Europe reaches annually a large sum. The density of population is very great.

MGR. LAVIGERIE, Archbishop of Algiers, has informed *Les Missions Catholiques* that it is in contemplation to increase the staff of the French Algerian Missionary expedition in Central Africa to ten priests, one of whom is to found a depot in the neighbourhood of Zanzibar for the missions of the interior.

WE gather from the *Colonies and India* that some interesting papers have appeared in the Ceylon press relative to the suitability of that island for the growth of Australian trees. The blue gum-tree does not seem to flourish under an elevation of 3,000 feet. The *Casuarina* grows freely even by the seashore. The *Grevillea robusta*, one of the most beautiful and most useful of Australian trees, had thriven well in Colombo itself, though it will not stand the full force of the sea breezes.

THE steam traffic in the Indian Archipelago has so largely increased since the opening of the Suez Canal that the roads of Batavia are found insufficient for the accommodation of the vessels, and the Netherlands Government have accordingly found it necessary to undertake the construction of a new port. This, we learn from the Manila papers, is situated in Cape Tanjong Priok, to the east of Batavia, and is to have communication with that city by means of a canal and a railway. The work of construction was commenced in 1877, and 3,000 men are at present employed on it. The new port, which is to be named after Prince Henry, will, it is expected, be finished in 1885.

THE last number of *Le Globe* contains the first instalment of a sketch by M. Veniukof of geographical discoveries in Asiatic Russia, translated by M. Metchnikof.

THE French Alpine Club has organised a tour for school boys for the Easter holidays. The excursionists will travel on foot in the two departments of Loiret and Loir et Cher, visiting Orleans forest, the banks of the Loire, Chambord Castle, and the forest of Fontainebleau, where the last frosty weather produced such extraordinary disorders. The regulations will be sent on request to the Secretaire-General of the Alpine Club, 31, rue Bonaparte, Paris. No limit of nationality is imposed. The excursion will last for seven days and be conducted by a staff of competent teachers.

A SPECIAL congress on the means of creating an inter-oceanic canal across the Darien Isthmus will be opened shortly by the Society of Commercial Geography of Paris.

BY a census taken in December last it appears that the population of Japan now numbers 34,338,304 souls. Yedo, which at one time had the reputation of being the most populous city in the world, contains 1,036,771 inhabitants and 236,961 houses.

NOTES

THE Copernican Society at Thorn has resolved to begin an international collection of funds for the erection of an observatory in that town, as a lasting monument to the great reformer of astronomy.

M. BAILLAUD, Professor of Astronomy to the Faculty of Sciences of Toulouse, has been appointed director for five years of the observatory of that city.

THE anniversary meeting of the Chemical Society was held on Monday, Dr. Gladstone, F.R.S., president, in the chair. The President presented his Annual Report on the state of the Society, which he characterised as affording ground for congratulation, the past year having been one of quiet prosperity. The Society numbers now over 1,000 members. Sixty-eight papers have been read and two lectures delivered by H. C. Sorby and S. H. Vines; the Faraday Lecture was delivered by Prof. Wurtz. The improved condition of the Society's library and journal was touched upon. In conclusion, the President urged the Fellows not to rest satisfied with the present attainments of the Society, but to promote research, and especially a general scientific culture in the workers, a culture which should promote largeness of view and prevent each investigator looking on his own subject as one of prime importance, to the exclusion of all others. The Report of the Research Fund Committee was then read, with a brief account of the investigations carried on in connection with the fund. After the customary vote of thanks to the officers, council, &c., the following officers and council were elected for the ensuing year:—President—Warren De La Rue, F.R.S. Vice-presidents—F. A. Abel, C.B., Sir B. C. Brodie, E. Frankland,

J. H. Gladstone, A. W. Hofmann, W. Odling, Lyon Playfair, A. W. Williamson, F. Field, J. H. Gilbert, N. S. Maskelyne, H. E. Roscoe, R. Angus Smith, J. Young. Secretaries—W. H. Perkin and H. E. Armstrong. Foreign Secretary—Hugo Müller. Treasurer—W. J. Russell. Other Members of Council—M. Carteighe, A. H. Church, W. H. Bartley, C. W. Heaton, E. Riley, W. C. Roberts, W. A. Tilden, W. Thorp, T. E. Thorpe, J. L. W. Thudichum, R. V. Tuson, R. Warington.

THE eminent algologist Dr. Rabenhorst has been compelled, in consequence of continued ill-health, to resign the editorship of the monthly cryptogamic journal *Hedwigia;* and it has now passed into the hands of Dr. G. Winter of Zürich, well known for his contributions to various departments of cryptogamic literature.

THE *Library Bulletin* of Harvard University is a publication much more interesting and valuable than its title would seem to imply. It is edited by the librarian, Mr. Justin Winsor, one of the greatest living authorities in all matters connected with libraries. We have before us No. 10 of the *Bulletin*, containing first of all a list of the more important accessions to the library between October 1878 and January 1879. This is a model list, and several of the entries are really elaborate essays, as that under the heading Maps, on Early Globes. The supplement to this list is devoted to articles, some of them of great scientific value. For example, under the title of "References in Analytic Geometry," we are furnished with a minute analysis of Descartes' Geometry. Prof. Goodall, under the title of "Floras of Different Countries" gives bibliographies of the Floras of Africa and America. In the supplement there is much other bibliographical material of literary and artistic value, each subject being continued in the supplements of successive *Bulletins*, until completed. Mr. Winsor intimates that he is preparing a list of all editions of Ptolemy's Geography, and desires detailed information of any editions that may be in foreign libraries. Altogether this *Bulletin* is one of the most valuable bibliographical publications we know of.

THE death is announced of Prof. Karmarsch, the well-known technologist. He was born in 1803. In 1823, when he was twenty years of age, appeared his first work, and his labours ended in 1872 with the publication of his greatly-valued "History of Technology." He was long director of the Hanover Polytechnic School, which was founded under his superintendence. He retired from active life in 1875.

THE French Minister of Public Works has given the required authorisation to M. Gaston Tissandier to establish Giffard's balloon in the Cours des Tuileries, and the works are progressing with great activity. The ascents are to begin on the first days of May, the price is to be reduced to 10 francs, and the admission fee for spectators to 50 centimes.

THE *Daily News* New York correspondent telegraphs that Mr. Edison has exhibited the working of his incandescent light in the illumination of his laboratory and factory, with excellent results, furnishing fourteen of the new lamps each from 18 to 20 candle power, on one circuit, giving a steady white light, much superior to the carbon, and equal to double the number of gas-jets. The generator was an ordinary Gramme machine of 2½-horse power. Mr. Edison states that he can now supply light for practical domestic use at less than half the cost of gas, but is experimenting for further improvements in the lamp and economy in the generator. He has discovered a new alloy, platinum and iridium, by the use of which he increases the number of lamps per horse power at least 50 per cent.

THE April number of *Mind* contains a paper of much interest by Mr. G. Stanley Hall on Laura Bridgman, the much-written-about American girl, who at an early age was deprived of nearly all her senses but that of touch; the paper is the result of a recent visit to Laura. Prof. Bain commences a series of papers on the life and character of John Stuart Mill.

THERE is a short and interesting article in the *Sanitary Record* of March 28 on the Registrar-General's method of estimating populations. It shows that the true method is not to take the average rate of increase during any decade to ascertain the increment of the following decade. The true rate of increase is obtained by the difference between the logarithms of any two decades.

THE number of lights for electric light-houses in France is to be increased by two important constructions, one on Planier Isle, off Marseilles, and the other at the mouth of the Gironde. There are at present in existence in France only three, one at Cape Grisnez and two at Cape La Heve, off Havre. These lighthouses are supplied with Alliance electro-magnetic engines.

THE session of the delegates of the Sociétés Savantes will be begun as usual at the Sorbonne after Easter, and M. Ferry will deliver an address on the occasion of the distribution of prizes.

A STRIKING and highly promising line of research has been recently adopted by Mr. Muybridge, of San Francisco, at the instance of Governor Stanford, viz., the instantaneous photography of animals in motion. Some of his earlier photographs of a fast-trotting horse presented attitudes wholly unexpected, and they were even thought absurd. The method latterly adopted seems to have been making the horse trot or gallop past twelve cameras, arranged in series, and by breaking threads stretched across its path, release an electric current, which effected exposure of the plates. Thus the flying steed was obtained in every position. Mr. Muybridge gave public exhibitions of what had been done. The small negatives were magnified into life size, and projected on a screen, so that every motion was visible. These exhibitions do not seem to have been appreciated by the San Franciscans. The *Scientific American*, however, and afterwards *La Nature*, have published cuts taken from the photographs, and much general interest has been awakened in these researches. Among those specially interested is Prof. Marey, who desired to be put in communication with Mr. Muybridge, as he wanted to ask his aid in solving certain physiological problems, so difficult to solve otherwise; *e.g.*, questions connected with the flight of birds. He had been dreaming of a kind of photographic gun, to seize the bird in an attitude or series of attitudes of flight. What beautiful zootropes, too, might be had! Mr. Muybridge's cartoons representing the fast gallop give a key to the breaking down of so many horses. It appears as though one fore-leg had to sustain the whole of the weight of horse and rider while the body is moved along five feet. And just before the foot is raised, a perpendicular from it would strike the back of the saddle; so that there is immense leverage, the centre of gravity being thrown so far forward of its support, and the tendons must have a terrible tension. These inquiries are being further developed by the liberality of Governor Stanford and the skill of Mr. Muybridge, and valuable results may doubtless be looked for.

AMONG recent lectures delivered at the Sorbonne was one by Prof. Marey, who has so admirably applied the graphic method in physiology. His subject was the circulation of the blood, and though (the auditory containing ladies) experiments involving the presentation of blood were naturally proscribed, he was able to give several striking demonstrations. One of these consisted in showing on an illuminated surface the phases of the heart beats of his assistant's and his own pulse, the beats being transmitted across the hall, by a thin tube, the pulsations actuating a small inscribing style placed before the electric lamp. He also exhi-

bited a number of his ingenious apparatus illustrating the circulation, working them with water.

THE "Sixth Annual Report" of the Michigan State Board of Health is of much more than local interest. The Board seems to be a body who have a very thorough and comprehensive idea of their duty, which is very faithfully carried out by their secretary, Mr. H. B. Baker. The Report contains inquiries into all sorts of subjects connected with the sanitary condition of the people of Michigan, and many of the results obtained are of general interest. For example, with regard to earthen vessels used for domestic purposes, we are told that to the glazing material used for the inside the oxide of lead is sometimes added, making, with the alkaline silicates, borates, &c., a very fusible and closely adhering glazing. But its use is very dangerous, especially if the vessel contains acid substances, such as pickles with vinegar; the glazing decomposes, and lead salts form, which either dissolve or become mechanically suspended in the contents of the jar, and there is great danger of chronic lead-poisoning. The Report also contains some useful remarks on the various substances used to enamel iron vessels. There is also a very careful study of the climate and topography of the lower peninsula of Michigan, the meteorology of Michigan for 1877, and other information of much value.

A NEW form of water-level indicator, we learn from the Society of Arts *Journal*, has lately been designed and constructed by the India-rubber, Gutta-percha, and Telegraph Works Company, Silvertown, and has been erected by them at the Leamington New Water-Works, where it is stated to be giving every satisfaction. The reservoirs from which the supply of water is distributed to the town are situated some half-mile from the pumping-station, and it was therefore found necessary to have some kind of indicator placed at the engine-house, in order to enable the man in charge of the engines to see at a glance the exact height at which the water stood in the reservoir, so that he might be able to regulate the rate of pumping accordingly. The indicator that has been placed at the engine-houses resembles somewhat, in outward appearance an ordinary round metal case clock; the dial, instead of being divided into hours, minutes, &c., is divided into twenty equal divisions representing feet, and corresponding to the rise and fall that is required to be registered. A hand on the dial points to one of the divisions, which at any particular instant corresponds to the height at which the water in the reservoir stands. This hand, for every foot rise in the level of the water, moves an equal number of divisions round the dial; whilst, as the water falls, the hand turns back in the other direction, so that it always points to the exact height at which the water stands in the reservoir. A single line of ordinary telegraph wire communicates between the indicator and the apparatus at the reservoir. This apparatus is so constructed that at every foot rise of the water one pole of a battery is brought into connection with the line for a certain space of time, and the current from the the battery actuating the indicator at the engine-house, causes the hand to move the requisite distance round the dial. On, however, the water falling, the opposite pole of the battery is brought into connection with the line, and this is made to cause the indicator hand to move in a contrary direction. The apparatus at the reservoir is actuated by an ordinary float and weight in the water, and is arranged in such a manner that the battery contacts are always of the same duration, irrespective of the rate at which the water may be either rising or falling. A variety of uses will at once suggest themselves to which this class of electric indicator might be advantageously applied, as it can be arranged, if required, to give a diagram on paper of the water level at stated intervals of times, instead of using a hand to point to the divisions on the dial, as in the present instance; also it is evident that it can quite as readily be made to give variations in inches as in feet. As a tide indicator it might be made very serviceable on many of our large rivers, and probably ere long we shall hear of some further uses to which this novel application of electricity has been applied.

A SHOCK of earthquake was felt at Hetzdorf and Oederan, Saxony, in the night from March 12 to 13. The shock had a north-westerly direction, and a violent storm was raging at the time. At Hall, in the Tyrol, a violent shock was felt on March 13, at 11.15 P.M., in the direction from west to east.

THE *Report* of the Glasgow Industrial Museum for 1878 is satisfactory, showing as it does that the institution, under the care of Mr. Paton, is in a fair way of developing into something worthy of a city of the first commercial importance.

WE have received a copy of the Hunterian Oration delivered at the Royal College of Surgeons on February 14 last, by Prof. Humphry. It is published by Macmillan and Co.

THE Spanish *Crónica Cientifica* of March 25 contains among other interesting papers a Catalogue of the Terrestrial Testaceous Molluscs of the plain of Barcelona.

PART I. has been sent us of "A Universal Dictionary for Architects, Civil Engineers, Surveyors, Sculptors, Archæologists," &c., &c., by Mr. W. J. Christy. The London publishers are Griffith and Farran.

PROF. VIRCHOW has left Berlin for Troy in acceptance of an invitation from Dr. Schliemann.

BULLETIN NO. 1 of vol. v. of the United States Geological Survey of the Territories, contains the following papers:—Notes on the Aphididæ of the United States, with descriptions of species occurring west of the Mississippi, by Chas. V. Riley and J. Monell; The relations of the horizons of extinct vertebrata of Europe and North America, by E. D. Cope; Observations on the faunæ of the miocene tertiaries of Oregon, by E. D. Cope; Notes on the birds of Fort Sisseton, Dakota Territory, by Chas. E. McChesney, Acting Assistant Surgeon, U.S.A.; Palæontological papers, No. 9: Fossils of the Jura-Trias of South-Eastern Idaho, by C. A. White, M.D.; Jura-Trias Section of South-Eastern Idaho and Western Wyoming, by A. C. Peale, M.D.; Fossil forests of the volcanic tertiary formations of the Yellowstone National Park, by W. H. Holmes; Palæontological papers, No. 10: Conditions of preservation of invertebrate fossils, by C. A. White; Supplement to the bibliography of North American invertebrate palæontology, by C. A. White and H. Alleyne Nicholson.

DR. C. V. RILEY has reprinted in a separate form the entomological papers contributed by him to the last meeting of the American Association for the Advancement of Science. They are: "The Philosophy of the Movements of the Rocky Mountain Locust," "A New Source of Wealth to the United States," "Notes on the Life-History of the Blister Beetles and on the Structure and Development of Hornia," "On the Larval Characteristics of Corydalus and Chauliodes, and on the Development of *Corydalus cornutus*," Biological Notes on the Gall-making Pemphigmæ."

THE additions to the Zoological Society's Gardens during the past week include a Green Monkey (*Cercopithecus callitrichus*) from West Africa, presented by Mr. J. N. T. Martheze; a Globose Curassow (*Crax globicera*) from South America, presented by the Rev. Ralph Cooper; a Grey-breasted Parrakeet (*Bolborhynchus monachus*) from Paraguay, presented by Miss Maria Hilhouse; a Common Peafowl (*Pavo muticus*) from India, presented by Mr. F. B. Hopkinson; a Laughing Kingfisher (*Dacelo gigantea*) from Australia, presented by Mr. F.

Belcher; five European Geckos (*Phyllodactylus europæus*) from Italy, presented by Prof. H. H. Giglioli, C.M.Z.S.; a Cape Ant-bear (*Orycheropus capensis*) from South Africa, purchased.

INTELLECT IN BRUTES

WE have another batch of letters on this subject, the essential points of which we shall endeavour to give in brief space:—

Mr. Wm. Hogg tells us of an incident he witnessed when calling on Mr. W. H. Michael, a gentleman well known at the parliamentary bar, who resides at Queen Anne's Gate, St. James's Park. While they were sitting in the study, the French window of which communicates with a garden at the back of the house, and had a crank latch by which it could be opened on either side, a cat presented herself outside the window, pleading for admission. She continued to plead for some time, and finding no help from within she resolved to trust to her own powers. Eying the latch, which was four feet above her, she made a spring, caught hold of the crank with her fore feet, and putting her hind feet against the other half of the window as a fulcrum she pressed open the window. This she would do several times in succession. Mr. Michael informed Mr. Hogg that the cat had never been taught to do this.

D. R. S. sends the story of a little terrier that left her puppies only once a day to be fed, gulping down hurriedly a great quantity of porridge. Returning quickly to her family she would put up all the porridge in order that she and her puppies might together enjoy a hearty meal. When the terrier was scolded for a fault it rushed away to a little distance and catching up anything it could get hold of at once—a bit of stick, a straw, a slipper or anything at hand—it would come coweringly and lay it down at our feet, with an expression of utter submission. If we were not propitiated it would run off a second time and bring another peace-offering, often in its distress catching things it would not at any other time have dared to touch.

M. W. T. writes:—A farmer, in Somersetshire, was going to a neighbouring village some three miles distant, and, not wishing to take his dog he ordered him home. The dog reluctantly obeyed. When the man arrived at a spot, about half way on his road, where the short cut he had taken across the fields joined the more circuitous road, he found the dog waiting for him. Evidently the animal had taken the longer route, which he doubtless knew, calculating on meeting his master at that point, and thus gaining his end without hindrance.

Mr. John Harmer, of Wick, Arundel, possessed a few years ago a very fine and intelligent tom-cat which was much addicted to plundering a rabbit-warren about a mile from his home. After a time it was noticed that before he proceeded on one of his expeditions "Sam" completed his toilet by wallowing in the filth turned out of the tame rabbits' hutches, he taking particular care that his neck and breast should be in as disgusting a condition as possible by smearing them up and down till both were saturated and the fur all matted together.

Mr. J. J. Cole of Mayland, Sutton, Surrey, writes:—It has been my custom to have—not a letter-box in a door in the usual way but the plate and flap in the bottom of a window sash near. I had a cat which often saw a servant go to the window on hearing the flap moved by the postman, and which, when shut out used to jump on to the window sill and rattle the flap and when the servant was seen through the glass jump down to be let in at the door. I knew a horse which during week days went round and round to the left, grinding in the cellar of a snuff maker in London. On Sundays his owner turned him out in a field at his place in the country where the horse went round and round all day long unwinding himself the other way. Why?

Mr. B. G. Jenkins describes a scene he witnessed between the large insect known as "daddy long-legs" and a small spider. The former got caught by one of its hind-legs by a pendant thread of cobweb about eight inches long, at the other end of which was the small spider. The spider cautiously descended on the thread, doubling it as he came, and secured the insect's leg more firmly. He then ascended about three inches, and drew the insect up about half an inch; but a violent resistance on the part of the latter induced him to give up the attempt. He, however, went up the thread, strengthening it as he went, and coming down again to the same place, evidently attempted once more to raise his prey, but without success, for the insect resisted so stoutly that it appeared to me to stretch the thread. The spider, Mr. Jenkins writes, saw clearly that the insect was too strong for him, that he would never be able to draw him up to the centre of his web, and that if he did not take very summary measures he would lose him altogether; so, on the principle that half a loaf is better than no bread, he set to work to secure a portion of it. The hind-leg of the insect, to which he had his web fastened, was composed of four jointed portions. Round three of these he busied himself weaving a web. Mr. Jenkins noticed particularly that he did not go up to the last jointed portion, that attached to the body. Having well secured these three, he moved up to the joint, and for a few moments appeared perfectly still. Suddenly the insect darted away, leaving three-quarters of its leg behind. What other explanation is there than that the spider disconnected it at the joint? Quietly ascending the thread, which he carried with him, and of course the leg as well, he properly placed the latter, settled down at the union of the two uppermost portions, gorged himself with juices from above and below, and then retired for the night.

Several correspondents express surprise at Mr. Henslow's position with regard to "abstract" and "practical" reasoning. They think that several of the instances adduced render that position untenable, and prove that in their degree the animals referred to showed themselves possessed of powers of "abstract" reasoning. With regard to the dog and bell story, Dr. Rae writes:—It was never intended to be understood that the dog associated the bell with "a *particular* maid," as Mr. Henslow puts it; any of the other servants would have done equally well. The dog could only show his reasoning powers by declining to ring the bell; for had he rung it, Mr. Henslow or any one else would naturally have said that the "brute" had shown no reasoning powers at all. Mr. Henslow has passed over without notice the fox and gun story, which, by his own definition, was as clearly a case of abstract reasoning as could be adduced, differing only in form of carrying into effect from what he would have recommended, which, if adopted by the fox, would have led to its destruction.

Dr. G. Frost sends the following good story:—

In answer to Mr. Henslow's request for an example of "abstract reasoning" in the lower animals (NATURE, vol. xix. p. 433), I beg to subjoin the following:—Our servants have been accustomed during the late frost to throw the crumbs remaining from the breakfast table to the birds, and I have several times noticed that our cat used to wait there in ambush in the expectation of obtaining a hearty meal from one or two of the assembled birds. Now, so far, this circumstance in itself is not an "example of abstract reasoning." But to continue: For the last few days this practice of feeding the birds has been left off. The cat, however, with an almost incredible amount of forethought, was observed by myself, together with two other members of the household, to scatter crumbs on the grass, with the obvious intention of enticing the birds. I think Mr. Henslow might now be convinced that animals also possess in an inferior degree that boasted reasoning power which is generally supposed to belong to man alone.

THE PLANE OF POLARISATION ELECTRO-MAGNETICALLY ROTATED IN A VAPOUR

IT is known that Faraday did not succeed in proving electro-magnetic rotation of the plane of polarisation of light in gases, nor have others succeeded. Considering the interest attaching to this question, Herr Kundt and Herr Röntgen lately thought to repeat the attempt with very strong currents and under the most favourable conditions. The result is that they have been able to prove the rotation, at least in the case of sulphide of carbon vapour. (Their researches have been communicated to the Munich Academy.)

Sulphide of carbon was chosen because, on the one hand, it shows a strong electro-magnetic rotation in the liquid state, and on the other, its vapour has a considerable tension, even at low temperatures. An iron tube was used for inclosure and heating of the substance; it was closed at the two ends with glass plates 1 ctm. thick, and itself inclosed in a tin-plate tube; so that steam could be led between the tubes to heat the inner tube throughout to 100°. The outer tube was surrounded by six large wire-coils, each having 400 windings of wire 3mm. thick,

through which was passed the current from sixty-four large Bunsen elements. A little sulphide of carbon was introduced into the inner tube, and the air having been driven out by vapour forming at ordinary temperature, the tube was closed and fixed in position, and steam was sent through the space round it.

When the whole tube had taken the temperature of boiling water the glass plates and the sulphide of carbon vapour within became quite transparent. A beam of light rectilinearly polarised by a Nicol was now sent through, and a Nicol at the other end extinguished it. The current of the sixty-four elements being now allowed to flow, a distinct brightening of the field was observed. The brightening became still greater when, after closing the circuit, the foremost Nicol was turned to darkness, and the current then reversed with a commutator. The rotation of the plane of polarisation occurred, as was to be expected, in the direction in which the positive current passed through the wire coils.

To test whether the rotation might not be due wholly or in part to the glass plates closing the inner tube, the experiment was made without any sulphide of carbon in this tube. A weak rotation, due to the glass, was indeed observed, much smaller than in the other case. To avoid this, however, as much as possible, the wire coils next the glass plates were shut out from the circuit. The four coils now traversed by the current were so far from the plates that their influence must have been very small, indeed the plates then gave no perceptible rotation. Sulphide of carbon having been again admitted, and the experiment repeated, there was a well-marked brightening as before, when the current passed. The amount was roughly estimated at half a degree.

It is thus proved that saturated sulphide of carbon vapour at about 100°, *in the magnetic field, rotates the plane of polarisation of light.*

Sulphuric ether was tried in the same way, but gave no effect.

The authors consider it can hardly be doubted that, with suitable arrangements, the rotation may be demonstrated in the case of unsaturated vapours and gases. They are engaged in making an apparatus which will enable them to examine permanent gases at very high pressures in the magnetic field, in order to prove the rotation in their case, and, if possible, to measure the phenomenon. "It would be specially interesting," they remark, "to ascertain whether oxygen rotates the plane of polarisation in the same direction as other gases."

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

A BROAD and liberal scheme has been published by the Cambridge Syndicate on the affiliation of local Colleges to the University as suggested in various Memorials. They have taken a large amount of evidence and have had interviews with deputations from Nottingham and Sheffield. They have also held conferences with a Committee of the Hebdomadal Council of the University of Oxford, with whom they find themselves in general agreement. The Syndicate recommend that application be made to the University of Cambridge Commissioners for the powers required to enable the University to affiliate local Colleges, and that the following conditions of affiliation be established by grace of the Senate. Any educational institution within the British dominions, in which the majority of the students are over seventeen years of age, may be admitted on condition that it be incorporated by Royal Charter, or established on a permanent and efficient footing; that the University shall be represented on its Governing Body, and undertake the general conduct of its Examinations; and that the connection between the University and an affiliated College shall be established and shall be terminable by a grace of the Senate, or by a resolution of the Governing Body of the College. Persons who have completed an approved course of three years at an affiliated College, passing satisfactorily the Examinations connected with that course, will be entitled to receive a University Certificate, and if they obtain honours in the final Examination connected with that course, shall be excused the previous Examination; and provided they obtain a degree by one of the Tripos Examinations will be permitted to take their degree after only six terms' residence at Cambridge. In each College there are to be three examinations yearly, the Annual College Examination, the First and the Second Examinations, the Annual College Examination is to be held in subjects taught with the sanction of the University, in the College, and be open to those students only who have satisfactorily attended the teaching in these subjects. To pass the First Examination every candidate will be required to satisfy the Examiners in (1) Arithmetic; (2) Euclid, Books I., II., and III.; and Algebra, to Quadratic Equations inclusive; (3) One of the following languages: Latin, Greek, French, Italian, German. Candidates will be at liberty to take up more than one language, and one or more additional subjects, including Heat, Experimental Mechanics, Chemistry, Botany, and Mathematics. 4. The Second Examination shall include four groups: (1) Ancient and Modern Languages, two to be taken. (2) Mathematics, one higher subject, pure or applied, being required. (3) Natural Science. Candidates pass in Elementary Chemistry and Physics, and also in one of the following:—Higher Chemistry, Higher Physics, Animal and Vegetable Physiology, Comparative Anatomy with selected portions of Zoology, Vegetable Anatomy and Physiology with Classificatory Botany, Geology and Physiography, Mineralogy. Candidates to pass in (1) English Constitutional History and (2) Political Economy or Logic, and subjects connected with History, Literature, and Philosophy. A pass in one group will give a pass in this second examination, and honours may be obtained on the minimum number of subjects. The Syndicate think it desirable to avoid if possible increasing seriously the severe strain caused by the outside work of the University. The sections and groups of the senior and higher local examinations are in general correspondence with the scheme, and the lectures at the centres are under the superintendence of the Syndicate for conducting local examinations and lectures. Thus there is machinery in existence which may, with some modifications, be conveniently and properly used. It is thought desirable that the Universities of Oxford and Cambridge should, as far as practicable, act in concert in conducting this great scheme of affiliation. It is recommended that the scheme be so administered as to be self-supporting.

THE Cambridge Council of the Senate propose to repeal entirely the few unrepealed provisions in the will of Dr. Woodward relating to the Professorship of Geology, and to frame a new statute on a plan already approved for the Professorship of Chemistry. The same plan is likely to be followed with regard to the chairs of Anatomy, Botany, and Mineralogy, the nomination of half the Electoral Board in the case of anatomy falling to the Board of Medical Studies and in the other professorships named, to the Board of Natural Science Studies.

IN consequence of the greater importance to be given in future to the first part of the Cambridge Natural Sciences Tripos, held in June, a practical and oral examination is to be held then, two extra days being allowed tor this.

THE Higher Senior Class of Mathematics in University College, London, which had been conducted by the late Prof. Clifford, has been intrusted during the summer term of the present Session to Mr. M. J. M. Hill, M.A., Fellow of the College, and fourth wrangler and bracketed equal Smith's prizeman this year at Cambridge.

DR. WITTROCK, the well-known algologist of Upsala, has been appointed lecturer on Botany, and curator of the botanical section of the museum at Stockholm.

THE commission of the Chamber of Deputies proposes to establish a compulsory system of education in France. Parents neglecting to comply with the provisions of the law are to be fined, and in certain cases to be sent to prison for a certain period. The expenses required for enlarging school accommodation and adding to the number of teachers are to be supported by the National Exchequer.

SCIENTIFIC SERIALS

American Journal of Science and Arts, March.—In the opening paper Prof. Norton contends that under varying conditions the ultimate molecules of bodies are subject to changes in the intensity of their attraction or repulsion, at a given distance of neighbouring molecules (temperature and chemical constitution remaining constant). Evidence of this is found in the phenomena of permanent distortion of materials after temporary subjection to a force of stress; in observed changes in the mechanical properties of materials, through tension, pressure, heat, &c.; change of mechanical properties of a body through presence of minute quantities of other substances; and certain facts in chemical physics (phenomena of solution, allotropy, the nascent

state, &c.). The hypothesis is advanced, that the ethereal atmosphere condensed round an atom by its attractive action consists of an atmosphere of luminiferous ether, and an envelope of electric ether immersed within this for a certain depth, an ethereo-electric atmosphere, in fact.—Some observations on flocculation of small particles (or their tendency to form, under moderate agitation, granular aggregates or compound particles of larger size), are described by Prof. Hilgard, and have important physical and technical bearings, especially on points in agriculture.—Prof. Dawson points out what he considers defects and errors in the method of investigation pursued by Prof. Möbius recently with regard to *Eozoon canadense*, leading to a decision adverse to the organic character of that object.—Mr. White offers some remarks on the Jura-trias of Western North America; Mr. Fontaine continues his notes on the mesozoic strata of Virginia, and Mr. Bannister contends for the hypothesis of the transition character of the Rocky Mountain lignite series, or Laramie group.—Some new species of anthozoa and cephalopoda added to the marine fauna of the eastern coast of North America, are described by Prof. Verrill; the cephalopoda have some specially interesting features.—Mr. Penfield gives analyses of triphylite.

Annalen der Physik und Chemie, No. 2.—In this number Herr Thoss communicates an interesting paper on artificial dichroism. He experimented (to produce it) in the three directions of making a coloured isotropous medium doubly refractive, colouring a doubly-refractive medium, and giving a colourless isotropous medium both colour and double refraction. The last series were negative in results. In the first series, plates of gutta-percha, indigo, and chrysamminate of potash gave convincing proof that there is no difference between double refraction produced mechanically and double refraction in crystals. It was found impossible to produce dichroism with pressure in coloured glass. Colouring matter in crystals is considered the real producing cause of dichroism. The subject of quickly alternating electric currents is treated by Herr Oberbeck, who notes as an important fact the diminution of the resistance of liquids by increase in the number of alternations of the transmitted current in unit time; this occurs only when the number becomes high, and the average time of passage of one constituent molecule to its neighbour in the direction of the current can no longer be regarded as infinitely small in comparison to the duration of the current. The author describes experiments on alternating currents in two induction coils, variously connected, and finds in the phenomena certain analogies to vibrations of the nature of sound and light.—Herr Lubarsch endeavours to show that the faultiness of past experiments on fluorescence has arisen only from the first of three causes assigned by Prof. Lommel, viz., absorptive action of the fluorescent liquid on the fluorescent light, in observation of the liquid mirror. He finds evidence of the generality of this law: in all fluorescent substances the more refrangible limit of the derived spectrum coincides with the place of strongest absorption in the absorption spectrum, or (where this is not distinctly perceptible) with the place of strongest fluorescence in the fluorescent spectrum. Substances with double fluorescence, as chlorophyll (the phenomena of which he describes), are not excepted from the law.—Herr Rudorff describes a simple and convenient apparatus for determining the specific gravity of powdered substances; Herr Wiedemann and Herr Schulze, an arrangement with which can be proved the dissociation of hydrate of chloral at 100°; Herr Wiedemann, experiments yielding the result that by passage of electricity a gas may become luminous far under 100°, &c.—A large part of the number is occupied with the concluding part of Kohlrausch's paper on electric conductivity, &c., already referred to.

Journal de Physique, February, 1879.—The opening paper by M. Jamin, on complements to the theory of dew is followed by one in which M. Lippmann shows that the depolarising property of a metallic solution is limited to the same metal as it contains; and that this electric reaction may be applied, in several cases, in testing for a metal, as a convenient auxiliary of chemical analysis. The electric work expended to produce polarisation is stored (he contends) not in the form of chemical energy, but in that of electrical, as in a condenser.—M. van der Mensbrugghe offers some remarks on measurement of the superficial tension of liquids, *apropos* of recent experiments by M. Terquem.—M. Gernez describes a method of observing the rotatory power of quartz at different temperatures, and which seems to meet the difficulties of the case better than that of M. Joubert and other physicists. Two quartzes of contrary rotation are fixed at the two ends of a tube, and only one is heated. A universal support or electro-diapason for inscribing and showing in projection vibratory movements is described by M. Duboscq.

SOCIETIES AND ACADEMIES

London

Royal Society, March 27.—"On the Organisation of the Fossil Plants of the Coal Measures. Part X." By W. C. Williamson, F.R.S., Professor of Natural History in Owens College, Manchester.

The still existing differences of opinion respecting the botanical affinities of the Sigillariæ give value to every new fact calculated to throw light upon the question. In 1865 Mr. Edward Wunsch, of Glasgow, made a discovery, which proves to have an important bearing upon it. He found, at Laggan Bay, in Arran, a series of rather thin carboniferous strata, separated by thick beds of volcanic ash, and in one of the carboniferous shales especially, he discovered the bases of the stems of numerous very large trees standing perpendicularly to the shales. These trees have been referred to by several authors as Sigillarian. In the summer of 1877 Mr. Wunsch and I employed quarrymen to make extensive excavations amongst these strata, for the purpose of adding to the extensive series of specimens which he had obtained, and the whole of which he kindly placed in my hands. The aggregate result of these explorations was to show that the conclusion previously arrived at, viz., that the stems had belonged to a grove of Sigillarian trees, was unsupported by a solitary fact. These stems were of very large size, showing that they had belonged to fully grown trees. None of them displayed any traces of leaf-scars, having outgrown the stages at which such scars would remain visible. Their outer surfaces were scored with deep irregular longitudinal fissures, resulting from internal growth and consequent expansion, and which appear to have been mistaken for the longitudinal grooves and ridges of a Sigillarian bark. Such, however, they certainly were not, since, in every instance, the surface bark had been entirely thrown off, and the fissures entered deeply into the subjacent bark layer. In most of the stems this comparatively thin bark layer was the only one that remained, the greater portion of the inner bark and the central vascular axis having disappeared, leaving a large cylindrical cavity, which was filled up with volcanic ash. These stems failed to display a single feature justifying the conclusion that they were Sigillarian.

In two of them the central cavity, instead of being filled with ash, was filled with miscellaneous heaps of vegetable matter, amongst which were large fragments of the vascular axes of various plants, such as Lepidodendra and Stigmariæ, but in one of the largest stems were five or six decorticated vascular cylinders of Diploxyloid stems, of the largest size, and which, though arranged parallel to the long axis of the cylinder which inclosed them, obviously did not belong to them, but had been floated in from without. The supposition that these had been young stems that had grown within the hollow protecting cylinders, from spores, accidentally introduced, is wholly untenable, since each one of these several vascular axes has been the centre of a stem fully as large as that within which we found them aggregated. Of course, these Diploxyloid vascular axes had the organisation which Brongniart and the younger school of French botanists which still upholds his views on this point, believe to be characteristic of true Sigillariæ—a conclusion from which I have long dissented.

The only fragments we found, that threw any light upon the character of the leaf-scars that had indented the surfaces of these fully-grown stems, was a well-defined example of the Lepidodendroid type.

We directed careful attention to the nature of the smaller fragments of branches and foliage which abounded in the volcanic ash with which the large stems were overlaid. These consisted of Lepidodendroid branches and twigs of all sizes and ages, and no doubt was left upon my mind that they were really the *disjecta membra* of the stems around which they were so profusely scattered. The only fruits that have been obtained from the same locality are Lepidostrobi, most of which contain macrospores and microspores. Unless we are prepared to believe that this Arran deposit contained, on the one hand,

numerous stems without branches, and, on the other, yet more numerous branches without stems, we must recognise in these specimens the complementary elements of a grove of Lepidodendroid trees.

One specimen found is a very important one. It has a mean diameter of six inches, and is either a small stem or a very large branch. Internally it exhibits the same structure as all the smaller Lepidodendroid branches, except so far as it is modified by size and age. But in addition to its other features, it exhibits *a very narrow* exogenous ring surrounding the ordinary Lepidodendroid one, thus giving some clue to the size attained by such branches before the internal organisation passed from the Lepidodendroid to the Sigillarian type.

The important discovery by Mr. D'Arcy Thompson, of Edinburgh, of young branches of Ulodendron with reproductive cones actually attached to the scars characteristic of the genus, finally settles the nature and functions of these scars, showing that they mark the positions from which bilaterally arranged deciduous organs of fructification have fallen.

The structure of *Calamostachys Binneyana* has had further light thrown upon it, sustaining my previously expressed convictions that it had a triquetrous axis, and that consequently its affinities were with Asterophyllites and Sphenophyllum, and not with Calamites. A specimen demonstrates that the six vascular bundles going to the six fertile sporangiophores were given off in pairs from the three truncated angles of a triangular vascular axis—an orientation absolutely indentical with that represented in similar sections of stems of Sphenophyllum, published by M. Renault. The recent discovery by Herr Stur, of Vienna, of a plant in which Sphenophylloid and Asterophyllitean leaves are found upon a common stem, establishes the correctness of my previous conclusions, as to the very close affinities of these two genera.

A large series of specimens from Oldham and Halifax has enabled me to investigate in detail the very curious objects to which Mr. Carruthers gave the name of Traquairia, and which that observer believes to be a form of Radiolarian life. Their very elaborate organisation can scarcely be made intelligible without the aid of plates. In a previous memoir (*Phil. Trans.* 1874, p. 56), I ventured to doubt the correctness of Mr. Carruthers' conclusions, and expressed my conviction that these objects resembled spores rather than protozoan skeletons. Further study of their details of structure has only strengthened this opinion which has also received the important support of Professors Hæckel and Strasburger, of Jena, both of whom have carefully studied my collection of specimens. These objects are small spheres—the sphere-wall of which is prolonged into a series of long radiating tubes not unlike the muricated species of a Cidaris. In their young state each murication gives off a delicate thread or threads, which ramified freely in an apparently mucilaginous or gelatinous, structureless, investing magma. In older specimens these threads developed into branching and radiating cylindrical tubes which, like the primary ones, had very thin walls. Within the outer sphere-wall, which consists of the coalesced bases of these branching tubes, were at least two other thin layers of membrane, and in several of the specimens the interior of the capsule is filled with cells, exactly like those seen in the corresponding cavities of Lycopodiaceous macrospores found in the Halifax deposits from which the finest Traquairiæ have been obtained. These objects differ considerably from all known reproductive structures; but I agree with Prof. Hæckel in his very decided rejection of them from the Radiolarian group of organisms, and with his conclusion that they are vegetable and not animal structures. Prof. Strasburger thinks it most probable that their affinities are with the macrospores of the Rhizocarpæ.

Myriads of the vegetable fragments both from Oldham and Halifax are drilled in all directions with rounded insect or worm borings, and further traces of these zylophagous animals are seen in innumerable clusters of small Coprolites of various sizes, the size of those composing each cluster being uniform.

Desirous of verifying Count Castracane's alleged discovery of Diatoms in coal, specimens of twenty-two examples of coal from various localities in Yorkshire, Lancashire, and Australia were reduced, after the Count's method, to a small residue of ash. This work was done for me in the chemical laboratory of Owens College through the kindness of Prof. Roscoe. Like Mr. F. Kitten, of Norwich, the Rev. E. O'Meara, of Dublin, and the Rev. G. Davidson, of Logie Coldstone, I have failed to discover the slightest trace of these organisms in coal.

The last objects described are some minute organisms from the carboniferous limestones of Rhydmwyn, in Flintshire, and which were supposed by Prof. Judd to have been siliceous Radiolarians from which the silica had disappeared and been replaced by carbonate of lime. I fail to find any confirmation of this conclusion. The objects appear to me to constitute an altogether new group of calcareous spherical organisms that may either have been allied to the Foraminifera or have had some affinities with the Rhabdoliths and Coccoliths. I have proposed for several species of the organisms the generic name of Calcisphæra. Myriads of objects of similar character, but of larger size, constitute the greater portion of a Corniferous limestone from the Devonian beds of Kelly's Island, U.S.A.

Additional light is thrown upon some Lycopodiaceous Strobili, fern-petioles, *Sporocarpous* or cryptogamic conceptacles, and other spore-like bodies, Gymnospermous seeds and stems.

Chemical Society, March 20.—Dr. Gladstone, president, in the chair.—The following papers were read:—On plumbic tetrethide, by E. Frankland and A. Lawrance. The authors prepared this compound by adding plumbic chloride to zinc-ethyl, and distilling the product in a current of steam. Ammonia, carbonic anhydride, carbonic oxide, cyanogen, nitric oxide, oxygen, and sulphuretted hydrogen, do not act on this substance at ordinary temperatures; sulphurous anhydride converts it into a white amorphous mass, consisting of diethylsulphone and plumbic ethylsulphinate.—Prof. W. Foster gave a verbal communication on the production of the higher oxides of iron, chromium, manganese, and bismuth. When the salts of the above metals are treated with an alkaline solution of sodic hypobromite, ferrates, chromates, permanganates, &c., are formed, oxygen being evolved. Copper sulphate solution, when mixed with the hypobromite solution, evolves oxygen at ordinary temperatures.—On the decomposition of water by certain metalloids, by C. F. Cross and A. Higgin. The authors conclude that pure sulphur decomposes water, uniting both with its oxygen and hydrogen; the decomposition is independent of atmospheric oxygen. Amorphous phosphorus decomposes lead acetate solution, but is without action on water at 100°. Vitreous phosphorus does not decompose water at 100° when air is excluded.—On the volumetric determination of chromium, by W. J. Sell. To the boiling solution containing chromium, acidified with sulphuric acid, permanganate is added until a pink tint remains after boiling for three minutes; the manganese is precipitated by the addition of sodium carbonate and alcohol, and filtered off; the chromic acid in the filtrate is then determined by iodine and hyposulphite. The author also gives details of a method of fusing chrome iron ore, by means of which an estimation of the chromium can be made in an hour and a quarter.

Geological Society, March 12.—Henry Clifton Sorby, F.R.S., president, in the chair.—Lazarus Fletcher, Arthur Samuel Hamand, William J. Pope, and George W. Slatter, were elected Fellows of the Society.—The following communications were read:—On perlitic and spherulitic structures in the lavas of the Glyder Fawr, North Wales, by Frank Rutley, F.G.S. He mentioned the fact that the lavas of Bala age in Wales were generally vitreous, and instanced some remarkable cases of spherulitic structure from that district. Prof. Judd stated that among the most ancient rocks of the north-west of Scotland were lavas showing spherulitic and fluidal structure. These were also common in the old red sandstone lavas. He thought that as the spherulitic, perlitic, and fluidal structures were in rocks of modern date confined to vitreous varieties, the inference was safe, when applied to ancient rocks, that they were once glass. Dr. Sheibner asked if an analysis of the rock had been made. If the rock was a true perlite, there should be about 80 per cent. of silica. If the rock was altered, one might expect a large excess of magnesia. Prof. Ramsay said that the character of these lava-flows was evident even without microscopic examination. He recapitulated the evidence which had persuaded him of this when surveying the district, and expressed doubt as to the rocks at the base of the Cambrian in North Wales being true lava-flows. Dr. Hicks said he thought there was no reason why a perlitic structure should not occur in rocks of Bala age. He thought the first spherulitic rocks recognised in this country had come from rocks of Arvonian age at St. David's. Mr. Bauerman said that modern lava-flows often cover very large areas, as in North America and India; so the mere distance of the Wrekin from Wales would be no difficulty. Mr. Rutley doubted whether spherulitic structure was

always connected with vitreous. He did not see that the presence of magnesia would prove or disprove alteration. He did not think a rock could be vitreous if solidified at a great depth, since it would hardly be able to cool with sufficient rapidity.—The gold-leads of Nova Scotia, by Henry S. Poole, F.G.S., Government Inspector of Mines. The author remarked upon the peculiarity that the gold-leads of Nova Scotia are generally conformable with the beds in which they occur, whence Dr. Sterry Hunt and others have come to the conclusion that these auriferous quartz veins are interstratified with the argillaceous rocks of the district. With this view he does not agree. He classified the leads in these groups according to their relations to the containing rocks, and detailed the results of mining-experience in the district, as showing the leads to be true veins by the following characters:—(1) Irregularity of planes of contact between slate and quartz; (2) The crushed state of the slate on some foot-walls; (3) Irregularity of mineral contents; (4) The termination of the leads; (5) The effects of contemporary dislocations; (6) The influence of strings and offshoots on the richness of leads. The author further treated of the relative age of the leads and granite, and combated the view that the granites are of metamorphic origin, which he stated to be disproved by a study of the lines of contact. He also noticed the effects of glaciation on the leads, and the occurrence of gold in carboniferous conglomerate.—On conodonts from the Chazy and Cincinnati groups of the cambro-silurian, and from the Hamilton and Genesee-shale divisions of the devonian, in Canada and the United States, by G. Jennings Hinde, F.G.S. After a sketch of the bibliography of the subject, the author described the occurrence of conodonts. In the Chazy beds they are associated with numerous *Leperditiæ*, some trilobites, and gasteropods; in the Cincinnati group with various fossils; and in the devonian strata principally with fish-remains; but there is no clue to their nature from these associated fossils. They possess the same microscopic lamellar structure as the Russian conodonts described by Pander. The various affinities exhibited by the fossil conodonts were discussed; and the author is of opinion that though they most resemble the teeth of myxinoid fishes, their true zoological relationship is very uncertain. The paper concluded with a classification of the conodonts from the above deposits.—On annelid jaws from the cambro-silurian, silurian, and devonian formations in Canada, and from the lower carboniferous in Scotland, by G. Jennings Hinde, F.G.S. After referring to the very few recorded instances of the discovery of any portions of the organisms of errant annelids as distinct from their trails and impressions in the rocks, the author noticed the characters of the strata, principally shallow-water deposits, in which the annelid jaws described by him are imbedded. A description was given of the principal varieties of form and of the structure of the jaws. They were classified from their resemblance to existing forms under seven genera, five of which are included in the family Eunicea, one in the family Lycoridea, and one among the Glycerea. The author enumerated fifty-five different forms, the greater proportion of which are from the Cincinnati group.

Meteorological Society, March 19.—Mr. C. Greaves, F.G.S., president, in the chair.—The following were elected Fellows of the Society:—R. Burniston, W. H. Crawford, J. Davies, The Earl of Derby, H. Downs, S. Egar, J. S. Hodgson, S. Hollins, T. M. Hopkins, H. Horncastle, C. W. Johnson, E. M. Nelson, and F. Wilkin.—The papers read were:—Dew, mist, and fog, by George Dines, F.M.S. The author has during the last two years made a number of experiments to determine the amount of dew that is deposited on the surface of the earth. The plan adopted was as follows:—Glasses similar to ordinary watch-glasses were procured; the surface area and the weight of each was ascertained. These glasses were exposed to the open air in the evening, being placed on different substances, viz., on grass, on slate, and on a deal board, the two latter being raised a few inches above the grass. A minimum thermometer was generally placed by the side of each glass. It is only on rare occasions that an amount of dew exceeding the 0·010 inch in depth has been deposited upon the measuring glasses, and out of 198 observations, in only 3 has that amount been exceeded. Fifty-eight observations give the amount from 0·010 to 0·005 inch: 107 from 0·005 to 0·001 inch; 22 less than 0·001 inch; and 8 observations no dew at all. The author thinks it may be fairly assumed that the average annual deposit of dew upon the surface of the earth falls short of 1·5 inch. There are two kinds of mist, the morning and evening; the morning mist is caused by the evaporation from the water and the moist ground taking place faster than the vapour is taken away; the air becomes saturated, but this does not stop the evaporation; the vapour continues to rise into the air, is there condensed, and forms mist, which gradually spreads over a wider surface. The evening mist is produced as follows:—The cold on the grass caused by radiation lowers the temperature of the air above it; the invisible vapour of water previously existing in the air is in excess of that which the air can retain when the temperature is lowered; the surplus is condensed, becomes a mist-cloud, and floats in the air just above the surface of the grass. Taken either separately or combined, the mists appear to the author totally and altogether inadequate to account for those dense fogs which at times overspread large tracts of country. Dense fogs near the earth are often accompanied by a clear sky above, when the sun may be seen reflected from the gilded vanes of our public buildings. After long consideration the author is inclined to attribute these fogs to some cause at present unknown to us, by which the whole body of the air to some distance above the surface of the earth is cooled down, and, as a consequence, part of the vapour in that air is condensed and forms what has been called an "earth-cloud."—On the inclination of the axes of cyclones, by the Rev. W. Clement Ley, M.A., F.M.S. The object of this paper is to call attention to the evidences recently afforded by the results of mountain observations to the theory that "the axis of a cyclone inclines backwards." The author first reviews the state of the question up to the present time, and details his own investigations, chiefly founded upon the movement of cirrus clouds; he then refers to Prof. Loomis's recent "Contributions to Meteorology," in which is discussed the observations at the summits and bases of several high mountains, the results of which fully confirm the theory that the axis of a cyclone inclines backwards. The discussion on this paper was adjourned till the next meeting.—Contributions to the meteorology of the Pacific. No. III. Samoan or Navigator Islands, by Robert H. Scott, F.R.S.

Physical Society, March 22.—Prof. W. G. Adams, president, in the chair.—New Member, Capt. Hastings R. Lees, R.N.—Capt. Abney, R.E., F.R.S., read a paper on obtaining photographic records of absorption spectra. Absorption spectra have hitherto been recorded by the difficult method of hand-copying; but the discovery by Capt Abney of a silver salt sensitive to all rays in different degrees renders the photographic method available. The records thus obtained are photographs of the spectrum of the naked light of the source and of that of the same light reduced by insertion of the absorbing material in its track, and these are taken parallel, so that the dark absorption lines can be readily compared. Examples of these were thrown by him on the screen. This method can be used as a new weapon in attacking solar physics and determining whether or not compound bodies exist in the sun. Absorption spectra to compare with the sun can be got for compound bodies by burning the matter in question in a flame in front of the slit and passing a bright light through the flame.—Prof. Guthrie, F.R.S., then read a paper on the fracture of colloids, as illustrated by experiments on the breakage of glass plates either by pressure or heating at the centre or round the circumference. Circular plates of glass, pressed at centre or circumference, break in radial lines. However supported, a plate breaks in the same fashion if heated in the same way. If heated in the middle the crack is peak-shaped, like an obelisk on a double pedestal, two cracks forming the outline, with sometimes a third down the middle. The two cracks unite before they reach the edge on one side, and (as afterwards pointed out by Prof. W. G. Adams) the three extremities of the two cracks all meet at right angles to the edge. The crackage varies with the size and shape of the plates, the flame, and kind of glass; but the type is the same for all. Cracks cross each other. Prof. Guthrie defined a crack as the line where the ratio of cohesion to strain is least, and likened it to the lightning flash. Mr. W. Chandler Roberts, F.R.S., said that he had observed once a volute spiral crack in dried hydrated silicic acid, and recommended Prof. Guthrie to study cracks in agate, which is the most perfect colloid known.

Geneva

Society of Physics and Natural History, November 6, 1878.—M. Raoul Pictet read a paper on temperature and on the general synthesis of all calorific phenomena. The purpose of this research is to prove the absence of rigorous definition of the word "temperature," the *petitio principii* on which the construc-

tion of all thermometers rests, and the confusion which exists in most of the treatises on physics between the terms: heat, sensible heat, latent heat, and temperature.—M. Arthur Achard described certain considerations relative to the useful effect of magneto-electric machines, and spoke especially on some experiments made by Prof. Hagenbach of Bâle with a Gramme machine (see *Archiv des Sc. Phys. et Nat.*, vol. lxiv. p. 332).—Prof. Schiff spoke of the electric currents observed in animals. Most of them proceed from the glands of the skin, which are veritable electrical apparatus. If we destroy the skin or cauterise it, currents are produced which are attributed to the muscles, but which proceed from the movements of the animal. The observations were made on the protics.

November 21, 1878.—Prof. Soret communicated the results of his researches on absorption spectra by means of the eye, especially with respect to ultra-violet radiations. He operated on the eyes of oxen and calves, and he found that the ultra-violet radiations were transmitted as far as the S line. The aqueous humour allows them to pass as far as V. The vitreous substance has a transparency much greater than the aqueous humour.—M. Raoul Pictet presented several considerations on the passage to a liquid state of compressed gases, and in that state the limit which is produced for each gas at a certain pressure and a certain temperature.

December 5, 1878.—M. J. M. Crafts showed a new thermoscope, a description of which he recently published, and the air-reservoir of which is only $\frac{3}{10}$th of a cubic centimetre. From experiments made with this instrument he concludes that the physical characteristics of different bodies are much less dissimilar at high than at low temperatures.—Prof. Schiff experimented before the Society on a seismograph of M. Ziegler, consisting of a tube of gold-beater's skin, with which he envelopes the member whose variation of volume he wishes to measure, corresponding to the beatings of the pulse. This large tube communicates its impressions to a registering apparatus by means of a very narrow tube.—Prof. Joh. Müller gave an account of very delicate microscopic observations made by him and M. Minks on lichens, and overthrowing definitely the theory of Schwendler (See *Arch. des Sc.* Jan. 1879, p. 49).

PARIS

Academy of Sciences, March 24.—M. Daubrée in the chair.—The following papers were read:—On the slow changes undergone by wine during its conservation, by M. Berthelot. These observations relate to bottles of port 100 and 45 years old respectively, which the author analysed. *Inter alia*, the cane-sugar in the older wine had disappeared almost completely; and there was very little in the other. The wines must have lost more than a fourth of their acidity through etherification. The amount of cream of tartar was much under the normal solubility. The alcohol was in like proportion to that of recent port, there had been little change in it, therefore, probably. As to gases, one litre of the wine contained 12·4 cc. oxygen, and 32·3 cc. nitrogen, without carbonic acid; corresponding to normal saturation of the wine by the gases of air. In saturation with oxygen this old wine contrasts with recent Burgundy wines, which have no trace of it in solution, but which contain CO_2, while the old ports have parted with this through diffusion.—Remarks on some points of crystallogy, by M. Lecoq De Boisbaudran. He makes inferences from the unequal resistances of different faces of a crystal to change of state. The solubility of the crystal must vary with its exterior form. The peculiar mode of regeneration of mutilated crystals is easily explained; also the influence of rapidity of growth on relative development of the different parts of a crystal, &c.—Communications on several geographical questions, by M. de Lesseps. These relate to inter-oceanic canals and a conference on the subject, to be held in Paris on May 15; news from M. Soleillet on the banks of the Niger, and from Serpa Pinto, announcing important discoveries on the course of the Zambesi; news also from M. Roudaire at Gabes.—Addition to a previous note on damming the Tiber at Rome, by M. Dausse.—Observations of Brorsen's periodic comet, by M. Tempel.—Formulæ relating to perturbations of planets, by M. de Gasparis.—On resolving equations, by M. Pellet.—On the solution in whole numbers of the equation $(1) aX^4 + bY^4 + dX^2Y^2 + fX^3Y + gXY^3 = cZ^2$, by M. Desboves.—Molecular vibrations in magnetic metals during passage of undulatory currents in these metals, by M. Ader. Such vibrations are thus had in all the magnetic metals, and give articulate sounds. To have them in all their intensity, a mechanical action must be opposed to the wires or bars, especially the inertia of two heavy masses at their extremities. The effects of these electrodynamic vibrations, and the conditions of mechanical actions to be opposed to the bars are quite the same as those the author has indicated for electro-magnetic molecular vibrations.—On ytterbine, the new earth of M. Marignac, by M. Nilson.—On *scandium*, a new element, by M. Nilson. The preparation of ytterbine (which he describes) furnished a substance with molecular weight 127·6 instead of 131, indicated by M. Marignac; and M. Nilson was led to suspect the presence of another earth, of lower molecular weight, mixed with the product examined. The spectroscope favoured this idea, and M. Thalen indicates the lines proper to the spectrum of the new earth. The name given to the new element is meant to recall its presence in gadolinite or euxenite minerals, found only in the Scandinavian peninsula hitherto. The atomic weight is under 90. M. Nilson remarks on some of its chemical properties.—On the cyanosulphite of potassium, by M. Etard.—Thermochemical study of alkalino-earthy sulphides, by M. Sabatier.—On various alcoholic iodides and bromides, by MM. De Montgolfier and Giraud.—On the formation of aurine, by MM. De Clermont and Frommel.—On the presence of lithine in rocks and in the waters of seas; consequences relative to saliferous strata and to certain classes of mineral waters, by M. Dieulafait. Lithine is as widely distributed as soda and potash, and accompanies these two bases in all rocks of primordial formation. It exists in the Mediterranean and other seas in such quantity that it can be recognised in the residue of evaporation of even one cubic centimetre. It concentrates notably in the sediments of salt marshes. Marls in small quantity give an intense spectrum of lithine. All waters mineralised in the primordial formation contain lithine, and all waters distinctly saline contain it in exceptional proportion.—Resistance of germs of certain organisms to the temperature of 100°; conditions of their development, by M. Chamberland. He describes two forms of *Bacillus*, whose germs have this resistance; boiling water several minutes or even an hour will not kill them.—On the presence in the blood and tissues, under spheroidal form, of certain liquids not miscible in water and which have penetrated through the lungs, by M. Poincaré. Spirit of turpentine and nitrobenzine are among the substances observed to have this effect. The fact bears on respiration of noxious vapours by workmen.—Anatomical and physiological study of nectaries, by M. Bonnier. He rejects Darwin's theory of the *rôle* of nectaries. Nectariferous tissues, floral or extra floral, emitting a liquid or not, form special nutritive reserves in direct relation with the life of the plant.—Experimental researches on the conditions of growth of root hairs, by M. Mer.—On a new disease of the Rubiaceæ of hothouses, by M. Cornu.—On halos and parhelias seen in the park of Saint Maur, by M. Renou.—On the unity of forces in geology, by M. Hermite.

JOHANNES MUELLER'S CLASSIFICATION OF PASSERES

Johannes Müller on Certain Variations in the Vocal Organs of the Passeres that have hitherto escaped Notice. The Translation by F. Jeffrey Bell, B.A. Edited, with an Appendix, by A. H. Garrod, M.A., F.R.S. (Oxford, at the Clarendon Press, 1878.) 4to. Plates.

MORE than thirty years ago was this celebrated treatise, now translated by Mr. Bell, published, but without attracting any notice in this country. It is true that some twelve months after the author's investigations were first communicated to the Academy of Sciences of Berlin (June 26, 1845), a brief abstract of them appeared in what was then, as it still is, our leading biological magazine (*Ann. Nat. Hist.*, xvii. p. 499), but no one here seems to have thought them worthy of further attention. Indeed, the principal British ornithologists had so long gone astray in pursuit of that will-o'-the-wisp—the "Quinary System," which seemed to have been revealed to the obscure vision of Vigors, and had so completely mystified themselves with hazy speculations concerning circles, types, affinities, and all the jargon of what was so loudly proclaimed to be *the* "Natural Arrangement," that it would have been hopeless to expect them to return to the paths of common sense. Their successors had to make the best of what was before them, and that best was obviously to leave it alone: for they doubtless found, even as we find to day, that all which had been written by the Quinarians was hopelessly unintelligible.[1] Preached, however, as this doctrine constantly was, amid terrific maledictions on all who hesitated to receive the "Circular System" as the orthodox faith, they were content to let its results pass unquestioned, and thus the "Natural" Orders and other groups, which were the invention of Vigors and some of his followers, were silently accepted, and they continued to be adopted by most British ornithologists until very recently, if indeed they have now gone wholly to their rest. There is nothing extraordinary in all this. No disputant is so difficult to overthrow as a mystic, and a mystic your Quinarian certainly was. He could, moreover—and the fact is worthy of note, since mystics are seldom so highly accomplished—write long and smooth sentences, irreproachable as to style or grammar, generally not deficient (allowance being made for certain false premisses) in logical arrangement, sometimes distinctly marked by wit, and always abounding in metaphor. They only lacked a plain meaning. If you pleaded that it was not easy to distinguish the boundaries of the metaphorical and the real, he politely intimated in reply that you were an ass, and deluged you with another torrent of mystic verbiage of the same kind. On raising further objection, your Quinarian began to lose his temper, and, metaphorically shaking "a bunch of fives" (namely, his fist) in your face, discharged at you a volley of well-assorted epithets, about the reality of which there could be no doubt. This is absolutely no exaggeration of some of the characteristics of the Quinarian controversy which may be found in certain publications since 1823, when Vigors unhappily began to apply to Ornithology the senseless fantasies which Macleay had a short time before evolved from the depths of his own imagination. Good work, very good work, was no doubt being done in the meanwhile by some British ornithologists, but the good work was wholly of a limited and special kind. Generalised or broad views were either not taken at all, or, if attempted, were propounded by men of comparatively poor ability, men who were unable to see their way through the baleful fogs that the Quinarian magicians had conjured up around them. It is not too much to say that for some forty years British ornithologists were wandering in a wilderness of words. Temminck's "Manuel d'Ornithologie," the second edition of which was published in 1820, and speedily became well known in England, it is true, kept some, who regarded it as a kind of gospel, from being utterly bewildered by the cloudy dreams of the Quinarians, for Temminck was a simple-minded Dutchman, who had no philosophical or pseudo-philosophical theories to support, no circular visions to relate, and no metaphorical phrases wherewith to encumber his statements. He wrote in French, and if his language appeared to Vieillot not to be the pure French of the Académie Française, it was easily understood by most Englishmen, and he consequently exercised an enormous influence on their mind—an influence which in time produced evil effects, though that is at present no business of ours to show.

During this period of darkness in England there were, however investigators in other lands pursuing what is now obvious to all to have been the right road. Unfortunately their investigations were published so as to be practically inaccessible to our countrymen, and the results at which they arrived were utterly unknown to British ornithologists. Thus we find Strickland, by far the best-informed man of his calling and time, saying, in 1844, that the labours of Wagler[1] and Nitzsch "have not fallen under my inspection." Accustomed as we are in these days to the rapid exchange of publications with our continental brethren, we might regard this at first sight to be a grave shortcoming, but commercial and postal facilities of intercourse with fellow-workers in foreign countries did not exist, and we are prepared to maintain that no very great blame is to be ascribed to British ornithologists of that epoch for not knowing what was being done abroad. The fault lay beyond them. There was first the heavy import duty on foreign books, which pre-

[1] The Quinarian system has so completely dropped out of use, that readers of this generation may be at a loss to find out what it really was. We therefore present them with the following "Symbolum Fidei," drawn up by a very orthodox Quinarian (Mr. Neville Wood), in 1836, in the hope that it will convey clear ideas to them:—"The first and fundamental principle inculcated by Macleay and his disciples is, that all nature moves in a circle, and that the series of beings is unbroken; and, secondly, that each group and each species has a double affinity. Every one of the higher groups has a binary division, viz. the normal or typical, and the aberrant, the former containing two, and the latter three, of the five subdivisions of which each of the higher groups is composed. We cannot here explain the doctrine of *analogy*—which is wholly distinct from affinity—but we can give an instance of it:—the Hedge Dunnock in the *Sylviadæ* represents the House Sparrow in the *Fringillidæ*; that is, the one bears the same relation to the *Sylviadæ* that the other does to the *Fringillidæ*, and *hence* they are said to bear an analogy to each other. The whole zoological series, before arranged in a simple chain, according to this system revolves in an almost infinite number of circles around man, from whom they may be said to degrade on all sides." It is pleasing to observe that a little further on the author states that "no one who supposes the Quinary System, or any part of it, to lead to Atheism, can rightly understand its principles."—*Ornithologist's Text-book*, pp. 30, 31.

[1] Referring probably to his "Natürliches System" of 1830, for his "Systema Avium" of 1827 had long before been reviewed in England (*Zool. Journ.* iii. p. 465).

vented international booksellers from existing, and made it far more difficult to obtain in London a work published in Paris or Leipzig than it now is to get one that has been printed in Chili or Japan. Next—perhaps it should have been placed first—there was the lamentable fact that so defective was English education, that few boys were taught to read a book in any modern language but their own. Enormous time was wasted at school over Greek and Latin, which, owing to the senseless method of teaching, were, as now, scarcely ever taught to any useful purpose. A smattering of French was sometimes picked up by boys when at home for the holidays, but that was all. German was an utterly unknown tongue. All this is of course notorious. To the ordinary English gentleman it mattered nothing, nor did it signify very much to the literary man, but on the man of science its effect was disastrous, and especially was it so to the naturalist. Most of Cuvier's works had been, it is true, translated, so they were open to all, but this was a very exceptional case. Probably no British ornithologist had ever heard of Merrem, Tiedemann, or Meckel; assuredly no British ornithologist was acquainted with their writings. Yarrell, Macgillivray, and Blyth had each made some advance in certain directions, and the last two were unquestionably not fettered by Quinarian bonds, but their advance was rather that of scouts than that of permanent occupiers. Later came Nitzsch, Dr. Cabanis, and the illustrious author of the work under review—in Germany, and—in Sweden, Sundevall; but still no effect was produced on our insular mind.

It was Nitzsch who first began the great work of critically examining the Linnæan Orders, *Passeres* and *Picæ*—the very names of which had passed out of use and were well nigh forgotten in this country, being superseded by the term *Insessores*. In his anatomical contributions to Naumann's excellent "Vögel Deutschland's," a work still far from being appreciated in England, in his treatise on the Carotid Artery of Birds—which unfortunately yet remains in the obscurity of its original Latin, and much more completely in his "Pterylographie"—edited after his death by Dr. Burmeister, and only translated into English for the Ray Society in 1867—the most important structural differences and affinities between the various forms so classed by Linnæus were clearly shown. The Order *Passeres* (or *Passerinæ* as Nitzsch called it) was revised and reconstructed, some genera being added and others excluded, while a majority of the Linnæan *Picæ* became the *Picariæ* of Nitzsch—a very heterogeneous assemblage it must be allowed—the old name being unsuitable, since the genus *Pica* was found to be truly Passerine. But Nitzsch had the opportunity of dissecting but few if any of the New-World forms, and consequently he did not know that many American *Passeres* differed essentially from those of the Old World in the structure of their vocal organs. This fact it seems was first ascertained by Macgillivray,[1] but he did not see its importance, which was really recognised by Müller, and the latter's discovery was the cause of the treatise now translated for us after so many years by Mr. Bell, and edited by Mr. Garrod.

[1] Müller in the work under review (Transl., pp. 5 and 6) makes the mistake, which his translator or editor might, we think, have corrected, of attributing the anatomical portions of the "Ornithological Biography" to Audubon! They are admittedly by Macgillivray, who is known to have also helped largely in the composition of that work.

Though ornithologists have by no means followed up Müller's investigations as they deserved, the period that has elapsed since their publication has not been altogether idly passed, and Mr. Garrod has enhanced the value of his coadjutor's translation by adding thereto an appendix bringing the knowledge of the subject almost "up to date," and incorporating the results of his own labours thereon. Müller, however, was no more free from error than his predecessors had been. He divided his "*Passerinen*"—to which he applied the Vigorsian title of *Insessores*—into three tribes:—(1) the *Oscines* or *Polymyodi*, "having the lower larynx formed partly by the trachea and partly by the bronchi, and possessing five or six pairs of muscles attached to the end of certain of the bronchial rings"; (2) the *Tracheophones*, "with the lower larynx formed exclusively by a modification of the lower part of the trachea"; and (3) the *Picarii*, "with the larynx either partly tracheal and partly bronchial, or wholly bronchial and with not more than three pairs of muscles."[1] The *Picarii* of Müller, however, form a group not quite commensurate with the *Picariæ* of Nitszch, and this is a point to which attention should be directed, as, owing to the very slight difference between the two names, one has been frequently written for the other, and the two groups deemed to be identical. Nitzsch very properly excluded what are now known as the *Tyrannidæ* from his *Picariæ*, while Müller, as improperly, included them among his *Picarii*. Both authors also erred in their conception of the family *Ampelidæ*, which, in the sense in which it is used by them comprises two very distinct groups, the *Ampelidæ* proper and the *Cotingidæ*. Nitzsch, whose experience had lain with the single European representative of the former, placed the family among his *Passeres*, while Müller, judging it would appear from the New-World genera, which are now more rightly held to compose the *Cotingidæ*, referred the family to his *Picarii*. It is nowadays abundantly clear that the true *Ampelidæ* are very normal *Passeres*, while the *Cotingidæ* are not *Passeres* in the most restricted sense. But it is impossible for us here to go into details. Mr. Garrod's appendix will show how and to what good purpose he, with the abundant opportunities he has enjoyed, has followed Müller's line of research, and has greatly extended it. We certainly wish he had more explicitly set forth, in a tabular form for instance, the general results of his continuous investigations. The want of some such summary is the only serious complaint we have to make against this book; and, regretting as we do its absence, we think we can perceive what has possibly been the motive of his abstention—his consciousness that there is yet much more to be done, that few conclusions drawn at present can be otherwise than general, and that fewer still can be final. On one important point, however, he corroborates what we imagine to have been a singularly interesting discovery of Prof. Huxley's, namely, the divergence of *Menura* (the Lyre-bird) from almost all the other *Passeres*, its only relative (and the relationship can hardly be very close) being *Atrichia*.

Our sincere thanks, and those of every English-speaking ornithologist, are due to all concerned in this book—to Mr. Sclater, whose influence with the Clarendon Press

[1] These definitions are taken from Prof. Huxley (*Proc. Zool. Soc.*, 1867, p. 471), being expressed with his usual admirable terseness.

Delegacy caused it to be undertaken; to Mr. Bell, who seems to have very efficiently performed the actual task of translation;[1] to Mr. Garrod for the Appendix already mentioned; and last, though not least, to Prof. Peters for supplying the use of the very plates which illustrated Müller's work.

OUR BOOK SHELF

Proceedings of the London Mathematical Society, vol. ix. (November, 1877, to November, 1878.) 279 pp. (Hodgson and Son, Gough Square, 1879.)

WE have, in previous notices, indicated the character of the papers contained in former volumes, and the same remarks apply equally well to the volume before us. We shall content ourselves, in our present notice, with giving the titles and author's names only of the more important papers.

Prof. Cayley, not so large a contributor as usual, furnishes a short paper "On the Geometrical Representation of Imaginary Quantities, and the Real (m, n) Correspondence of Two Planes," and another equally short, "On the Theory of Groups." There are brief notes "On a Generalised Form of Certain Series," by Mr. Glaisher; "On the Transformation of Elliptic Functions," by Dr. Klein, of Munich; "On Certain Extensions of Frullani's Theorem," by Mr. C. Leudesdorf; "The Flexure of Spaces," by Mr. C. J. Monro; "On the Relation between the Functions of Laplace and Bessel," by Lord Rayleigh; "Notes on Normals," and "The Decomposition of Certain Numbers into Sums of Two Square Integers by Continued Fractions," by Mr. S. Roberts. Longer papers are: "On the Singularities of the Modular Equations and Curves," by Prof. H. J. S. Smith; "On Partial Differential Equations with Several Dependent Variables," and "On a General Method of Solving Partial Differential Equations," by Prof. Lloyd Tanner; "A Method in the Analysis of Plane Curves," by Mr. J. J. Walker; "On Conjugate Four-piece Linkages," by Mr. A. B. Kempe; and "A New Method of finding Differential Resolvents of Algebraical Equations," by Mr. R. Rawson. M. Halphen contributes a long and valuable paper on "The Characteristics of Systems of Conics."

Physical papers are "On the Electrical Capacity of a Long Narrow Cylinder, and of a Disk of Sensible Thickness," by Prof. J. Clerk Maxwell; "On the Conditions for Steady Motion of a Fluid," by Prof. Lamb; "Notes on the Solution of Statical Problems connected with Linkages and other Plane Mechanisms," by Prof. A. B. W. Kennedy; "On the Astatic Conditions of a Body acted on by given Forces," by Prof. Minchin; and "Progressive Waves," by Lord Rayleigh. Mr. H. McColl contributes a paper in two parts bearing on logic and probabilities, viz., "The Calculus of Equivalent Statements."

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

Brorsen's Comet

I OBSERVED Brorsen's comet, about 8h. on March 29, through a whitish haze that extinguished the small stars near it. It appeared about the seventh magnitude, by estimation 3′ in diameter, its light very much condensed in the centre and approximately circular.

On April 4 I obtained the following places, although the moonlight much diminished its brilliancy:—

1874.		G.M.T. h. m. s.		App. R.A. h. m. s.		App. decl. ° ′ ″
April 4	...	8 29 59	...	2 56 53·7	...	+ 25 42 36
,,	...	8 38 31	...	2 56 55·3	...	+ 25 42 56

At the first observation the comet was compared with the star Arg. + 25°, No. 485; at the second with Arg. + 25°, No. 496 (Bonn Obs., vol. vi.). The observations admit of more accurate reduction.

The correction to the ephemeris of Herr Schulze (reproduced in NATURE, vol. xix. p. 510) is—

In R.A. ... ... − 5ˢ·0 | In decl. ... ... − 31′ 20″

On both evenings when the equatorial was set to the position given in the ephemeris (with Strasser's correction, A.N. 2250) the comet was not in the field of a low power. The above correction to the declination may prevent loss of time in finding the comet.

G. L. TUPMAN

1, Vanbrugh Park, Blackheath, April 6

Madagascar Forms in Africa

A PARAGRAPH in a recent number of NATURE (p. 470) mentions the discovery of a new species of *Ouvirandra* in Eastern Africa, the genus being hitherto supposed to be peculiar to Madagascar. The plant in question, which was collected by Dr. Hildebrandt, is, however, as has been pointed out by Dr. Trimen and myself (*Gardeners' Chronicle*, February 1, p. 149), not a species of *Ouvirandra*, being destitute of the fenestrated leaves, which is the only distinguishing character of that not very sound genus. It is, in fact, a well-known and widely-distributed African plant, *Aponogeton leptostachyus*, E. Mey. Dr. Hildebrandt, when lately in this country, fully assented to this identification.

A more novel fact in the same connection is the discovery by my colleague, Prof. Oliver, of a new monimiaceous plant amongst the collections of Gustav Mann in East Tropical Africa. The order itself, though represented in Tropical America and Asia, has hitherto been unknown in Africa, although the Mascarene Archipelago is well supplied with species, and one at least is known from the Comoro Islands, whence its remarkable fruit was sent to the Kew Museum by Dr. Kirk.

W. T. THISELTON DYER

Transportation of Seeds

IN NATURE, vol. xvii. p. 390, which through the carelessness of my agent has only just reached my hands (together with the numbers for August, September, October, and part of November), I see Mr. Francis Darwin notices the penetration of certain grass seeds through the skin of sheep. It may interest him and your readers to know that I can corroborate this from what I have witnessed here and at the Cape of Good Hope.

In passing a butcher's shop in Noumea, lately, I was struck with the appearance of a fore-quarter of mutton. On a closer examination I found it so full of grass-seeds that it resembled a ham just unpacked from its bag of chaff. Many of the seeds had still their long thin tails drawn through the flesh like threads interlacing each other in every direction. On questioning the butcher, he said they rarely killed a sheep that was not more or less punctured.

All our sheep are imported for slaughter from Australia or Norfolk Island. This particular one came from the former place.

At the Cape of Good Hope I have skinned "spring-bucks," in which the shanks were pierced through and through with these "awms" and small thorns. My wonder has been how the animals could endure the pain of moving, but I suppose they do not suffer as we do.

E. L. LAYARD

British Consulate, Noumea, New Caledonia, February 1

Rayons de Crépuscule

WHAT does Mr. Abbay call (vol. xviii. p. 540), the "low country" in Ceylon? If he means the sea-board generally, I

[1] We might take exception, perhaps, to his rendering of the title, which, we think, might have been more literally and better expressed by "On the Hitherto Unknown Diversities of Type in the Singing Organs," &c.

can assure him that, while magistrate at Point Pedro, five-and-twenty years ago, I used almost nightly to see "rayons de crépuscule" in the most glorious perfection for months together. Point Pedro is the extreme northern point of the island, with a splendid sea horizon. I shall never forget the beauty of the tints.

E. L. LAYARD

British Consulate, Noumea, New Caledonia, February 1

Salmon in Rivers of the Pacific Slope

IN a notice of the Report of the U.S. Commissioner of Fish and Fisheries, in NATURE, vol. xix. p. 430, the reviewer refers to the statement in a "memorandum respecting the American salmon and white fish recently introduced in New Zealand by Dr. James Hector," that "so far as yet observed, the adult fish all die after spawning and never return to the sea." The reviewer writes: "We shall be glad to have some authoritative statement with regard to the above fact, as without some explanation it seems too extraordinary for belief."

Dr. Hector in the above remark refers to the so-called "Californian Salmon" (*Salmo quinnat*) when in its native waters. There must be some exceptions to the rule as above stated, for Mr. Livingstone Stone, in his evidence in the same volume (p. 806), testifies that in the Columbia full-grown fish of this species are caught in considerable numbers, nearly exhausted, on the *back* of the drift-nets, in July and August, but it is nevertheless almost strictly true.

In the Fraser River, British Columbia, the general opinion is that the salmon never return to the sea except accidentally in a dying state. The Indians, who are generally well informed on such points, affirm this. The late J. K. Lord, in his "Naturalist in British Columbia," (vol. i. p. 40, *et seq.*), is very clear on the same point. It is, moreover, almost certain from the tumultuously rapid character of the Fraser, that the salmon hatched in its upper waters—in some instances 600 miles from the sea—never return there till mature and ready to spawn, and that this act is their last. They show no disposition to attempt to go back to the sea. I have seen them in great numbers in small streams tributary to the North Thompson, in August, spent, their silvery colour turned to a livid red (with the exception of the fins and tail, which are darker) but still heading persistently up stream, and continuing to do so, till from sheer weakness the current carried them away. In fording the brooks, the disturbance of the water causes those possessing sufficient vitality to scatter in all directions, but interrupts only for a moment their dogged struggle. At this season, in most years, dead salmon in great numbers are found floating down the stream, or stranded on the bars and banks of the river.

In Okanagan, Shuswap, and other lakes, there is a smaller fish, which may be a "land-locked" salmon, but of which I was not able to preserve specimens. The Indians say that it does not come from the sea, but lives in the deep waters of the lake, till in August it enters certain streams to spawn. Like the salmon it becomes, when spent, first blotched with pale red, and eventually altogether of that colour and without silvery lustre, the flesh at the same time losing its pink tint. It possesses the same instinct of struggling against the stream till it dies. I have seen them in brooks within a stone's throw of the lake, endeavouring with their remaining strength to keep themselves from being carried back into it.

Lord makes an exception of the "fall" or "dog-tooth" salmon (*S. lycaodon*), of which he supposes some go back to the sea, and return to the rivers in following years. It remains, however, an undoubted fact, that by far the greater part of the prodigious number of salmon entering the Fraser every year, perish. The fish appears to refuse food, and is not caught in the river by bait or fly, though frequently taken by trolling with fish or spoon-bait in the salt water.

It is much to be desired that a systematic investigation of the species of salmon frequenting the Fraser and other rivers of British Columbia should be made, embracing their habits and the course of their migrations. The subject is an interesting, but very intricate one.

GEORGE M. DAWSON

Geological Survey of Canada, Montreal, March 27

The Marsupials of Australia

THE peculiarities of the structure of the marsupials of Australia are so remarkable and their habits are so unlike those of the placentals of the Old World, that probably no apology is needed for venturing to lay before your readers a short account of one of these peculiarities possessed by certain genera, which I believe has escaped the observation of most naturalists, and may prove interesting to some of your subscribers.

The inferior maxillary or lower jaw-bone of almost all known mammals consists of two bones united together with more or less rigidity by a strong cartilage, which allows no play or independent movement whatever, and which practically firmly unites them into one bone.

The formation of the inferior maxillary of the Macropidæ, or kangaroos, is an exception, however, to this rule; instead of being united by a cartilage, the two rami of the lower jaw are jointed at their point of contact with a hinge somewhat resembling that upon which the two shells of a bivalve move, that is, upon corrugations which project from the two edges and fit accurately into one another.

These two rami extend a short distance beyond the point of contact, and into their terminations are fixed two long procumbent incisor teeth, the only two incisors possessed by this family in the lower jaw. Immediately in front of this joint, that is, at the root of the procumbent incisors, a circular muscle embraces the two rami of the jaw, the contraction of which has the effect of bringing the inner edges of the procumbent teeth together; upon its relaxation or the contraction of another set of muscles, placed probably at the extremities of the rami, where they hinge upon the facial bones, the incisors are separated the extreme distance allowed them by the ligaments around the joint. The action of separating the teeth is probably connected in some measure with the action of opening the jaws, as I not unfrequently found that when the mouth was widely opened, the teeth themselves became separated.

The muscular action of uniting the incisors may be said to be exemplified in the case of a pair of shears when the blades are closed by a grasp of the hand, and the force is applied between the fulcrum and the point of resistance.

In Prof. Owen's work upon the "Anatomy of the Vertebrates," the following passage appears, showing that he was aware of a certain looseness of connection of the two rami, but probably not aware of the completeness of the construction with its separate functions. After certain references to the wombat he says, "In other marsupials the rami of the lower jaw are less firmly united at the symphysis; they permit independent movements of the right and left incisors in the kangaroos, and in the opossum both the rami of the lower jaw and all the bones of the face are remarkable for the loose nature of their connections."

In the work upon "Odontography" by the same distinguished writer, various references are made to the lower incisors of the macropidæ, but his readers are in every instance led to believe that their trenchant margin is their outer edge, and I believe it has escaped his observation altogether, that the inner margin where the two teeth come in contact has the principal cutting edge.

Mr. G. R. Waterhouse was aware of the inner trenchant margin as in his "Natural History of the Mammalia," he refers to these incisors as having "cutting external and internal margins." Further on he says—"In *Macropus major* (and, perhaps, in some nearly allied species), the rami of the lower jaw are loosely attached at the chin, and at the apex they are free, and the animal has the power of slightly separating the lower incisors, so that their outer cutting edges are brought more closely in contact with the upper incisors than they otherwise would be." Were this, however, the only utility of the loose attachment at the symphysis, what function has the cutting inner margin to perform?

An examination of those incisors will disclose the following facts:—

If the jaw of one of the macropidæ is examined immediately after death, when the muscles are relaxed, it is found that the smallest pressure upon the base of the rami suffices to open the lower incisors to the extent of about one-fourth of an inch in larger specimens, and about one-eighth in the smaller Pademelons or Halmaturi. The inner edges of the procumbent teeth will then be seen to be sharp, but strongly supported by a considerable thickness of enamel immediately in rear of the edge, and when the teeth are united by the contraction of the muscles, they fit so perfectly throughout their whole length that they will grasp a hair at any point between the base and the apex. On the other hand, the outer margins of these teeth are blunt and somewhat rounded, and when the jaw is closed and at rest, instead of fitting on to the teeth of the upper jaw, as represented in diagrams in Owen's "Odontography," the

two procumbent teeth rest upon a pad or projecting palate which rises from the inner base of the upper incisors, and whose surface is nearly upon the level of the edges of the upper teeth themselves; the lower incisors, therefore, are only brought into contact with the upper incisors by protruding the jaw forward.

I have, moreover, examined many specimens of the *Macropus major*, or kangaroo, and of varieties of the Halmaturus known as wallabies and pademelons, when they have been mortally wounded and under the influence of the spasmodic muscular contractions which occur at the point of death, and I have repeatedly found that they will alternately open the two incisors to their full extent, and unite them again with the energy which characterises all the muscular movements of an animal in its death-struggle.

If a small object, for instance the blade of a knife, is inserted between the teeth when fully extended, the animal will immediately grasp it with its incisors, which he will do without closing the jaw, showing that the movement is not absolutely dependent upon the action of closing the jaws, although, as I have said above, I believe it usually accompanies it.

The Phalangists or Australian opossums closely resemble the macropidæ in their dental formation, but they possess partially-developed canines in the upper jaw, whilst the latter have none in either jaw except in very early life; but although these opossums have their two procumbent incisors similarly situated, they probably do not possess the power of utilising them in the same manner; I have examined some specimens, but have failed so far to find more than the looseness of connection at the symphysis referred to by Prof. Owen.

In the genus which is represented by the Phascolarctos or native bear of Australia, which possesses the same lower incisors but distinct canines in the upper jaw, this arrangement is certainly wanting, as the rami of the lower jaw are firmly united.

This remarkable formation of the lower jaw of these kangaroos and wallabies is possibly an interesting instance of the retention of a construction, and of a set of muscles in a class of animals which have constantly required their aid to sustain life, which in other families of the animal kingdom have become rigid by ossification and cartilaginous formations, and by atrophy of the muscles in consequence of disuse.

The great plains and deserts over which these marsupials wander in search of food afford an exceedingly precarious supply of pasture in consequence of droughts and bushfires, which not unfrequently follow a superabundance of herbage. These animals, by means of their procumbent teeth which they make use of as shears, are thus enabled to cut off any green shoots or half-buried remains spared by a scorching sun, and obtain nourishment where any grass-feeding placental would certainly starve.

It is in consequence, I believe, of the power which is by this means given to these marsupials of eating scanty pasturage closer to the ground than any other animal, that in the great pastoral districts of New South Wales and Queensland it has been found that they are far more destructive of food than any stock that can be put upon the land, and in places where wallabies and pademelons are exceedingly numerous, it is noticeable that the native grasses in the particular localities which they frequent become completely destroyed, and that such places remain ungrassed until fresh seed is scattered over them by the winds.

HENRY WELD BLUNDELL

Gordon Downs, Queensland, December 5, 1878

Measuring the Velocity of Sound in Air

THE following simple way of arriving at the velocity of sound in air occurred to me lately:—Standing on a straight staircase between two blank walls (brick, and papered), which I find to be $32\frac{1}{2}$ inches apart, I clap my hands. The effect from each clap is a brief musical sound, metallic in character, and of quite appreciable pitch. It arises, doubtless, from the disturbance travelling to and fro between the walls. The pitch I find to be, as nearly as possible, G sharp (in the fourth space). Now, the number of *complete* vibrations per second, corresponding to this note, seems to be about 205 (see Deschanel's "Natural Philosophy," p. 820). This implies that the disturbance, when I clapped my hands, made 410 excursions across the space per second. Consequently, $410 \times 32\frac{1}{2} = 13,325$ inches = 1,100 feet. This is exactly the number Deschanel gives as the velocity of sound in air at 50° (approximately our mean annual temperature).

M.

Snow Flakes

WHILST walking home on March 26, about one in the morning, snow began to fall very gently; but instead of the usual powdery or feathery appearance, each flake consisted of a distinct plate, in some cases perfect six-pointed crystals. I measured some of them, and the largest were as much as five-eighths of an inch across. On taking up a handful the appearance was still more remarkable; instead of the white opaque body one usually sees, the mass was pearly and semi-transparent, and so strongly resembling boracic acid, that I should have had some difficulty in distinguishing a handful of each substance by sight alone.

Near the lamps the effect was very beautiful, more especially when the road became covered, luminous points appearing in all directions, which scintillated like stars as one walked along, whilst many of the falling crystals reflected iridescent hues on nearing the ground.

When out of the town I ignited a piece of magnesium wire, and the effect was most brilliant.

It was a cold, dull night, barometer falling.

Burton-on-Trent FRANK E. LOTT

Rats and Water Casks

IN 1840, in a voyage from Sydney, *viâ* Madras, to London, about three weeks after leaving the latter, it was found that a number of water-butts, on their heads in the between-decks, were leaking. On examining them we ascertained that as many as ten or twelve butts had been perforated by rats; three or four were entirely empty from the leakage so caused, while the remainder contained ullages from about half to a few gallons. In every case the stave had been eaten through just above the chime hoop, and those which had been apparently most recently operated on had only been perforated so as to cause a slight weeping, while the empty ones showed an opening as large as an ordinary vent-peg hole. The rest of the voyage a tub placed in the square of the main hatchway was kept constantly supplied with water, besides one or more square tins of water on the main deck.

In the above voyage we stayed a week in Madras, and in loosing the foretop-gallant-sail on leaving, a rat and five or six young ones fell to the deck; and the sail was found to be so much eaten and full of holes, made to form and line the nest, that the sail had to be unbent and replaced.

Gurnet Bay, March 31 E. J. A'COURT SMITH

P.S.—The ship was the *Cornwall*, East Indiaman, Capt. Cow.

HEINRICH WILHELM DOVE

PROF. HEINRICH WILHELM DOVE was born at Liegnitz, Silesia, on October 6, 1803, and at the age of eighteen passed from the schools of that town to the Universities of Breslau and Berlin, where for the next three years he devoted himself assiduously to the study of mathematics and physics. In 1826 he took his degree of Doctor of Philosophy, his thesis on the occasion being an inquiry regarding barometric changes; and it is further significant of his future life-work that his first published memoir was a paper on certain meteorological inquiries relative to winds, these two subjects holding a first place in the great problem of weather-changes.

Dove began his public life as tutor and Professor at Königsberg, where he remained till 1829, being then invited to Berlin as supplementary Professor of Physics. His strikingly clear-sighted, bold, and original intellect turned instinctively to that intricate group of questions in the domain of physics which comprise the science of meteorology, and his success in these fields as an original explorer was so marked and rapid that he soon achieved for himself a seat in the Royal Academy of Sciences, and some time thereafter was raised to the distinguished position of the Chair of Physics in the University of Berlin.

Among the scientific and fashionable circles of Berlin he took first rank as a lecturer, the combined qualities of accurate science, fine imagination, lucidity of style, com-

manding presence, and the extent over which his utterances were heard, marking him out as the Arago and Brewster of Germany. Germany showered on him in profusion those honours and offices which it gracefully and gratefully bestows on learning and science; and perhaps there is no learned or scientific society of any note that has not the name of Dove enrolled among its honorary members. After a protracted and hopeless illness he died on Sunday last, April 6, in the seventy-sixth year of his age.

In the Royal Society's Catalogue of scientific papers, the lists under Dove specify 234 memoirs written between the years 1827-73. These show him to have been a successful worker and investigator in electricity, optics, crystallography, and in such practical matters as measures and the art of measuring, or the metric system of civilised nations. But it was to meteorological inquiries he devoted his full strength and all the powers of his mind, and, by his herculean but well-directed labours he has written his name in large imperishable characters on the records of science.

His fame rests on the successful inquiries he carried out with a view to the discovery of the laws regulating atmospheric phenomena which apparently are under no law whatever. The work he will be long best known by is his isothermals and isabnormals of temperature for the globe, in which work one cannot sufficiently admire the breadth of view which sustained and animated him as an explorer during the long toilsome years spent in its preparation. Equally characterised by breadth of view, and what really seemed a love for the drudgery of detail even to profuseness when such drudgery appeared necessary or desirable in attaining his object, are his various works on winds, the manner of their veering and their relations to atmospheric pressure, temperature, humidity, and rainfall, and the important bearings of the results on the climatologies of the globe; on storms and their connections with the general circulation of the atmosphere; the influence of the variations of temperature on the development of plants; and the cold weather of May—to which may be added the valuable system of meteorological observations he gradually organised for Germany, and the many full discussions of these which he published from year to year.

It is no small praise to pass on his work to say that those views he propounded, which subsequent researches are likely to modify materially, are those he arrived at by methods of investigation necessarily defective at the time. Thus, for instance, in inquiring into the law of storms, it was not in his power to work from isobaric charts, seeing that the errors of the barometer and their heights above the sea were known in but few cases. When we consider the condition in which he found man's knowledge of weather and the large accessions and developments it received from his hand, the breadth of his views on all matters connected with the science and the well-directed patience, rising into high genius, with which his meteorological researches were pursued, there can be only one opinion, that these give Dove claims, which no other meteorologist can compete with, to be styled "the Father of Meteorology."

THE INSTITUTION OF NAVAL ARCHITECTS

THE twentieth session of the Institution of Naval Architects has now been brought to a close. The meeting, with Lord Hampton in the chair, was held at the house of the Society of Arts, John Street, Adelphi, and was well attended throughout. One of the latest developments in ship-building is shown in the paper on "The Structural Arrangements and Proportions of H.M.S. *Iris*," by W. H. White, Assistant-Constructor of the Navy. The construction of the *Iris* marks a new era in the British Navy, being the first vessel built wholly of steel; she is an unarmoured dispatch vessel, specially designed for high speed and great coal endurance. Her principal dimensions are: length between perpendiculars, 300 feet, breadth, extreme, 46 feet, mean load draught, 19 feet 9 inches, displacement, 3,735 tons.

Special attention has been paid to resistance to torpedo attack by constructing the hold in twenty-one separate compartments and the double bottom and bunkers in forty; with the additional weight thus introduced, it is still found that there is a saving of weight in the hull by the use throughout of steel amounting to 12 per cent., or 175 tons. The engines take 28 per cent of the displacement, and 20 per cent. is available for coal, which is estimated to be sufficient for steaming 7,000 knots at a speed of 10 knots per hour. The speed attained by the *Iris* on the measured mile was 18·6 knots, with an expenditure of 2·3 indicated horse-power per ton of displacement as compared with 14 indicated horse-power, required by a torpedo vessel.

In striking contrast with the *Iris* we have the monster proposed by Rear-Admiral J. H. Selwyn in his paper "On the most Powerful Ironclad." The author of the paper has long advocated some modification of the circular ironclad first proposed by Mr. Elder some years ago, and carried out with some alterations by Admiral Popoff. The vessel here proposed is 370 feet in length 220 feet in breadth, with a draught forward of 18 feet and aft 13 feet. Her armament is to consist of twenty 80-ton guns, or eight 100-ton and eight 80-ton; these are to be mounted in two gun-pits on the Moncrieff hydro-pneumatic principle. The guns are carried on a turn-table of the full size of each gun-pit, the floors of which are composed of steel bars set on edge to provide for ventilation, but to keep out shell fragments; the breast-work round each will consist of 30 inches of armour-plating. The guns would be raised by hydraulic power to fire over the breast-work, recoiling automatically under cover for re-loading. The vessel would be protected with a belt of 30-inch armour round the water-line, and a thickness of 25 feet of coals stowed inside it. There would be two Perkins hydraulic engines of 21,000 horse-power for propulsion and steering, and these would be at once available for keeping the vessel afloat in case of a leak. The author estimates that if a hole 10 feet square were made by a torpedo, the engines would be able to keep the water under, while danger of sinking by such damage is much lessened, if the engines are partially disabled, by the large number of water-tight compartments. It cannot be denied that the Russian Popoffkas have been far from successful, especially in facility of steerage, which was one of the main advantages claimed for them, but it can only be determined by an actual experiment whether our naval authorities can overcome the difficulties in speed and steering which have baffled the Russian Admiralty. Even if a vessel as here proposed could not be made sea-going, or to attain a 16-knots speed as claimed, she would at least be more valuable as a harbour defence than a Spithead or Plymouth breakwater fort, and could be adapted to some sites at a less cost in proportion to the weight of armament.

"Armour for ships" by Mr. Barnaby, C.B., Director of Naval Construction, consists of a general review of the progress of armour-plating from its introduction in 1854 down to the present time. The description of the steel turret-plates manufactured by Messrs. Schneider at Creuzot, 32 inches thick, and weighing 65 tons, is not without significance in the present state of depression in the iron trade of this country, but some consolation is to be obtained from the account given of the steel-faced plates of Messrs. Brown and Cammell which shows that some progress is still being made nearer home. The paper by Admiral Sir R. Spencer Robinson, K.C.B.,

F.R.S., gives an exhaustive statement of the experiments that have been made on various targets at Shoeburyness, representing the armour of different ships. A table is given showing the displacement, thickness of armour, and proportion of the former to the latter in ships of different types; this ratio varies from 6·38 in the *Warrior*, 4·00 in the *Alexandra*, to 2·95 in the *Dreadnought*, and 2·50 in the *Glatton;* thus the last may be considered the most heavily-armoured vessel in proportion to size in the navy. The penetration of shot of different diameters and weights with various velocities is given, and the experiments show that it is proportional to the energy of the shot on impact whether due more to velocity or weight, and inversely proportional to diameter of shot; also that the resistance of solid plates is proportional to the square of their thickness. The resistance of composite targets is treated at some length, and a comparison drawn between the various forms adopted in existing ships and the Millwall shield designed by Mr. Hughes, in which the latter is shown to be preferable; but the questions of steel and steel-faced armour which are now attracting the attention of artillerists are not gone into, and are only referred to with the evident feeling that the end of the battle between guns and armour has not yet come.

The paper "On the Resistance given to Screw-Ships by the Action of the Screw-Propeller, and how to Remedy it," by Robert Griffiths, points out an important difficulty in screw-propulsion which has only recently been recognised. A screw-propeller obtains the resistance to drive the ship forward by accelerating the velocity of the currents of water flowing past the stern of the vessel; as in different parts of the screw's disk these currents are encountered at different velocities, the resistance to a blade is not uniform throughout a revolution. In experiments made at Devonport by towing a screw-pinnace, it was found that the water flowed through the lower half of the screw disk nearly at the speed at which the boat was towed, but in the upper half it was so dragged by the boat as to flow past the screw at only half that speed. In dynamometer diagrams, taken with H.M.S. *Rattler*, it was shown that the thrust of the screw varied from 2·9 to 4·1 tons in each revolution. The increase in the resistance of the ship, due to the working of the screw above that due to the ship herself when towed at the same speed, and which Mr. Froude has shown to be 40 or 50 per cent., is considerably greater when the upper currents are more accelerated than it would be if the acceleration were uniformly given to the whole column of water passed through by the screw disk. The author proposes a screw-propeller so constructed that the blades always meet with equal resistance. The blades are so made that more than half their surface is aft of the centre line, so that the pressure on their surface tends to lessen the pitch; they are also made movable in the boss, but so connected that by decreasing the pitch of one, that of the other is increased; when, therefore, one blade meets with more resistance than the other, the increased pressure causes it to turn and throw some of the work on the other.

In his paper on naval guns, Mr. C. W. Merrifield vigorously attacks the Woolwich type of gun, pointing out the disadvantages and absolute futility of the increasing twist in rifling at present adopted. It is now four or five years since this was first done by Prof. Osborne Reynolds, and, aided by the *Thunderer* explosion, it is to be hoped that the time is drawing near when the subject will receive the consideration of the War Department. The author also lays great stress on the advantages of breech-loaders over muzzle-loaders, regarding the latter now, with its complication of gear and fittings, as inferior to the former, even in the simplicity always claimed for it.

Amongst other papers read at the meeting are the following:—"On Sir William Thomson's Navigational Sounding Machine," by P. M. Swan, in which the accuracy of this now well-known apparatus is amply testified by a large number of observations; and a paper by Mr. J. Scott Russell, F.R.S., "On the true Nature of the Wave of Translation, and the Part it plays in Removing the Water out of the Way of a Ship with least Resistance."

OUR ASTRONOMICAL COLUMN

NOTE ON 72 OPHIUCHI (O. Σ. 342).—The publication of the entire series of observations of this suspected double star, made at Pulkowa to 1876, does not lessen the difficulty of arriving at a definite conclusion as to its duplicity or otherwise. On November 1, 1841, it was noted double magnitudes 4 and 7 on Struve's scale, and, no doubt attached to the observation; on May 14, 1842, it appeared single, but at the epoch 1842·72 it was again double, the measures giving for position, 156°·6, and distance, 1″·3. Subsequent observations gave the following results:—

1844·85	...	Single, or with only a suspicion of elongation at 63°; images excellent.
1845·62	...	With very good images; no companion seen.
1846·49	...	Single, or perhaps slightly wedged at 87°.
1847·50	...	Pos. 162°·4, dist. 1″·61, but there was a doubt if the object observed was not an optical illusion.
1847·70	...	Pos. 168°·1, dist. 1″·6. M. Struve says: "I feel sure of the duplicity, but the images are not very good."
1848·79, 1850·50, 1851·51	...	Single.
1851·67	...	Pos. 166°·3, dist. 1″·49. After the observation a note was added—"This is only an optical deception."
1852·63	...	Single; under excellent atmospheric conditions.

This last observation appearing decisive, M. Struve considered that 72 Ophiuchi should be omitted from the list of double-stars, and in the following years only examined it once (1859·66), when it was again single under very favourable conditions. But in 1876 he found reason to modify his view: at 1876·67 the satellite was seen very distinctly, with position 156°·0, distance 1″·60; a fortnight later there were only very slight impressions of a satellite, and M. Struve remarked that the principal star of 70 Ophiuchi presented an analogous phenomenon, though less distinctly. Hence arose the suspicion that the said impressions were caused by accidental conditions of the air and the instrument. Nevertheless, on considering the preceding observations and the fact of their being made without the least recollection of anterior ones, M. Struve thinks their approximate agreement cannot be attributed to chance, and that we are necessarily led to infer that the star is really double, but the companion undergoes considerable and rapid variation of brightness. It is worthy of note that only three weeks before the Pulkowa observation of 1859, when the star was pronounced single, Secchi had recorded of it: "Certainly double, and well separated," his measures giving the position 3°·75, distance 0″·61.

THE VARIABLE STAR χ CYGNI.—According to the later observations of Dr. Julius Schmidt at Athens, it is probable that the next maximum may occur on or about April 25, and the next minimum about December 14. At the last observed maximum on March 14, 1878, the star was hardly a fifth magnitude, which is about the mean brightness in that phase, the extreme limits of variation being two magnitudes or 4m.—6m. according to Prof. Schönfeld; at minimum it descends to 13m. No formula has yet been deduced which will represent satisfactorily the totality of the observations, commencing with those of Kirch the discoverer in 1686; considerable

irregularities following no law so far discovered occasionally presenting themselves. This is particularly evident if we compare Argelander's last formula in vol. vii. of the Bonn observations with the observed times of maxima during the last fifteen years. The place of the true χ Cygni of Bayer, which is the variable, is, for 1880·0, in R A. 19h. 45m. 57·3s., N.P.D. 57° 23′ 18″; it therefore follows the star to which Flamsteed attached this letter, 4m. 4s., and is south of it 50′·6; Flamsteed's star ought to be called by his number, 17 Cygni. At the times when he was looking for Bayer's χ, as Argelander has remarked, the variable would be near a minimum; hence his observing the nearest star of similar brightness.

THE MINOR PLANETS IN 1879.—Advanced sheets of the *Berliner astronomisches Jahrbuch* for 1881, containing places of the small planets during the present year have been circulated amongst observers, the ephemerides for the planets coming into opposition early in the year, some time since. There are positions of the first 187 members of this group, with the exception of Nos. 99 and 155, for which sufficient data are not available. Only two out of the number approach the earth at opposition, within her mean distance from the sun: *Isis*, on June 20, is distant 0·995, with a south declination of 25°, and *Hertha*, on September 12, 0·988, just upon the equator. No. 154 travels as far south as 50½° about July 14.

BRORSEN'S COMET.—The observations of this comet made at Arcetri and Kremsmunster from March 10 to 19 with Dr. Schulze's other elements, fix the time of perihelion passage to about March 30·5716 G.M.T., which is nearly twelve hours later than that assigned by calculation. The following ephemeris is founded upon this corrected epoch for arrival at perihelion:—

For 12*h. Greenwich M.T.*

EDISON'S LAMP

A COMMUNICATION in yesterday's *Daily News*, from a New York correspondent of that paper, gives a glowing, and to all appearance justifiably so, account of Mr. Edison's success in attaining a form of electric lighting that seems to be in all respects much superior to anything hitherto produced. The first impression made on the correspondent was the mild effect of the light on the eyes, its steadiness, and the absence of that ghastly hue which seems to be an invariable accompaniment of the carbon. This new form of light has only been attained after many disappointments on the part of Mr. Edison, who, however, has all along been confident of success.

During the past two months the progress towards its present perfection has been very rapid. Chiefly contributing to this result has been the discovery of a new alloy, the fusing-point of which is much higher than either platinum or iridium, in fact, than any known metal. This discovery is spoken of by some of Mr. Edison's chief *employés* as the greatest achievement of his life. This alloy also reduces the cost of the valuable metals used in each lamp to such a point as to do away entirely with Prof. Tyndall's criticism. It is said to possess properties heretofore unknown, or at least undefined by scientific men. Not only has it cheapened the cost, but the union of the metals has increased the illuminating power to such a degree that six lights are now obtained per horse power where only four were possible with the pure platinum coil. Six lights per horse-power is the number authoritatively stated, but Mr. Edison's chief assistant does not hesitate to predict that eleven lights will eventually be obtained for each horse-power. This is not expected from the Gramme machine, however, which is now used; but is hoped for after the completion of the new generator, which a dozen of the most skilled workmen at Menlo Park are now engaged in constructing.

The lamp itself takes many forms. In some instances it is attached to the wall, like a gas bracket, and in many others it hangs from the ceiling and takes the external form of a glass globe, capped by brass or nickel attachments. There is none of the hissing, sputtering, and flickering observable in the carbon lamps. The lamp which attracts most attention is, in appearance, a St. Germain student lamp, without the reservoir for the oil. It stands in the middle of a small table, and two fine covered copper wires alone connect it with the main conducting cables from the Gramme machine. In this the *Daily News* correspondent tells us, are embodied all the latest improvements. He also tells us that there cannot possibly be any mistake, as Mr. Edison has taken crucial precautions in all directions. There is nothing in the lamp itself that gives any idea of its construction. The cunning device for rendering the flame steady is in reality the idea of the quadruplex telegraph applied to heat instead of electricity. Now that the new alloy has been discovered, its twofold purpose of preventing fusion and steadying the light is no longer served. The expansion of the tiny key, or switch, breaks the current for the fraction of a second, and permits the actual, though imperceptible, cooling of the incandescent coil. This connection is made and broken many times during each second, so that to human eyes the light is constant as the sun. The movement of a finger and thumb converts the glowing meteor before us into a night lamp for a sick-room. Again, it is seen at one-candle power, then at two, and so on. It is as manageable as a tallow dip, and much more satisfactory. It will not go out of itself, and needs no care. The little coil of wire is hermetically sealed in the glass chamber. It is not in a vacuum, but the chamber is filled with air. There is a sensitive spot on the metal cap in which the glass tube sits, and the expansion of the air manipulates the switch. The heat of the metal itself, therefore, is no longer relied on. The inventor explains that after all manner of severe tests this has been found the easiest and the least easily deranged manner of controlling the light. The difficulty of making thin plates of metal of equal density and weight rendered the previous method impracticable for small lights, although it will probably be the best form in which to secure the desired result where the lamps are to show lights of great intensity.

As there seems no reason to distrust the evidence of the *Daily News* correspondent, it may be accepted that Mr. Edison has succeeded in going a long way to solve some of the difficulties connected with the practical adoption of electric lighting. It is stated that in a few months the Edison Company will be prepared to supply the light to such private consumers as may desire it at at least one-third or one-fourth the cost of gas.

EXPERIMENTAL RESEARCHES ON THE REPULSION RESULTING FROM RADIATION[1]

II.

HAVING completed the experimental investigation of the amount of repulsion produced by radiation on disks of various kinds, and coated with different substances, I turned my attention to the amount of repulsion produced when polarised light is allowed to fall on a plate of tourmaline suspended in vacuo in a torsion balance. It was originally thought that a slice of tourmaline, being black to a ray of light polarised in one plane, and white to a ray polarised in the other plane, would be repelled when the incident light was quenched by it, and not affected when the incident light passed through it. Experiments, however, prove that this action does not exist in any

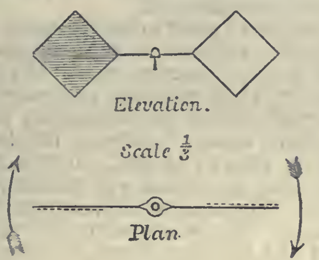

FIG. 4.

appreciable degree, the repulsion resulting from radiation being almost entirely a surface action, whilst the action of a tourmaline on a ray of polarised light is one in which thickness is necessary.

I next examined the effect of shape in influencing the amount and direction of repulsion. These experiments were for the most part tried with the apparatus shown in Fig. 3 (p. 513, part I.). Through the open top access can readily be obtained, and disks, plates, &c., can be quickly tested by being fixed to the extremities of a pair of aluminium arms, with a glass cap in the centre, rotating on the needle-point. Plates, 12 millims. square, cut from thin aluminium foil, were mounted diamond-wise on arms, and supported on the needle-point inside the bulb. The plates were lampblacked on sides facing

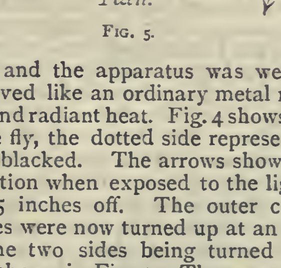

FIG. 5.

opposite ways, and the apparatus was well exhausted. The vanes behaved like an ordinary metal radiometer in respect to light and radiant heat. Fig. 4 shows the elevation and plan of the fly, the dotted side representing the one which was lampblacked. The arrows show the direction of positive rotation when exposed to the light of a standard candle 3·5 inches off. The outer corners of the aluminium plates were now turned up at an angle of 45°, 4 millims. of the two sides being turned up, leaving 8 millims. flat, as shown in Fig. 5. They were lampblacked on the inside, as shown in the figure by dots. A lighted candle 3·5 inches off caused very slow and feeble positive rotation. On shading the light from the black side, the bright side was repelled, causing positive rotation; and on shading the light from the bright side the black was repelled, causing negative rotation.[1] The positive repulsion was, however, rather stronger than the negative repulsion, so that, when both sides were illuminated, the force was only that due to the difference of these repulsions.

A hot glass shade is a convenient means of heating the bulb, by immersing it in a hot-air bath, without the liability of introducing action of rays other than those emitted by hot glass. On inverting a hot glass shade over the bulb in the above experiment, negative rotation was produced which changed to positive on cooling. Both these rotations were stronger than that given by the candle. The experiment was varied (1) by 6 millims. of the sides being turned up instead of 4; (2) by folding the plates across the vertical diagonal and then across their horizontal diagonal; (3) by attaching flat

FIG. 6.

plates to the arms at an angle of 45°, blacking them on the insides away from the bulb, and repeating the experiment with plates blacked on the outsides. The results obtained show that when flat plates are taken blacked on alternate sides, the rotation is normal or positive, *i.e.*, the black side is repelled. When the outer corners of each plate is turned up so as to keep the blacked surface on the concave side, the positive rotation is either diminished, stopped, or converted into negative rotation, according to the amount of surface of the plate which has been turned up. The favourable presentation of the surface of the vanes to the inside of the bulb has more influence on the movement than has the colour of the surface. Radiometers constructed with silver flake vanes set at an angle

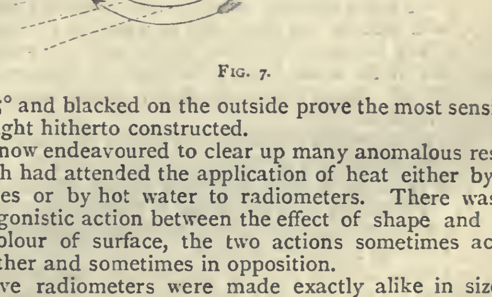

FIG. 7.

of 45° and blacked on the outside prove the most sensitive for light hitherto constructed.

I now endeavoured to clear up many anomalous results which had attended the application of heat either by hot shades or by hot water to radiometers. There was an antagonistic action between the effect of shape and that of colour of surface, the two actions sometimes acting together and sometimes in opposition.

Five radiometers were made exactly alike in size of bulb, shape of vanes, and degree of exhaustion, only differing in the material of which the vanes were composed. No. 1 was made of mica, 0·003 inch in thickness; No. 2, of mica, 0·0005 inch in thickness; No. 3, of pith,

[1] Continued from p. 514.

[1] I call the rotation *positive* when the black or driving side is repelled, and *negative* when the side which under ordinary circumstances would be the driving side, moves towards the light.

0·05 inch in thickness; No. 4, of aluminium, 0·002 inch in thickness. These four radiometers were plain on each side, no lampblack being applied. Their appearance is shown in Fig. 6. No. 5 was made of aluminium, identical with No. 4, but the vanes were lampblacked on each side instead of being bright. Had the vanes pointed radially there could have been no tendency for any one of the flies to move either way, but being inclined, the normal movement, on exposure to radiation, should be in the direction of the arrows—a direction which I called the *positive* direction.

In Fig. 7 the candle is represented shining on the bulb of the mica-vaned radiometer. The rays of light pass through the first wall without action. They then meet the mica, and that also being transparent, the rays pass through it likewise, and then escape through the opposite side of the bulb as is shown by dotted lines, without absorption and consequently without doing work. But in addition to light the candle is radiating ultra-red dark heat-rays, which in great measure are arrested by the glass, and raise its temperature. The inner surface of the bulb then becomes the surface on which molecular pressure is generated, which may be called the *driving* surface; this is shown by the shading next the candle. This molecular disturbance presses on the mica-vane which is in front of it, and drives it round in the direction of the arrows as if it were subjected to a bombardment of small shot. The vanes, in fact, may be said to be blown round by what may be likened to a wind, which however is not *molar* but *molecular*, inasmuch as there is no wind

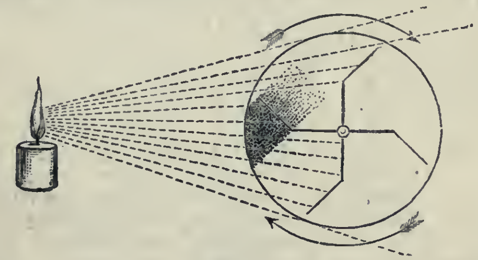

Fig. 8.

in the sense of an actual transference of gas from one part of the bulb to the other.

In Fig. 8 I have endeavoured to represent part of the action which takes place when the candle shines on the aluminium radiometer. The light passing through the bulb falls on the aluminium plate, and raising its temperature, causes pressure to be exerted on all sides. The molecules rebounding from the face next the glass, cause increased molecular pressure on that side, and produce movement in the direction of the arrows, or positive rotation. As each vane passes the candle it takes up heat, and acquires extra *driving* energy. As it swings round, the opposite side of the glass acts as a *cooler*, and by the time the vane has completed the circle, and has radiated away some of its extra heat, it is ready to recommence the cycle of transformation—light, heat, molecular pressure, motion.

Unlike mica, which generates very little pressure on its surface, the aluminium fly carries sufficient driving power to enable it easily to pass the dead centre opposite the candle. Therefore, as soon as the candle has shown on the aluminium radiometer long enough to warm the vanes a little, rotation readily continues.

The action of the pith radiometer is similar to the aluminium, except that the dissipation of pressure from the back surface of the pith will be almost *nil*. The pith, moreover, being sensitive to the heat-rays, and being a non-conductor, moves quicker than the aluminium, which requires time to get warm throughout.

The agreement between theory and observation, so far, seemed exact. I now tried numerous experiments with dark heat applied in various ways to these five radiometers. The results I obtained led me to think that the kind of dark heat might vary in refrangibility according to its source, and that the rays from hot water, hot glass, and hot metal, might affect the materials composing the vanes in a different manner, and being absorbed by one body and transmitted by another, might cause the positive or negative rotation which I obtained. I immersed the five radiometers in boiling water, and after cooling again immersed them in water only a few degrees above the temperature of the room; the results were similar to those I had previously obtained with water of 70° C. The radiometers were covered successively with hot shades of English, French, and German glass of different thicknesses, and at different degrees of temperature. The bulbs were also heated with a gas or spirit flame, but no uniform results were obtained.

A funnel was then heated in boiling water, and allowed to rest on the five radiometers in succession. They all moved in the *positive* direction, except the bright aluminium radiometer, which remained stationary. When the funnel was removed, the two aluminium and the thick mica radiometers rotated positively till they were cold. The funnel was allowed to cool. It was then inverted over a radiometer, and steam was passed through for a second or two. The same experiment was repeated with each radiometer. The results were now equally uniform with those of the last experiment, but the rotation was

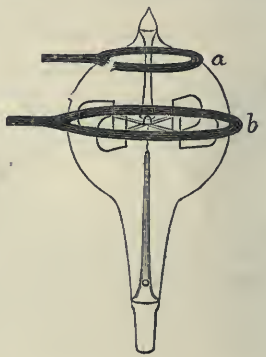

Fig. 9.

negative, the bright aluminium fly moving the best o all, and the pith fly the least.

I repeated the experiment with a thick brass ring, the internal diameter of which was about half that of the bulb (Fig. 9, *a*) and then with another brass ring a little larger in diameter than the bulb, *b*, Fig. 9. These rings were each heated to about 400°. With the first the rotation was *negative*, while in the second all the flies revolved in the *positive* direction. The two brass rings were made red hot, and held in position till the flies were in rapid movement, when the rings were removed and the hot part of the bulb dipped into cold water, so as to chill the glass quickly, and still keep the fly warm. These experiments proved that when heat is applied round an equatorial ring of the bulbs the rotation is always in the positive direction. The hot ring of glass generates molecular disturbance, which presses towards the centre and strikes the sloping vanes, driving them round as if the wind were blowing on them. In Fig. 10 I have tried to represent this action. The positive movement is independent of the material of which the fly is made, and is only slightly increased or diminished according to the conducting power of the fly for heat. The lighter the weight of the fly to be driven round, the easier it moves, and the heavier the fly the longer it keeps in motion after it is once started.

When heat is applied to either pole of the bulb *negative* rotation takes place. The molecular pressure proceeding

from a hot pole of the bulb will strike the *inner* surface of the sloping vanes. and driving them before it, will cause a rotation which appears *negative* to an observer, although it is really *positive* to the direction of pressure. Fig. 11 sufficiently illustrates this mode of action. The heat is supposed to be applied near the centre, and the molecular pressure, radiating on all sides, presses the vanes chiefly on the inner surfaces. The anomalous results obtained when the radiometers were heated with hot glass shades or hot water are thus accounted for. Polar heating gives *negative*, and equatorial *positive*, rotation, and when both are applied together by immersion in hot water, the direction of motion is governed by the stronger of these two forces.

In my description of Fig. 7 (p. 534) I showed that the glass heated by the ultra-red rays became hot, and acted on the driving surface, generating molecular pressure, and causing the sloping vanes to turn in the positive direction. At the same time the vanes get warm and become themselves sources of molecular pressure. The amount of molecular pressure thus generated depends on the capacity of the material of the vanes to absorb heat. Thin mica will hold very little, thick mica will hold more, and aluminium will hold most. This extra capacity for heat causes more molecular pressure to proceed from the aluminium and thick mica, and generates a proportionate amount of driving power on the surfaces of the vanes, turning them in the positive direction, and supplementing the action of the equatorial ring of hot glass.

The next subject of investigation was the action of radiation on cones, cylinders, and cup-shaped vanes. A pair of

FIG. 10.

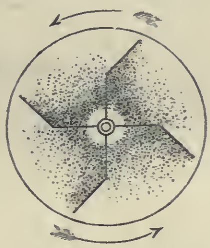

FIG. 11.

thin aluminium disks, cut half across the diameter, were bent into cones and mounted on two arms as a radiometer, the cones facing opposite ways. Several experiments were tried and repeated with cones of different material. The movement which appeared most anomalous was the attraction observed when a candle was allowed to shine on the hollow side of a cone or cup-shaped radiometer, the light being screened off the retreating side. Further experiments, however, showed that the effect of bending the plates, or of making cones of them, is to produce a more favourable presentation to the inner surface of the glass bulb. Radiation falls from the candle on the aluminium; some is reflected and lost, but a portion is absorbed, to be converted into thermometric heat or heat of temperature. Aluminium being a good conductor of heat, and the thickness of metal being insignificant, it becomes equally warm throughout, and a layer of molecular disturbance is formed on each surface of the metal. At a low exhaustion the thickness of this layer is not sufficient to reach from the metal cone to the side of the glass bulb; as the exhaustion increases, this layer extends further from the generating surface, until at a sufficiently high exhaustion the space between the side of the glass bulb and the adjacent portion of the metallic cone is bridged over, and pressure is exerted between the two surfaces. Fig. 12 shows how this pressure will act. The direction of pressure is indicated by dotted lines issuing from the metal cone. The more favourable presentation offered by the cone causes the pressure to be greatest between the glass bulb and the outside of the cone; the pressure from the inside of the cone and from the outside, away from the side of the glass, is dissipated without acting, but the pressure between the glass bulb and the side of the cone nearest to it is active; the cones, therefore, are pressed round in the direction of the arrows, and the motion has the appearance of *attraction*.

Cones being inconvenient in shape, I employed portions of cylinders wherewith to shape the vanes, and I ultimately found that cups were more easily affected by radiation than portions of cylinders, whilst they are more easily fashioned. I found that a four-armed cup-shaped aluminium radiometer, the cups being bright and 10 millims. in diameter, and the radius of the curvature being 6 millims., rotates in the light as well as a flat vaned instrument. I sealed one of these instruments on to the mercury pump. During exhaustion accurate observations were taken of the number of revolutions per minute caused by one or more standard candles 3 inches from the centre of the bulb. I also took observations of pressure, and the exhaustion was carried to a very high point. Fig. 13 shows the curve plotted from these observations, taking the rarefaction of the air in millionths of an atmosphere as abscissæ, and the number of revolutions a minute as ordinates. The curve traced through the dots representing observations illustrates the gradual increase of sensitiveness up to a certain point of rarefaction, and the sudden drop after that point is reached.

To still further investigate the action of dark heat on the vanes, I contrived an apparatus to which I could apply a very intense source of heat always ready in the

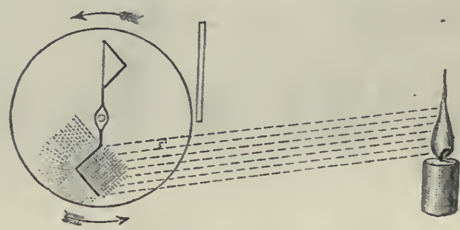

FIG. 12.

same place, the heat not having to pass through glass, and being completely under control as to intensity and time of action. The instrument with which I performed the great number of these experiments is shown in Fig. 14. The cylinder is sealed at the top so as to permit of the highest possible exhaustion. It is drawn off narrow at the end, and a stem is sealed in to hold a needle-point. To the narrow end a fine tube is attached to connect the apparatus to the mercury-pump. Round the needle is placed a ring of fine platinum wire, *a a*, the ends of which are joined to thicker platinum wires passing through the glass. The fly consists of four square vanes of clear mica, *b b*, inclined at an angle of 45° to the horizontal plane and supported on light aluminium arms. Above the vanes is a flat disk of clear mica, *c c*, having a glass cap in its centre, and easily rotating on a needle-point. The vanes and the mica disk are supported independently of each other on separate needle points, which are held in glass rods, *d*, *d*, *d*. A current of electricity from two Grove's cells, turned on or off by a contact key, gives the power of making the wire ring, *a a*, red hot when desired.

The normal or positive movement of the disk is in the opposite direction to that of the vanes; thus, if the positive movement of the vanes is in the direction of the hands of a watch, the positive movement of the disk is in the opposite direction. With the apparatus full of air at the ordinary pressure (bar. = 761 millims.) the direction of rotation, both of the vanes and disk, is *positive* when the platinum wire is ignited. The speed of the vanes is 13·3 revolutions a minute, and that of the disk 1 a minute

At a pressure of 80 millims. the disk does not rotate. The vanes rotate *positively* but slowly.

At 19 millims. no movement whatever takes place. The disk and vanes are as still when the wire is heated as when it is cold.

At 14 millims. the disk remains stationary. The vanes move slowly in the *negative* direction.

At 1 millim. the disk rotates in the *positive* direction slowly, whilst the vanes rotate *negatively* rather fast; the disk commences to rotate in the same direction as the vanes at a speed of three revolutions a minute.

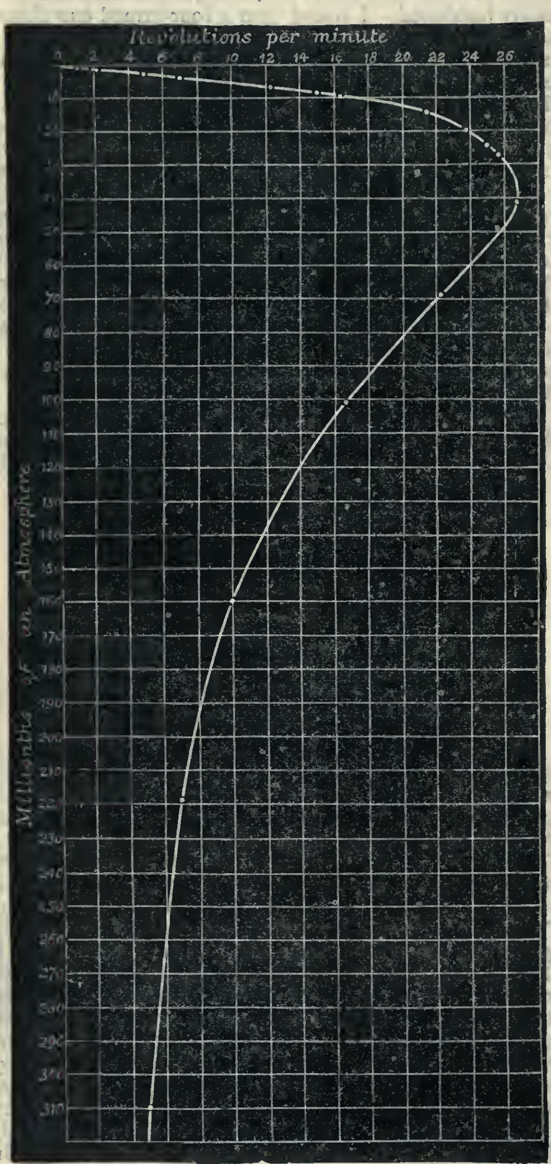

FIG. 13.

(At low exhaustions I speak of millimetres of pressure, but at high exhaustions I prefer to count in millionths of an atmosphere.)

At a pressure of 706 millionths of an atmosphere the direction keeps the same as at 1 millim. in each case, but the disk makes ten revolutions and the vanes forty revolutions a minute.

At 294 millionths, the speed of the disk and vanes is exactly alike, both rotating together in the same direction. Up to this pressure and at some distance beyond, the vanes have been gradually diminishing whilst the disk has been increasing in speed. At a pressure of 141 millionths the disk rotates rapidly, *positively*, but the vanes do not rotate at all. At a little higher exhaustion than the last, viz., at 129 millionths, a great change is observed. The vanes which were still now rotate in the *positive* direction at a speed of 100 revolutions a minute, whilst the disk rotates as before, but with a little diminished velocity. I have previously shown, in a paper to the Royal Society, that the viscosity of air at a rarefaction of 129 millionths of an atmosphere is only a little less than its viscosity at the normal density, and hence it is certain that the vanes at a speed of 100 revolutions a minute exerts a considerable drag upon the disk when it rotates in the opposite direction.

As the rarefaction increases above this point, the speed of both the disk and vanes increases till those of the latter exceed 600 revolutions a minute.

To carry these experiments to a much higher exhaustion it was necessary to modify the apparatus. The complex apparatus I now employed is shown at Fig. 15. Only the upper part of the pump *a b* is shown. It has five fall tubes and is fitted with a small radiometer, *c*, and a McLeod measuring apparatus, *d e*, to enable the degree of exhaustion in the apparatus to be ascertained. The phosphoric anhydride, for absorbing aqueous vapour, is contained in the horizontal tube *f*. In order as far as possible to prevent the passage of mercury vapour, three long narrow tubes *g g* are introduced between the pump and the apparatus to be exhausted; the one nearest the pump is filled with precipitated sulphur, the centre tube contains metallic copper reduced from its oxide, and the third tube phosphoric anhydride. At *h* is a vacuum-tube containing aluminium wires, and having a capillary bore for examining the spectra of the residual gas. An induction coil and battery are connected with the tube by wires. From the tube *h* two tubes branch off, one of them, *i*, leads to the "viscosity" apparatus contained in the case *k*, and the other, *j*, goes to the apparatus to be exhausted.

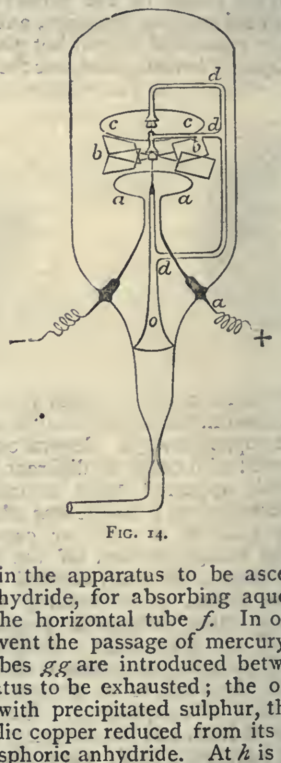

FIG. 14.

The apparatus *s*, containing the rotating disk and vanes, is sealed to the tube *j*. The platinum ring is ignited by the battery *t*. On the top of the ring rests a disk of mica, H, lampblacked on the upper surface; this cuts off direct radiation from the hot ring, and diffuses the heat somewhat over the surface of the black mica. Instead, therefore, of the molecular pressure starting from

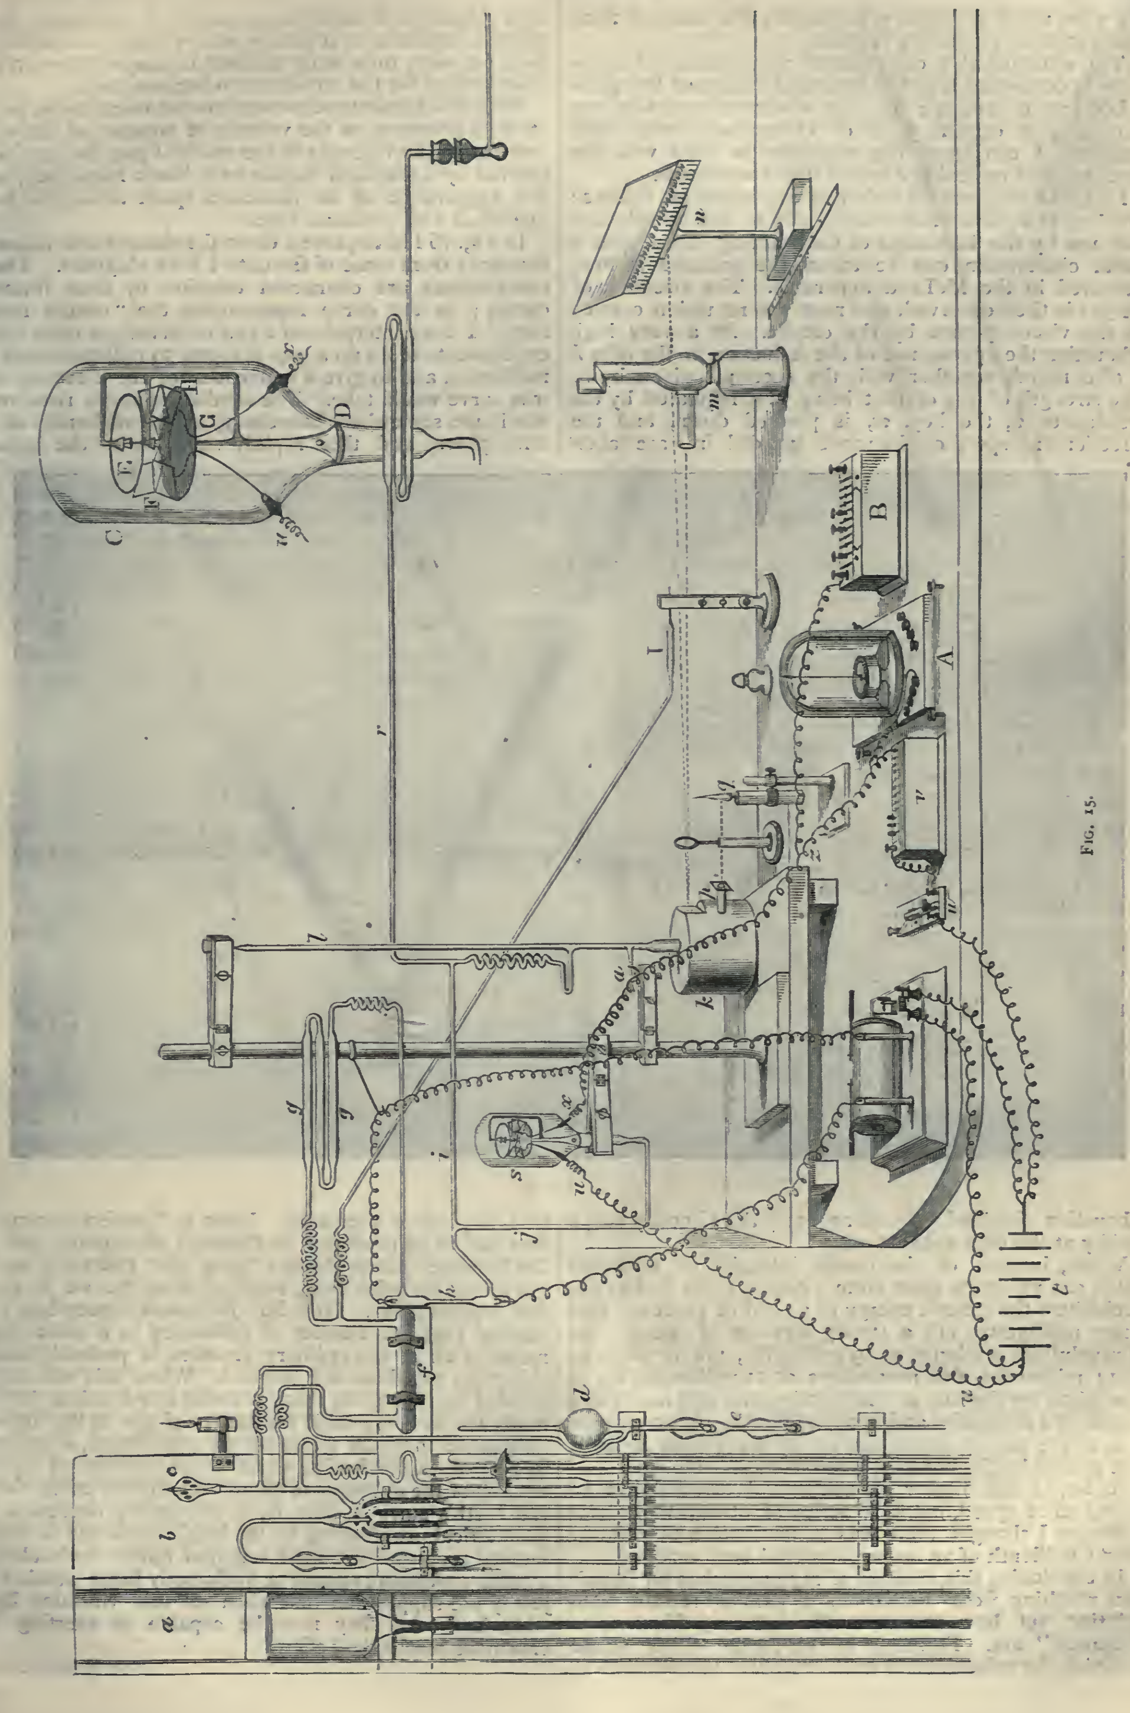

Fig. 15.

the wire, as in previous experiments, the blacked mica now becomes the driving surface.

The whole of this complicated arrangement of apparatus is connected together by actual fusion of the glass tubes one to another; no joint whatever occurs in any part, and a certain point of exhaustion being once attained, I can leave the apparatus to itself with the certainty that no leakage from without can occur.

I take an observation with this apparatus as follows: Arriving at a point when a depression of the contact-key tells me by the behaviour of the rotating disks that a useful observation can be taken, the pressure is first measured in the McLeod apparatus. The viscosity of the gas is then observed, and next the repulsion exerted on the viscosity-plate by the candle. At a very high exhaustion the appearance of the induction in the tube *h* is also noted, together with the spectrum given by it. The strength of the current being first regulated by the resistances *v*, the key, *w*, is pressed down, and the direction and speed of the vanes and disk in *s* are taken by a chronograph recording to tenths of a second. Frequently duplicate or triplicate observations are taken at each pressure, time being allowed to elapse between the observations for the apparatus to become cool.

With this apparatus observations can therefore be taken at each pressure, on the velocity of rotation of the disk and vanes, the viscosity of the residual gas, the repulsion exerted by a standard candle on a black mica plate, and the appearance of an inductive spark through a tube furnished with platinum wire.

In Fig. 16 I have plotted down the observations taken in air-vacua from some of the data I have obtained. These observations are connected together by lines forming curves; in the curve representing the "candle repulsion," I have interpolated a few observations from other experiments to fill up a gap between 59 millionths and 14 millionths, and to give a better idea of the direction the true curve would take. The candle repulsion rises to a maximum somewhere between 59 and 14 millionths of an atmosphere, and then rapidly sinks up to the highest

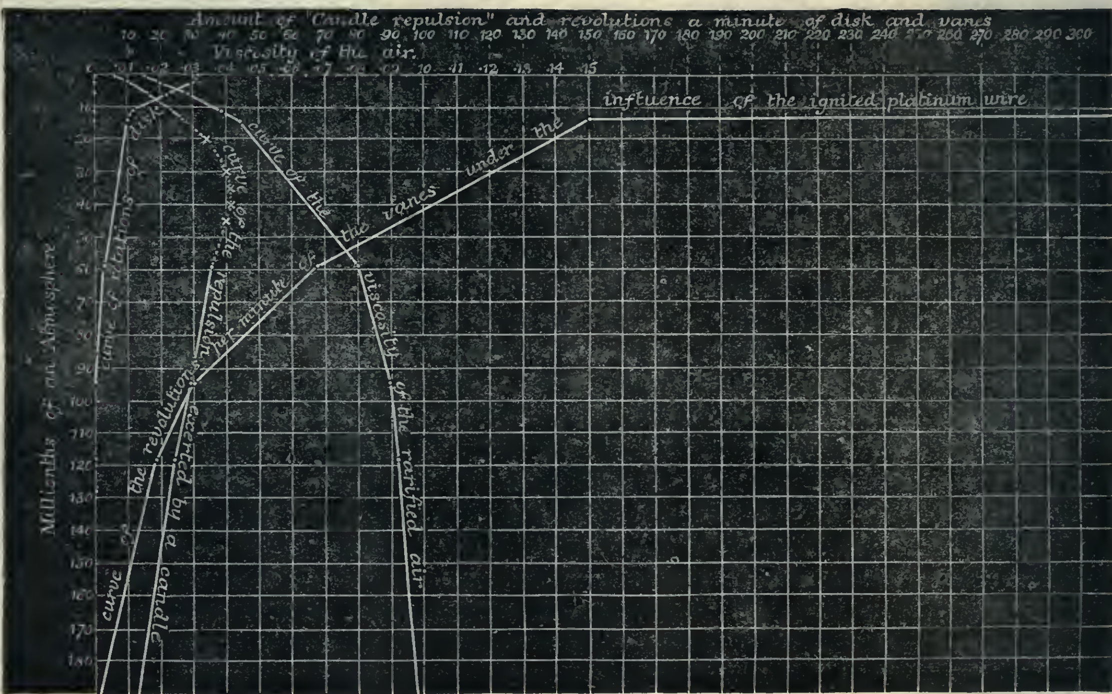

Fig. 16.

exhaustion obtained. Simultaneously the viscosity drops rapidly at the high exhaustions.

When, instead of the feeble intensity of radiation which can penetrate glass from a candle some inches off, I substitute the intense energy of a red-hot platinum wire a few millimetres off, a steady increase of speed from 67 revolutions a minute at 59 millionths, 150 revolutions at 14 millionths, 600 revolutions at 11 millionths, up to over 1,000 revolutions at 6 millionths, and still increasing speeds at 2 millionths and at 0·4 millionth. At an exhaustion, where the repulsion set up by the candle is least, that caused by the hot wire is greatest.

In air, at still higher exhaustions, I could detect no falling off of speed, but in a series of observations with hydrogen I thought there was a diminution of velocity after 1 millionth of an atmosphere had been reached.

In concluding this abstract of my researches on Repulsion resulting from Radiation, I cannot refrain from pointing out how erroneous the ordinary ideas of a "vacuum" are. Formerly an air-pump which would diminish the volume of air in the receiver 1,000 times was said to produce a vacuum. Later a "perfect vacuum" was said to be produced by chemical absorption and by the Sprengel pump, the test being that electricity would not pass, this point being reached, when the air is rarefied 100,000 times. Now Mr. Johnstone Stoney has calculated that the number of molecules in a cubic centimetre of air at the ordinary pressure is probably something like one thousand trillions. When this number is divided by 2,500,000, there are still four hundred billion molecules in every cubic centimetre of gas at the highest exhaustion to which I carried the experiment, illustrated in Fig. 16—a rarefaction which would correspond to the density of the atmosphere about seventy-five miles above the earth's surface, that is, if its density decreases in geometrical progression, as its height increases in arithmetical progression. Four hundred billion molecules in a cubic centimetre appear a sufficiently large number to justify the supposition that when set into vibration by a white-hot wire they may be capable of exerting an enormous mechanical effect.

W. Crookes

THE MIRROR OF JAPAN, AND ITS MAGIC QUALITY[1]

THE lecturer commenced by referring to the vast differences between the Chinese and the Japanese nations, of which the English people, as a rule, do not seem to be aware. He instanced various points of contrast; one of the most important being the intensely oriental secluded character of the private life of the Chinese on the one hand, and the Japanese dwelling in houses unfurnished and left wide open to the public gaze on the other. But why, he asked, in this comparative absence of nearly all that we should call furniture, does one article pertaining to the ladies' toilet—the bronze mirror with its stand—hold so prominent a position?

This mirror of the Far East is usually circular, from three to twelve inches in diameter, made of bronze, and with a bronze handle covered with bamboo. The reflecting face is generally more or less convex, polished with a mercury amalgam; the back is gracefully ornamented with a well-executed raised design representing birds, flowers, dragons, a geometrical pattern, or some scene in Japanese mythical history. Occasionally there are also one or more Chinese characters (signifying long life, happiness, or some similar idea) of polished metal, in bold relief. The general appearance of the back of the mirror, therefore, is something like that seen in the accompanying figure.

It might at first sight be surmised that the elaborate head-dresses of the ladies in Japan, combined with the painting of their faces, furnished an explanation of the prominence given to the metal mirror. But that this is not the case is easily seen from the fact that it is in the Imperial Palace, where the court ladies, still preserving the simple fashion of ancient days, merely comb back their long black tresses, and so have least need of a looking-glass, that the Japanese mirror receives the highest respect. A foreigner meets the mirror in the temples, in the hands of the street-conjuror, in pictures of the infernal regions, and in the regalia of the Japanese sovereigns, and for some time after his arrival in Japan, feels as an Oriental ignorant of biblical history might when unable to understand the constant repetition of the cross in Roman Catholic countries. But at length he hears that the mirror is part of the Japanese religion and mixed up with the "divine right of kings"; that it is the most precious of the possessions of a Japanese woman, and constitutes the most important part of the *trousseau* of a bride, and "the two Great Divine Palaces" at Isé, in which was deposited the first made mirror, have in the eyes of the Japanese the same importance as has the Holy Sepulchre for the Greeks and Armenians, and Mecca for the Mohammedans.

And to realise the reason of this, the stranger must learn that there is a famous ancient myth in Japan, which was recounted by the lecturer, detailing how the sun-goddess in a rage shut herself up in a rocky cave, and how the other gods to dispel the darkness thus caused, used various artifices to entice her forth, the most successful ruse being the manufacture of the first historical mirror, in which, seeing her face, she was drawn forth by her curiosity and jealousy. He will also learn how in the supposed creation of the Japanese Empire, the sun-goddess is reputed to have handed this mirror (with the two other "god's treasures," which, together with a mirror, at present constitute the regalia of the Emperor) to her grandson with these words, "Look upon this mirror as my spirit, keep it in the same house and on the same floor with yourself, and worship it as if you were worshipping my actual presence."

After describing many interesting points in connection with this strange mirror-worship of the Japanese, as seen in the palace and in the cottage, the lecturer went on to say that to the majority of those present the investigation of the so-called *magic* properties of the Japanese mirror would probably prove of yet more interest.

This magic property, which is possessed by a few rare specimens coming from the East, is as follows: If the polished surface is looked at directly, it acts like an ordinary mirror reflecting the objects in front of it, but giving, of course, no indication whatever of the raised patterns on the back; if, however, a bright light be reflected by the smooth face of the mirror on to a screen, there is seen on this screen an image formed of bright lines on a dark ground more or less perfectly representing the pattern on the back of the mirror, which is altogether hidden from the light.

When this appearance is seen for the first time it is perfectly startling even to an educated mind, and if the source of light is sufficiently bright, as for instance a tropical sun, it is difficult for the observer to divest himself of the idea that the screen is not perforated with cuts, corresponding with the pattern on the back of the mirror, and illuminated from behind.

This strange phenomenon was known to both Sir David Brewster and Sir Charles Wheatstone, both of whom were of opinion that it was produced by trickery on the part of the maker. Sir David Brewster, for example, says in the *Philosophical Magazine* for December, 1832: "Like all other conjurors, the artist has tried to make the observer deceive himself. The stamped figures on the back (of the mirror) are used for this purpose. The spectrum in the luminous area *is not an image of the figures on the back*. The figures are a copy of the picture which the artist *has drawn on the face of the mirror*, and so concealed by polishing that it is invisible in the ordinary lights, and can be brought out only in the sun's rays."

Prof. Ayrton then related how he had been quite unable to find for sale in any of the shops of Japan one of these magic mirrors, which was supposed in Europe to be a standard Japanese trick, and he explained how he had at length ascertained that with regard to this so-called magic mirror, the Japanese were the people who knew least about the subject.

But these magic mirrors were known to the Chinese from the earliest times, and one of their writers spoke about them in the ninth century of the Christian era. They call them *theou-kooang-kièn*, which means literally, "mirrors that let the light pass through them," this name,

[1] The Friday evening discourse at the Royal Institution, January 24, by Prof. W. E. Ayrton.

of course arising from a popular error on the subject. The Roman writer Aulus Gellius, who lived seventeen centuries ago, referred to mirrors that sometimes reflected their backs and sometimes did not. From the great antiquity of these Chinese magic mirrors, the German writer Herr Sterne has concluded that it is probable that the mirrors with secret signs and figures of imps on the back, which formed a portion of the stock-in-trade of the witches of the middle ages, were of Eastern manufacture. The Italian historian Muratori gives an account of the magic mirror found under the pillow of the Bishop of Verona, who was afterwards condemned to death by Martin Della Scala, as well as of the one discovered in the house of Colla da Rienzi, and on the back of which was the word "Fiòrone." But of these magic mirrors, which have played so important a part, not only in the priestcraft of China, but also in the oracles of the Greeks and Etruscans, and in the witchcraft of the middle ages, inquiry has shown that Japanese literature makes absolutely no mention.

Is it, then, that such mirrors cannot be found in Japan? Undoubtedly they cannot be bought on inquiry at the shops, but Prof. Ayrton's investigations have shown that if a careful examination with properly arranged light be made of a large number of the ordinary Japanese bronze mirrors, a few, perhaps 2 or 3 per cent., will be found showing the magic property clearly.

The lecturer then referred to the extracts he had made from a large portion of that which had been written in various languages regarding the explanation of the phenomenon. He mentioned that the earliest explanation was given by a Chinaman, Ou-tseu-hing, who lived between 1260 and 1341, and who also had the impression that the magic property of the mirror was produced by an artifice; for he wrote: "When we turn one of the mirrors with its face to the sun, and allow it to throw a reflection on a wall close by, we see the ornaments or the characters which exist in relief on the back, clearly. Now the cause of this phenomenon arises from the employment of two kinds of copper of unequal density. If on the back of the mirror a dragon has been produced while casting it in the mould, then an exactly similar dragon is deeply engraved on the face of the disk. Afterwards the deep chisel cuts are filled up with denser copper, which is incorporated with the body of the mirror, which ought to be of finer copper, by submitting the whole to the action of fire; then the face is planed and prepared, and a thin layer of lead or of tin spread over it.[1]

"When a beam of sunlight is allowed to fall on a polished mirror prepared in this way, and the image is reflected on a wall, bright and dark tints are distinctly seen, the former produced by the purer copper, and the latter by the parts in which the denser copper is inlaid."

Ou-tseu-hing adds that he has seen a mirror of this kind broken into pieces, and that he has thus ascertained for himself the truth of this explanation.

In a paper communicated some years ago to the French Academy of Sciences, the well-known French writer on China, M. Stanislaus Julien, says: "Many famous philosophers have for a long time, but without success, endeavoured to find out the true cause of the phenomenon which has caused certain metallic mirrors constructed in China to have acquired the name of magic mirrors. Even in the country itself where they are made, no European has up to the present time been able to obtain either from the manufacturers, or from men of letters, the information which is so full of interest to us, because the former keep it a secret when by chance they possess it, and the latter generally ignore the subject altogether. I had found many times in Chinese books details regarding this kind of mirrors, but it was not of a nature to satisfy the very proper curiosity of the philosopher, because sometimes the author gave on his own responsibility, an explanation that he had guessed at, and sometimes he confessed in good faith that this curious property is the result of an artifice in the manufacture, the monopoly of which certain skilled workmen reserve to themselves. One can easily understand this prudent reticence when we remember that the rare mirrors which show this phenomenon sell from ten to twenty times as dear as the rest."

The prevalent idea has been that the phenomenon of the magic mirror was caused by a difference of density in the various parts of the surface, either produced intentionally or accidentally; and this, the lecturer explained, arose from two causes, first, from the common belief that the patterns on Japanese and Chinese mirrors were, like those on ordinary coins, produced by stamping; the other, because the distinguished European philosophers who had examined into the question had investigated with considerable success, experimentally, how such mirrors might be made, but they had not, the lecturer thought, directed their attention to the examination of the question—How was the phenomenon in these rare eastern mirrors actually produced?—obviously a very different question.

Prof. Ayrton mentioned that he and Prof. Perry were led to take up the investigation from a very remarkable fact pointed out by Prof. Atkinson, of Japan, viz., that a scratch with a blunt iron nail on the back of one of these magic mirrors, although it produced no mark on the face of the mirror which could be seen by direct vision, nevertheless became visible as a bright line on the screen when a beam of sunlight was reflected from the polished face of the mirror. The lecturer mentioned that after trying several experiments with polarised light, &c., Prof. Perry and himself availed themselves of a very simple method of investigation, but one which had apparently not suggested itself to previous observers. On one occasion, when some of their students were using lenses to endeavour to make the exhibition of the phenomenon more striking, it occurred to them that the employment of beams of light of different degrees of convergence or divergence would furnish a test for deciding the cause of the whole action. For while, if the phenomenon were due to the molecular differences in the surface—the commonly received opinion—the effect would be practically independent of the amount of convergence of the beam of light; on the other hand, if it by any chance were due to portions of the reflecting surface being less convex than the remainder, a complex *inversion* of the phenomenon might be expected to occur, if the experiment, instead of being tried in ordinary sunlight, were made under certain conditions in a converging beam—that is, the thicker portions of the mirror might be expected to appear darker instead of lighter than the remainder.

[Experiments were then shown of the image cast on the screen: (1) when a divergent beam of light fell on the mirror, (2) when the beam was parallel, (3) when the beam was convergent; and it was seen (1) the pattern appeared as bright on a dark ground, (2) the pattern was invisible, (3) the pattern appeared as dark on a light ground.]

Again, by allowing a parallel beam of light to fall on it, and interposing a double convex lens between the mirror and the screen, we can make the image show the pattern either as a bright on a dark ground, or as dark on a bright ground, or not at all, merely by causing the screen to be: 1st, nearer the lens than the conjugate focus of the mirror; 2nd, farther than the conjugate focus; 3rd, at the conjugate focus. [This experiment was here shown.] Now it can easily be proved by simple geometrical optics that each of these effects would be produced if the thicker parts of the mirror were a little less convex than the remainder. [This was explained by various geometrical

[1] This probably refers to the mercury-amalgam which is used in polishing, and which Ou-tseu-hing mistook for lead or tin.

diagrams.] And lastly, if the phenomenon was, as the previous experiment would lead us to conclude, due not to unequal reflecting power of the different portions of the surface of the mirror, but to minute inequalities on the surface, in consequence of which there is more scattering power of the rays of light falling on one portion than on another, then, since rays of light making very small angles with one another do not separate perceptibly until they have gone some distance, it follows that if the screen be held *very near* to the mirror, the apparent reflection of the back, the magical property, in fact, ought to become invisible. And this also, it was shown, was exactly what happened when the screen was made almost to touch the polished surface.

The lecturer then proceeded to explain why a *divergent* beam emitted by a bright luminous *point* at some fifteen feet distance from the mirror gave the best effects.

We have therefore strong reasons for favouring the "inequality of curvature" theory. In order, however, to make the explanation quite certain, the lecturer said he had made a small concavity and a small convexity on the face of one of the mirrors, by hammering with a blunt tool, carefully protected with a soft cushion to avoid scratching the polished surface, and he showed by experiment that the concavity reflected a bright image and the convexity a dark one, when the pattern on the back appeared bright, but when the light was so arranged that the pattern appeared as dark on a bright ground, it was the convexity which appeared as the bright spot and the concavity as the dark one.

Guided by all that precedes, we are led to the undoubted conclusion that the whole action of the magic mirror arises from the thicker portions being flatter than the remaining convex surface, and even being sometimes actually concave. But, in spite of this irresistible conclusion forced on us by the experiments previously mentioned, it must be admitted that it seems extraordinary how such small inequalities in the surface of the mirror, so small in fact that the eye quite fails to detect them, can, even with a proper arrangement of the light, produce on the screen an image of the pattern on the back as sharp and clear as is seen with a good specimen of the magic mirror.

The next question arises, why is there this difference in the curvature of the different portions of the surface? The experience that Prof. Ayrton had gained from an examination of a large number of Japanese mirrors supplied, in part at any rate, the answer to the question. No thick mirror reflects the pattern on the back, not one of the many beautiful mirrors exhibited at the National Exhibition of Japan in 1877, and which the lecturer was so fortunate as to be able to experiment with in a darkened room with a bright luminous point at some twelve feet distance, showed the phenomenon in the slightest degree; some good old mirrors in the museum of the Imperial College of Engineering, and which belonged to the family of the late Emperor, the Shogun, of Japan, failed to reflect any trace of a design, and some old round mirrors without handles, which he had also tried, were (with the exception of one which was immensely prized, and brought to him wrapped in five distinct silk cases, and the heirloom of the family of a nobleman) equally unsuccessful.

Again, it is not that the pattern is less clearly executed on the backs of these choice mirrors, since the better the mirror the finer and bolder is the pattern, but what is especially noticeable is that every one of these mirrors is, as a whole, far thicker than an ordinary Japanese mirror, and its surface is much less convex.

This naturally led him to inquire how are Japanese mirrors made convex? Are they cast so, or do they acquire this shape from some subsequent process? His search through all the literature at his disposal—European, Japanese, Chinese—on the subject of mirrors failed to elicit the slightest hint; he was therefore compelled to perform the somewhat difficult task of obtaining information from the Japanese workmen themselves. Eventually he ascertained that while practically all Japanese mirrors were convex, the surface of each half of the mould was flat, and that the curvature was given to the mirror after casting in the following way: the rough mirror is first scraped approximately smooth with a hand-scraping tool, and as this would remove any small amount of convexity had such been imparted to it in casting, it is useless to make the mould slightly convex. If, however, a convex or concave mirror of small radius is required, then the surface of the mould is made concave or convex. On the other hand, to produce the small amount of convexity which is possessed by ordinary Japanese mirrors the following method is employed, if the mirror is thin, and it is with thin mirrors we have especially to deal, since it is only in these mirrors that the apparent reflection of the back is observed. The mirror is placed face uppermost on a wooden board, and then scraped or rather scratched with a rounded iron rod about a third of an inch in diameter, and a foot long, called a *megebo*, "distorting rod," so that a series of small parallel scratches is produced, which causes the face of the mirror to become convex in the direction at right angles to the scratches, but to remain straight parallel to the scratches, in fact it becomes very slightly cylindrical, the axis of the cylinder being parallel to the scratches. This effect is very clearly seen by applying a straight-edge in different ways to the face of an unpolished mirror which has received a single set of scratches only. A series of scratches is next made with the *megebo* in a direction of right angles to the former, a third set intermediate between the two former, and so on, the mirror each time becoming slightly cylindrical, the axis of the cylinder in each case being parallel to the line of scratches, so that eventually the mirror becomes generally convex. Some workmen prefer to make the scratches with the *megebo* in the form of small spirals, others in the form of large spirals, but the general principle of the method employed with their mirrors appears to be always the same—the face of the mirror is scratched with a blunted piece of iron, and becomes slightly convex, the back, therefore, becoming concave.

[Mirrors were here exhibited, one with its surface flat, although somewhat rough, just as it came from the mould after casting; a second that had received one set of parallel scratches with the *megebo*, and which by means of a straight edge was shown to be slightly cylindrical; and a third on the face of which the operation of scratching had been completed, and which was therefore slightly convex.]

After the operation with the "distorting-rod" the mirror is very slightly scraped with a hand-scraping tool to remove the scratches, and to cause the face to present a smooth surface for the subsequent polishing.

In the case of thick mirrors the convexity is first made by cutting with a knife, and the distorting-rod applied afterwards. But in connection with this cutting process of thick mirrors, there is one very interesting point. If the maker finds, on applying from time to time the face of the mirror to a hard clay concave pattern, and turning it round under a little pressure, that a portion of the surface has not been in contact with the pattern, in other words, that he has cut away this portion too much, then he rubs this spot round and round with the *megebo* until he has restored the required degree of convexity. Here again, then, scratching on the surface produces convexity.

Now, why does the scraping of the "distorting rod" across the face of the mirror leave it convex? During the operation it is visibly concave. The metal must receive, then, a kind of "buckle," and spring back again so as to become convex when the pressure of the rod is removed. It might in such a case reasonably be expected that the thicker parts of the mirror would yield less to

the pressure of the rod than the thinner, and so would be made less convex, or even they might not spring back, on the withdrawal of the rod and so remain actually concave. Again, since we find that scraping the face of the mirror is the way in which it is made convex, and the back therefore concave, we might conclude that a deep scratch on the back would made the back convex and the face slightly concave. Such a concavity would, as we have proved, explain the phenomenon of the bright line appearing in the reflection of sunlight on the screen, which was observed by Prof. Atkinson to correspond with the scratch on the back.

After the scratches produced by the *megebo* are removed the mirror is polished with whetstones and then with charcoal. The face now becomes fairly smooth, but it still generally contains some few cavities; these the maker fills up from a stock of copper balls of various sizes which he has at hand. (It was probably the presence of these bits of copper that led Ou-tseu-hing to believe that the explanation of the cause of the magic mirrors was the inlaying of different metals.) The face of the mirror is finally rubbed over with a mercury amalgam containing 50 per cent of tin, by means of a small straw brush or the hand.

The lecturer then referred to the various metal mixtures employed by the Japanese in making their mirrors, the best being composed of 75 per cent. of copper, 23 of tin, and 2 per cent. of a natural sulphide of lead and antimony.

Although the Japanese have paid no attention to the magic mirror, which has created such interest in Europe, they have, in connection with their priestcraft, employed mirrors on the surface of which, if looked at obliquely, could be seen the faces of saints, but which were not in any way connected with the pattern on the back of the mirror. [Photographs of such mirrors were projected on to the screen.] The lecturer also exhibited two mirrors of this kind which he had had made in consequence of the belief expressed by one of the Japanese mirror-makers that the phenomenon of the so-called magic mirrors was produced by chemical action on the surface. But the result of the experiment had been that if the face of a mirror which had been chemically acted on was polished until every trace of the marks disappeared for direct or oblique vision, then they also disappeared in the image produced by reflecting a beam of light on to a screen, and consequently that it did not seem possible, as far as his experiments had gone, to produce, by means of chemical action on the surface, a mirror fulfilling all the conditions of the magic mirror.

He concluded by saying: "It appears, then, contrary to what is commonly believed, that the magic of the Eastern mirror results from no subtle trick on the part of the maker, from no inlaying of other metals or hardening of portions by stamping, but merely arises from the natural property possessed by certain thin bronze of buckling under a bending stress, so as to remain strained in the opposite directions after the stress is removed. And this stress is applied partly by the distorting rod, and partly by the subsequent polishing, which, in an exactly similar way, tends to make the thinner parts more convex than the thicker."

GEOGRAPHICAL NOTES

THE April number of Petermann's *Mittheilungen* contains a paper of considerable geographical and geological value by Dr. Edmund Naumann, on the Plain of Yedo, Japan; it is accompanied by several illustrations and a fine map. Lieut. Onatzewich's account of his cruise in the clipper *Wssadnik* to the north of Behring Strait in 1876, is well timed in connection with the *Vega's* sojourn in that region. Dr. von Scherzer contributes an interesting paper on anthropometry, and Capt. Johannesen describes the voyage of the *Lena* from the mouth of the River Lena to Jakutsk. The monthly summary contains, as usual, many interesting items.

THE February number of the *Bulletin* of the Paris Society gives M. Savorgnan de Brazza's paper on his Ogowé expedition, the results of which we have already stated. A valuable and detailed notice of Dalmatia is contributed by M. de Sainte-Marie, and the number contains the recent correspondence of Dr. Crevaux from Guiana, referred to last week. The *Nouvelles* are continued.

AS we stated last week, though M. Soleillet has got so far on his journey to Timbuktu, it must not be forgotten that some fifteen years ago Lieut. Mage and Dr. Quintin reached the same place, and that after being detained as prisoners for eighteen months by the present Sultan Ahmadu, they were refused permission to embark on the Niger, and compelled to return to the coast *re infectâ*. Indeed, just as we go to press we learn that a telegram sent to the French Société de Géographie announces that the progress of M. Soleillet has been cut short. He was stopped by Ahmadu, the Emperor of Segou under the pretence that the roads are insecure in the north of his government. M. Soleillet has returned to St. Louis.

WITH reference to our note last week (p. 516) on the Conference in connection with the Inter-oceanic Canal, M. Maunoir, Secretary of the Paris Geographical Society, writes us that the Conference is to be held on May 19 under the auspices of that Society and not of the Society of Commercial Geography. The Congress, M. Maunoir writes, will not have any particular project in view, but will give an impartial hearing to the various projects brought before it. The various solutions of the questions proposed will be propounded by their authors, and, if deemed advisable, the Congress may in the end give its approval of one or other of the projects.

THE April number of the *Church Missionary Intelligencer* states that letters have been received from the missionary reinforcements who are travelling up the Nile to join the Nyanza expedition. They only reached Lado opposite Gondokoro, on October 10; after three weeks stay at that Egyptian station they reached Regiaf on November 7. The cause of delay, we are told, has been that the Nile has been unusually high, and the immense quantity of water loosened great masses of reeds and papyrus which formed floating islands and blocked up the river, besides which, owing to a deficiency of fuel between Khartoum and Lado, they remained fast bound during the whole month of September some distance south of Sobat, and the missionaries saw no living beings (besides the men on board) but "pelicans, fishes, and a white-headed eagle or two."

ANNEXED to the recently issued report of Her Majesty's Consul on the newly-opened port of Wênchow, is a very interesting map of the three Chinese provinces of Chekiang, Fukien, and Kiangsi, showing the means of communication by land and water between the principal cities and districts. The object of the map is more especially to point out the position of Wênchow as regards some of the most important districts in these provinces, the names of which with their products are given.

GARIBALDI has snubbed the Italian New Guinea expedition, so that it may now be regarded as nipped in the bud.

THE collection of funds instituted by the Dutch Central Committee for Arctic Exploration for the renewed outfitting of the *Willem Barentz*, which vessel is shortly to start on another expedition of some eighteen months' duration, is progressing so favourably that it may be reasonably expected that the 50,000 florins which are required for the expedition will soon be completely subscribed.

NOTES

In the interests of British science we have refrained now for some time from referring to the evil days which have fallen upon one of the most reputable of our learned societies. The time, however, has now come when silence is impossible. At the meeting of the Royal Astronomical Council yesterday, the Astronomer-Royal, in consequence of the recent action of the Council—an action inevitable when the present constitution of that body is considered—resigned his seat at the board. We cannot too much regret that this Society, the traditions of which are second to none in Europe, should have been utilised for some years past by an advertising clique who have everything to gain by their connection with a body of honourable students of science. The withdrawal of men long known for their astronomical work from the Council commenced some time since. It has now culminated in the resignation of the Astronomer-Royal, and we are informed that other resignations are to follow; indeed, a man of scientific repute risks somewhat in being found amongst the Councillors. Surely the Fellows of the Royal Astronomical Society of London are strong enough to remedy such a state of things as this.

At the meeting of the Council of the Royal Society, held last Thursday, the following fifteen candidates were selected to be recommended for election. The day fixed for the election is Thursday, June 12:—J. Anderson, M.D., Rev. M. J. Berkeley, H. Bessemer, Prof. A. Crum-Brown, W. L. Buller, Sc.D., G. H. Darwin, Prof. J. D. Everett, Prof. F. S. B. François de Chaumont, Prof. G. D. Liveing, G. Matthey, G. J. Romanes, A. Schuster, Ph.D., Prof. H. G. Seeley, B. Williamson, and T. Wright, M.D. The following have been elected Foreign Members of the Society:—Arthur Auwers, Berlin; Luigi Cremona, Rome; Jean Louis Armand de Quatrefages, Paris; Georg Hermann Quincke, Heidelberg; Theodor Schwann, Liége; Jean Servais Stas, Brussels.

Macmillan and Co. will publish shortly the following literary and scientific remains of the late Prof. W. K. Clifford. (1) A volume of mathematical papers which have been read before the Royal Society or contributed to scientific journals; Mr. Wm. Spottiswoode, F.R.S., will probably see this collection through the press. (2) Two volumes of collected essays and lectures, edited by Mr. Leslie Stephen and Mr. Frederick Pollock; Mr. Pollock will also contribute a biographical introduction to this work. (3) A small volume containing three popular lectures on "Seeing and Thinking."

We regret to see by the Civil Service Estimates that the amount to be devoted to "Purchases and Acquisitions" in the Department of Zoology of the British Museum during the present financial year has been reduced by one-fourth, *i.e.*, from 1,200*l.* to 900*l.* It seems rather absurd that a Government which has shown its anxiety to meet the claims of science by giving 4,000*l.* a year to be distributed in "aid of research" by the Royal Society, should have taken such a step as this to save a miserable 300*l.*, especially when it was the universal complaint of naturalists that the sum previously granted was wholly inadequate to the purpose. We cannot help thinking that the Trustees and their Secretary are in fault in this matter.

A further circular, in addition to that referred to on p. 472, has been issued by the Meteorological Office, with regard to the conditions on which weather information will be supplied. These conditions are too detailed to be noticed here, but they show a desire on the part of the Office to give every facility both to residents in London and in the country to obtain descriptions of the actual state of the weather and forecasts for not more than one day in advance. No doubt a copy of the circular may be obtained on application at the Office, 116, Victoria Street, S.W.

M. Renan was elected a few months ago a member of the Académie Française to fill the place vacated by the demise of M. Claude Bernard, the celebrated physiologist. On Monday, last week, he pronounced, before an immense audience, the *éloge* of his predecessor, in which he mentions that Claude Bernard must be considered as being the real founder of physiology in France. No public course of lectures was given before 1845, when M. Bernard established a laboratory, in the rue Saint Jacques, near the Panthéon. It was in this institution that the illustrious Academician conceived the idea of the great experiments which rendered his fame universal. But the establishment failed, M. Bernard having collected not more than five or six pupils.

The Council of the Society of Arts offers one gold and three silver medals for the best suggestions founded upon evidence already published, for dividing England and Wales into districts for the supply of pure water to the towns and villages of each district.

"A Citizen and Fishmonger" very pertinently asks in Tuesday's *Times* why it is that while we hear so much from time to time of the City Guilds' Technical College, and of the Society for University Extension in London, we hear nothing of any proposal for the utilisation of Gresham College?

The *Times* Geneva correspondent writes that the Lake of Neuchâtel is just now lower than has ever before been known, and continues to yield rich rewards to the researches of antiquarian explorers. Prof. Forel found, a few days since, at the lacustrine station of Corcelet, an earthenware vase dating from the age of bronze. On the bottom of the vase are plainly visible the impressions made by the fingers of the prehistoric potter in the plastic clay. Of these fingers—or, rather, of the thumb and forefinger, for the other digits are unfortunately lacking—the professor has taken a plaster of Paris cast and submitted them to a minute examination. He pronounces the maker of the vase to have been a woman. There are two impressions of the thumb and three of the forefinger. The prints left by the nails are perfect—that of the thumb, which must have been regular, well-shaped, and of an elegant convexity, measures in length twelve millimetres, in breadth eleven millimetres; the length and breadth of the finger-nail, equally well modelled, are eleven and nine millimetres respectively, the transverse convexity representing a curve or rise (*flèche*) of two millimetres. These nails, considers M. Forel, can only have belonged to a female hand. The vase has been placed in the cabinet of antiquities in the Vaudois Cantonal Museum at Lausanne. Another investigator, who has been cutting trenches in ground left bare by the abatement of the waters of the lake, has arrived, after careful examination of the *débris* and relics which his explorations have brought to light, at some interesting conclusions concerning the way in which certain of these lake-dwellings were destroyed, the time of the year when they disappeared, and the level of the lake at the epoch of their extinction. He believes they were destroyed by fire. This opinion he bases on the fact that, in all his explorations, he finds the same mixture of gravel and sand blackened and interspersed with charcoal and partly burnt seeds and bits of wood. This *débris* has evidently been carried to its present position by the waters of the lake, and varies in thickness according to the inclination of the slope on which it has been deposited. In other places besides those where the trenches have been cut, similar indications are observable—for example, at Bied, where, in sinking for the foundations of a house, a lacustrine cemetery was some time ago discovered; and at Colombier, where a stream running over the dry bed of the lake near the shore has laid bare *débris* identical with that brought to light by the excavations in question. From the quality and quantity of the winter stores, such as nuts, seeds, and berries,

found among these remains, the burning of the lake-dwellings probably occurred in spring or early summer. In one place a vessel was found filled with acorns, which, not being a favourite food, would naturally, it is presumed, be left to the last, and only used in default of something more palatable. From these facts and considerations it is inferred that at the time when many, if not all, the lake villages of Neuchâtel fell a prey to the flames, its waters were at the height usual with them in spring before their level had been artificially lowered by the engineering operations recently undertaken for confining within their channels the streams of that part of the Jurassic range which dominates the valleys of Neuchâtel and Morat.

THE death is announced, on Tuesday, at the age of eighty-two years, of Sir Anthony Panizzi, formerly Principal Librarian of the British Museum.

WE regret to announce the death of Herr Ludwig Reichenbach, an eminent German botanist and zoologist. He died at Dresden on the 18th ult., aged 86 years.

THE German scientific world is much gratified at the distinction conferred upon Dr. Julius Schmidt, of Athens, by the French Academy of Sciences, which recently honoured Dr. Schmidt by presenting him with the Prix Volz in recognition of his work on the moon. This prize is only given for important astronomical work, and has not been awarded since 1870.

THE various German societies for the protection of animals are now keenly discussing the vivisection question and have arranged a congress, which will shortly meet at Gotha, and which is to fix the final resolutions.

DR. J. E. TAYLOR has concluded the seventh winter series of scientific discourses at the Ipswich Museum. These have been free, and the average attendance has been 500 per night. Dr. Taylor regards the local collection of the Ipswich Museum as probably one of the best geological museums in Europe. He deserves credit for his exertions in spreading a knowledge of science in the district in which he lives.

ON Easter Monday and following day, the Geologists' Association will have an excursion to Weymouth and Portland.

WE have received a small pamphlet of eighty pages, containing the numerous opinions which have been expressed on Prof. Church's position with reference to the Agricultural College at Cirencester. The result of the conduct of the College authorities is likely to be the establishment of a rival institution, to be ready in October next. If it be the case, as is so generally alleged, that the Cirencester institution is a failure so far as agricultural education is concerned, we cannot be sorry that steps should be at once taken to supply the want.

WE have received the first two parts of a very fine "Atlas of Histology," by Dr. Klein and Mr. E. Noble Smith. The work is intended to be a pictorial and literal representation of the structure of the tissues of man and other vertebrates, its chief aim being to teach not so much the history of histology as histology itself in its modern aspect. The delicate illustrations are executed with wonderful care and beauty.

THERE was a slight shock of earthquake on the 3rd inst. at Cadiz.

IN the year 1877 Mr. Clark Mills, of Washington, the well-known sculptor, visited St. Augustine, Florida, in the interest of the Smithsonian Institution and of the Peabody Museum in Cambridge, for the purpose of taking casts of the heads of certain Indian prisoners in Fort Marion. These prisoners had been captured some years before, and sent to Florida for safe keeping, and were in charge of Capt. R. H. Pratt, of the Army. Most of them had been guilty of grave offences against life and property. A visit to and interviews with these Indians have constituted the staple of the correspondence of visitors to St. Augustine for several years past. During the year 1878 this station was broken up, some of the Indians being released, and others transferred to Hampton, Virginia, where, under the charge of General Armstrong, there is an establishment for the education of certain negroes. By authority of the War Department, Capt. Pratt has recently gathered up a large number of Indian youth of both sexes, and taken them to Hampton, where they are subjected to moral and mental training, and show a great aptitude for learning. Quite recently, at the request of the Smithsonian Institution, Mr. Mills visited Hampton, and with the assistance of Capt. Pratt, has made a series of excellent casts of some fifty Indians of both sexes and different ages. They will in time be reproduced, properly worked up, and exhibited in the National Museum, which will thus, in more than a hundred busts from life of the American aborigines, possess a very remarkable anthropological collection. Numerous applications have been received from the anthropological museums of Europe for copies of these busts.

THE Gauss monument for the city of Brunswick is now very nearly completed, the casting taking place in the studio of Prof. Howald, at Brunswick, after Herr Schaper's model, the well-known Berlin sculptor. The figure will measure nine feet in height, and the great mathematician is represented in a fur coat with a book in his left hand, bearing the inscription "Disquisitiones," the work which rendered his name immortal. The head is said to be a masterpiece of the plastic art.

SOME new experiments on digestion (in which portions of the stomach in living dogs were isolated, and their phenomena studied) have been recently described by Herr Heidenhain in Pflüger's *Archiv*. He arrives at these two (preliminary) conclusions:—(1) Purely mechanical stimulation acts only locally on secretion of gastric juice; (2) The secretion (act), however, extends beyond the place of stimulation to distant parts of the mucous surface, when absorption occurs at that place. In other words, we must distinguish a primary and a secondary secretion. The primary is small and is produced by mechanical effect at the place of stimulation; the secondary is abundant and depends on the act of digestion, in so far as absorption is connected with this, in the stomach.

WE learn that experiments have been made at Mont Valérien by the French Ministry of War with a number of portable Gramme electro-magnetic machines and portable lenses for directing the rays to a great distance and exploring the horizon during night with the same accuracy as during open daylight. The optical apparatus is mounted on a special waggon and weighs no more than two or three tons. It has been ascertained that the machines can travel with the same velocity as mounted artillery. The electric light and directing-lines can also be used for signalling in a known direction at an immense distance, as from Paris to Orleans, if placed at a sufficient altitude.

RECENT researches by Herr Ammon prove that the gas-absorption of dry ground depends on various factors—varying with the state of mechanical division, and chemical nature of the constituents of the ground, and the temperature and nature of the gas. (Quartz, clay, lime, hydrated iron oxide, gypsum, and humus were examined as to their behaviour with various gases of the atmosphere and the ground under different conditions.) Physical forces have an undoubted *rôle* in the condensation, *i.e.*, the gases are held and condensed by surface-attraction of the particles of the soil; and as this attraction is a function of the surface the effect is greater the smaller the particles. But che-

mical forces seem to have often a larger share in the effects; this appeared most distinctly in the remarkable absorbing power of hydrated iron oxide, and soils containing most of it; which can only be attributed to chemical changes undergone on access of gases, in consequence of the easy decomposition of the constituents. The same holds good for humus materials; whereas with the other constituents the physical "moment" comes out more prominently. Those gases which are easily brought into the liquid state (H_2O, H_2S, CH_4, NH_3, and CO_2), and which undergo changes easily (NH_3, SH_2), are absorbed in greater measure by the constituents of soils, than gases which are not readily liquefied (O). Temperature has great influence; with increase of it the power of condensing gases diminishes. It is notable that at temperatures between 0° and 10° the gas absorption again diminishes. (A fuller account of these researches will be found in *Der Naturforscher* for March 15.)

ANOTHER new Italian journal has come to hand, *Vita Nuova*, published fortnightly. It is devoted to literature, science, and art, and the scientific notes seem to us to be done with care and discrimination, containing occasional information on scientific work in Italy. It is published at Padua.

THE *Colonies and India* states that excellent accounts have been received from Tasmania. Stone exceedingly rich had been discovered in the Alpine reef, Fingal district, estimated to yield 200 ounces of gold to the ton. Gold had also been discovered at Castray River in the North Meredith Range on the west coast.

MM. FIGUIER AND DE PARVILLE have issued their *Année Scientifique*, which is a summary of all the notable discoveries made during the past year.

THE additions to the Zoological Society's Gardens during the past week include a Black-backed Jackal (*Canis mesomelas*) from South Africa, presented by Mr. E. J. Redman; a Red and Yellow Macaw (*Ara chloroptera*) from South America, two Yellow-fronted Amazons (*Chrysotis ochrocephala*) from Guiana, presented by Mrs. Kelly; two Silver Pheasants (*Euplocamus nycthemerus*) from China, presented by Mr. W. Soper; two Bernicla Geese (*Bernicla leucopsis*), two Brant Geese (*Bernicla brenta*), a Bean Goose (*Anser segetum*), two Common Geese (*Anser domesticus*), two Ruddy Sheldrakes (*Tadorna rutila*), two Common Pintails (*Dafila acuta*), two Gadwalls (*Anas strepera*), four Chiloe Widgeons (*Mareca chiloensis*), two Common Widgeons (*Mareca penelope*), two Garganey Teal (*Querquedula circia*), two Common Teal (*Querquedula crecca*), European, four Canada Geese (*Bernicla canadensis*), a Summer Duck (*Aix sponsa*) from North America, two Mandarin Ducks (*Aix galericulata*) from China, three Australian Wild Ducks (*Anas superciliosa*) from Australia, a Wild Goose (*Anser ferus*), three Common Ducks (*Anas boschas*), British Isles, presented by Mr. R. J. Balston, F.Z.S.; a Tuberculated Lizard (*Iguana tuberculata*) from Trinidad, presented by Dr. J. F. Chittenden, C.M.Z.S.; two Mississippi Alligators (*Alligator mississippiensis*) from the Mississippi, presented by Lord Francis Conyngham, M.P., F.Z.S.; a Common Lobster (*Astacus vulgaris*), British Seas, presented by Mr. R. J. Milestone; two White-rumped Roe Deer (*Capreolus pygargus*) from Eastern Asia, a Chinese Water Deer (*Hydropotes inermis*) from China, received in exchange; two Common Boas (*Boa constrictor*) from South America, deposited; eight Indian Jerboa Rats (*Gerbillus indicus*) from India, purchased.

VIRCHOW ON THE PLAGUE

AT a recent meeting of the Medical Society of Berlin Prof. Virchow gave (by previous request) his views on the subject of the Plague of Astrakan. The following is a brief outline of his address (which appears in the *Revue Scientifique*) :—

The information received about the plague is very uncertain and conflicting, necessitating reserve in giving an opinion. Russia is to be reproached for failure to send competent observers of the disease.

The first question is, What is the true determinant of the malady? No one would hesitate to say that the *buboes*, or swellings of the lymphatic glands, take the first place. But it is still doubtful whether or not certain acute forms occur without glandular tumour. (It is not merely the exterior glands that are referred to.) Typhoid fever, the most nearly related disease, is, of course, always (except in children) marked by a peculiar affection of the glands.

The pestilential bubo, like the alterations characterising many of our indigenous infectious diseases, consists in a cellular hypertrophy, with more or less hyperæmia and hæmorrhage. We come again to an obscure point in asking, how does a bubo of this kind ulcerate? The ulcerations in typhoid fever show suppuration, *within the glandular tissue*, round a dry mortified centre. Accounts by some of the best observers of pestilential bubo affirm suppuration *round the gland*. But the chief point is, what is the prime cause of the suppuration? And here I cannot affirm that the abscess of the gland arises from mortification of the gland. Some observers speak only of a softening of the substance. If partial mortification induced the ulcerations distinguishing plague, as they do those of typhoid fever, the analogy between the two diseases would be more marked.

Though we do not really know whether glandular affections are, from the outset, an essential character of the disease, they yet present the essential criteria for diagnosis of the plague.

[Prof. Virchow proceeds to object to Hirsch's view regarding the Indian Plague of Pali, in 1838, which showed peculiar symptoms, as a particular species of plague. Either it was the plague or it was not the plague. If the malady of Astrakan were a peculiar Indian plague we should not be warranted in identifying it with the well-known plague of the Levant, for this alone is the true plague. Hæmorrhage of the urinary organs (as in the plague of Pali) is very common even in the Oriental plague; but he would not therefore create a special hæmaturic species of the plague, but say that hæmaturia is often a symptom of the plague. He does not now refer either to this plague of Pali nor to a known endemic plague, restricted to two districts of the Himalayas.]

Another special character of Oriental plague is carbuncle; it occurs in nearly a fifth of the cases; the symptoms are like those of ordinary contagious carbuncle. There is no sufficient evidence of carbuncle in internal organs. Then there are the petechiæ, or spots, and interior hæmorrhages. Tumour of the spleen seems very constant, and of great importance, and we find also tumefaction of the liver and kidneys. The swellings of the glands, the carbuncles, and the petechiæ are the most important symptoms.

At the beginning of most pestilential epidemics a Committee of doctors has generally declared that it was not the plague. They pronounced it petechial typhus. This was the case immediately before the outbreak of the plague at Rescht, when the disease had been long confined in Kurdistan and Mesopotamia. M. Tholozan was the first to say it was plague, and that the case was that, not of a great epidemic, but of a latent disease, spreading slowly and attacking only a few. It is indubitable that we have there a true centre, whence the disease gradually spread, and I do not see why we should go to India, where the disease has not prevailed for many years past. Proceeding logically, we shall accept this course: From Kurdistan and Mesopotamia to Persia and on to beyond the Caspian. Even if the present cases on the other side of the Caspian were accompanied by pneumorrhagia, I would not hesitate to say they belonged to the plague proper, and that the disease is the same as that in Mesopotamia. The symptoms are very different from those of petechial typhus, the disease which the Turkish doctors affirmed. If near Salonichi (Xanthi) there be really petechial typhus accompanied by *Metastasis bubonica*, I fear it is the plague. It remains to keep our eyes open and see what happens after the return of the Russian army from the infected country (an occurrence which may well rouse grave apprehensions).

What has been done for our protection is little apt to tranquillise us. A blockade comprising all the frontier as well as the coast, from the Baltic to the Black Sea, seems to me illusory.

One example of severe quarantine has occurred in this century in the case of the plague at Noja, in Bari (Kingdom of Naples), in 1815. Trenches were dug, and three cordons of sentinels were

formed (the third round the entire province), with orders to kill whoever tried to break the blockade and did not stop at the first summons; and some individuals were actually killed. But I cannot think an entire country is able to protect itself thus. Examination of passports would be excellent if those who deliver passports and certificates of health were angels. But the Russian functionaries are men, and think like men. The impossibility of always getting true certificates of origin has been seen in the case of the cattle plague. I consider, however, that pressure should be exerted on Russia to form a blockade of the infected districts. And especially it should be seen to, that the returning Russian army does not bring any pestilential germs with it. As to restrictions on communications by land, the greatest of these are ineffectual for the end desired.

I cannot give an opinion as to whether the matters which are now forbidden to be imported into the German Empire may propagate the plague. The negative does not seem to suffice. We know that the skin or hair of an ox affected with carbuncle may engender contagion after several months in distant countries; we should not forget this, and we have not the right to say that garments, linen, bedclothes, &c., are perfectly innocuous.

A word on two points relative to disinfection. On Prof. Pettenkofer's advice, the German empire has decided for sulphurous acid as a means of disinfection. I question if this substance would penetrate linen, clothes, wool, &c., in such a complete way as to annihilate all germs. In my opinion a better plan is disinfection of clothing, &c., by dry heat in a chamber surrounded by steam-pipes, the temperature being raised to 120° C. or more. This plan is more rational and easy, and damages the objects least.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

In the Cambridge Senate, last Saturday, Mr. Balfour, a recent examiner in the Natural Science "Specials" for the B.A. degree, spoke of the schedule for botany, to which we referred recently, as extremely unsatisfactory and incomplete; histology was altogether neglected, physiology was very unsatisfactorily dealt with, and cryptogamic botany was almost entirely omitted. He was in favour of an examination in elementary biology being substituted, and practical work being required. Physiology should be made a separate subject. Prof. Humphry spoke in favour of reducing requirements in schedules to the narrowest range, in order to make natural science attractive to men. Mr. Trotter thought the schedule in botany an absurdly small representative of a year's work for a man supposed to have no other definite study. Mr. Bettany found fault with the present constitution of the Board of Natural Science Studies, which dealt with too many subjects, each being insufficiently represented by men engaged in teaching and research. No doubt it is hard for many to realise that biology has very many distinctive aspects, each of which must be represented by proficiency in them to prevent injustice and injury to scientific progress. Hindrances also arise from the fact that many of our present leaders and directors of study were developed before the full recognition of cell-study, embryology, and the like, as the basis of sound biology.

Dr. Alexander Dixon, Professor in the University of Glasgow, has been elected to the Professorship of Botany in the University of Edinburgh, vacant by the resignation of Dr. Balfour.

SCIENTIFIC SERIALS

The *Archives des Sciences Physiques et Naturelles* (February, 1879), contain the following papers of interest:—On the hydrocarbons obtained through the action of methyl-chloride upon benzole in the presence of ammonium chloride, by MM. E. Ador and A. Rillet.—On the theory of *timbre* and particularly on that of vowels, by Dr. Schneebeli.—On the scientific principles of the fine arts; essays and fragments on the theory, by E. Brucke, followed by remarks on optics and painting, by H. Helmholtz.—On some rare mosses, by J. E. Duby.—Stratigraphical study of the south-western part of the Crimea, by E. Favre.—Natural history of batrachia, by Fr. K. Knauer.—On apogamic ferns and on apogamy generally, by Prof. A. de Bary.—On the prolification of the fruit of mosses, by Dr. N. Pringsheim.—On polyembryony, by Dr. Ed. Strasburger.

The *Journal de Physique* (March) contains the following more important papers:—On spectroscopes with direct vision and great dispersion, by M. Thollon.—On the logograph, by M. Barlow.—On a new phenomenon of static electricity, by M. E. Duter.—Note on spectrophotometers, by M. A. Crova.—On the vibratory motion generated in the air and in space by electric sparks, by E. Mach.—On the electricity of air, by Rob. Nahrwold.

SOCIETIES AND ACADEMIES

London

Royal Society, March 13.—"On the Influence of Coal-dust in Colliery Explosions." No. 2. By W. Galloway. Communicated by Robert H. Scott, F.R.S., Secretary to the Council of the Meteorological Office.

The first experiment is made with a very simple apparatus consisting of a continuous pipe about 18″ in diameter, which conducts a small portion of the return air from the point at which it is ejected into the atmosphere by the ventilating fan, to a convenient spot on the level of the surface, where it escapes as a strong current, amounting to 1,251 cubic feet per minute. About 6 feet from its point of exit a lamp can be placed in the centre of the current, and at a distance of about a foot still nearer the origin there is a means of allowing coal-dust to fall into and mix with the passing air. It is found that when the coal-dust is added the air becomes instantly inflammable, showing that all the return air in the workings may be easily brought into the same condition by a sudden disturbance such as that caused by a local explosion of fire-damp.

The second experiment is intended to illustrate the effects of an explosion of fire-damp in a dry mine containing coal-dust. One part of the apparatus represents a gallery with coal-dust lying on its floor as well as in the horizontal timbers, the buildings and other rough surfaces at its top and sides; another part represents a cavity in the roof containing an explosive mixture of fire-damp and air. When the explosive gas is ignited the flame sweeps down into the gallery, the disturbance raises the coal-dust, and the results are exactly those that have been foreseen. The gallery is a wooden pipe 14 inches square inside, by 79½ feet long. The explosion-chamber is a sheet-iron cylinder lined with thin wooden laths; it is 5 feet high by 15 inches in diameter, and it stands vertically on the top of the gallery at a distance of 5 feet from one end. Currents of air of different quality can be made to pass along the gallery from the end next the explosion-chamber, which can be isolated by means of a valve, to the other end which is open to the atmosphere; thus the return air of the mine can be made to traverse it, or a current of pure air, or a current of air mixed with any required proportion of fire-damp. At the point where they enter the gallery these air-currents are heated by a steam cylinder, which occupies part of the space between the explosion-chamber and the nearer end, so as to assimilate their temperature to that of the air in a mine. The coal-dust is spread along the floor of the gallery, and some is laid on shelves so that it may more easily mix with the air when it is disturbed.

The explosive mixture is made by admitting about half a cubic foot of fire-damp into the explosion-chamber at its upper end, while a corresponding quantity of air is allowed to escape through a plug-hole at its lower end. The bottom of the explosion-chamber is separated from the gallery by a diaphragm of paper during this part of the operation. After the requisite quantity of fire-damp has been admitted, its volume having been accurately measured so as to guarantee that the results will always be the same, the mixture is effected by rapidly revolving a small fan, situated at the top of the explosion-chamber, and so constructed as to draw in air from the centre of the chamber, and throw it out at the circumference. From the point at which the fan draws in its air a 4-inch pipe descends to near the bottom of the explosion-chamber, and when the fan is revolved the air is drawn up through this pipe and discharged at the top of the chamber, from which it finds its way again to the bottom, and so on. The circulation established in this way is so rapid that a perfect mixture can be made in half a minute. The explosive mixture is ignited by means of a spark from a powerful magneto-electric machine.

When there is no coal-dust in the gallery the flame of the fire-damp explosion does not extend further than from 7 to 9 feet from the bottom of the explosion-chamber.

When the gallery contains coal-dust, on the other hand, on the floor and on the shelves referred to, and when it is filled with the return air of the mine the explosion traverses its whole length, and shoots out into the air to distances varying from 4 to 15 feet. The flame of the fire-damp explosion is thus magnified ten times by the presence of the coal-dust and the return air.

When pure air is employed instead of return air, other things remaining the same, the explosion is only about one-half as extensive; and when an artificial mixture of air and fire-damp is employed, of the same composition as the return air, without its excess of moisture, the explosion is stronger than with the return air. The arrangements whereby pure air and air and fire-damp can be used have only been recently completed, and few experiments have been made with them as yet.

Although the apparatus employed in this experiment appears to be on too small a scale to solve the coal-dust question unequivocally, the results obtained with it appear to be sufficiently conclusive to enable us to affirm that an explosion, occurring in a dry mine, is liable to be indefinitely extended by the mixture of air and coal-dust, produced by the disturbance which it initiates.

The only means of avoiding the dangers due to the presence of coal-dust in mines appears to be to carefully and constantly water the roadways leading to and from the working-places.

It is very interesting to be able to mention a fact in connection with watering the roadways which, although not mentioned in Mr. Galloway's paper, is well worthy of a place here, viz., that the Abercarne explosion, ramified through every part of the workings, which were exceedingly dry and dusty, with the exception of one district from which it was entirely cut off by 200 yards of a very wet roadway, and that the men in the latter district not only escaped unhurt, but hardly felt the explosion. The wetness of this roadway was due to natural causes.

April 3.—"On the Thermal Conductivity of Water," by J. T. Bottomley, Lecturer in Natural Philosophy and Demonstrator in Experimental Physics in the University of Glasgow. Communicated by Prof. Sir William Thomson, LL.D., F.R.S.

The result arrived at by the experiments described, is that the thermal conductivity of water may be taken at from ·0022 to ·00245 in square centimetres per second.

Some experiments have been made on the thermal conductivity of solution of sulphate of zinc, a solution which happened to be convenient for preliminary trials. The specific heat of solution of sulphate of zinc at different densities, which it is necessary to know for comparison as to thermal conductivity of that liquid with water, has been determined.

Experiments are now being carried on on this subject with the assistance of a grant from the Government Fund of 4,000*l*.

Anthropological Institute, March 25.—Mr. E. B. Tylor, D.C.L., F.R.S., president, in the chair.—Mr. Henry Seebohm, F.Z.S., gave some interesting particulars respecting the native races of Arctic Siberia, accompanied by an exhibition of ethnological objects collected in that region. In 1874 he visited Lapland, of which he gave some account, and in the following year he proceeded from St. Petersburg to Archangel, and thence 600 miles eastward, where he first came in contact with the Samoeïdes, and obtained some particulars about the Voguls, who dwelt across the Ural range. But his most adventurous journey was in 1877, when he accompanied Capt. Wiggins on his expedition for the exploration of Arctic Siberia. After travelling 2,500 miles from London to Nishni-Novogorod, they took sledge thence, and pushed on 3,500 miles farther, until they reached the Arctic Circle. In the Tartar villages there which they visited they found that the crescent predominated over the cross, and what still more surprised them, it seemed to be the symbol of a superior civilisation and order. The native languages were akin to the Turkish. The copper-coloured Buriats, who dwelt behind the Baikal Mountains, were a somewhat different race, and bore a strong resemblance to the Chinese. The Ostiaks and Dolgans were located on the colossal river Yenisei, which was reckoned the third largest river on the face of the globe. The Tungoosks were settled on one of its chief tributaries. The costumes, weapons, tools, smoking-appliances, reindeer-harness, snow-shoes, snow-goggles, idols, &c., of these and kindred tribes were shown, together with a remarkable case of prehistoric bronzes, found in ancient Siberian graves, and thought to be from 4,000 to 5,000 years old.—A paper was read by Sir Charles Nicholson, Bart., D.C.L., LL.D., on some rock carvings found near Sydney, New South Wales. Rude carvings of human and other animal forms, especially kangaroos and fishes, including the whale, had been found at various points of the coast of New Holland, from Cape Howe to Moreton Bay. The present natives had no tradition as to their origin, yet there were no good grounds for refusing to regard them as works of indigenous art. Col. Vigors had copied many of them, and a number of his drawings were handed round. One of these carvings represented a wall thirty feet long. Those found in Sydney cavern included a kangaroo at bay and a man erect, with out-stretched arms. Another class of similar carvings were chromatic. They were found on the north-west coast, and had been plausibly supposed to be the work of Malay pearl-fishers or shipwrecked sailors.

Zoological Society, April 1.—Prof. W. H. Flower, LL.D., F.R.S., president, in the chair.—An extract was read from a letter addressed to the Secretary by Mr. Carl Bock, respecting the habits of the Mountain Antelope of Sumatra (*Capricornis sumatrensis*), of which he had obtained a living specimen destined for the Society's collection.—Mr. J. W. Clark exhibited and made remarks on a drawing of a Dolphin belonging to the genus *Lagenarhynchus*, which had been lately taken off Ramsgate.—Prof. Flower exhibited a coloured drawing of a young female of the common Dolphin (*Delphinus delphi*) lately taken off the coast of Cornwall, and made some observations on the published figures and geographical distribution of the species.—The birds' eggs collected during the *Challenger* Expedition were exhibited. The series was stated to contain about 250 eggs belonging to fifty different species. Amongst these were eggs of the Sheathbill (*Chionis minor*) from Kerguelen, and of the Wandering Albatross (*Diomedea exulans*), from Marion Island.—Prof. Mivart exhibited a figure of and made remarks upon a Kestrel with abnormal feet, in the collection of the Marquis de Wavrin, at Brussels.—Mr. R. Bowdler Sharpe, F.Z.S., read an account of the collection of birds made by Mr. F. W. Burbidge, in the Sooloo Islands. A new Jungle Fowl was described as *Gallus stramineicollis*, and a new Parrot as *Tanygnathus burbidgii*.—A second communication from Mr. Bowdler Sharpe, consisted of a list of the birds of Labuan Island and its dependencies, founded principally on the collections formed during the last four years, by Governor Ussher and Mr. W. H. Treacher, but including also descriptions of a large number of eggs carefully collected by Mr. Hugh Low. One new species, *Cypselus lowi*, was described.—A communication was read from Mr. R. Collett, C.M.Z.S., containing the description of a new fish of the genus *Lycodes*, from the Pacific, which he proposed to call *Lycodes pacificus*.—A communication was read from Prof. Garrod, F.R.S., containing an account of the variations in the trachea and tracheal muscles in the different forms of gallinaceous birds.

Institution of Civil Engineers, March 25.—Mr. Bateman, president, in the chair.—The paper read was on the electric light applied to lighthouse illumination, by Mr. J. N. Douglas, M. Inst. C.E. The author showed the progress of lighthouse luminaries from wood and coal fires to the introduction of tallow candles, fatty oils, mineral oils, coal gas, and electricity.

Statistical Society, March 18.—The president, G. J. Shaw Lefevre, M.P., occupied the chair.—Mr. H. H. Hayter, the Government Statist of Victoria, read a paper on the colony of Victoria; its progress and present position.—The following were elected as Honorary Members:—M. le Dr. E. Janssens, of Brussels, M. Arthur Chervin, of Paris, Signor Gerolamo Boccardo, of Genoa, and Prof. Dr. Fr. Xav. von Neumann-Sfallast, of Vienna.

Victoria (Philosophical) Institute, April 7.—Two papers were read, one by Thomas Karr Callard, F.G.S., and one, taking some special points, by Prof. Boyd Dawkins, F.R.S. The subject was the contemporaneity of man with the extinct mammalia (as taught by recent cavern exploration), and its bearing upon the question of man's antiquity. The first paper contended that the cavern evidence points to the more recent extinction of the mammalia referred to, rather than to the remote existence of man.

BOSTON, U.S.A.

American Academy of Arts and Sciences, March 12.—Prof. W. A. Rogers presented a paper on the coefficient of expansion of the brass bars used by the U.S. Coast Survey for standards of length. In order to compare different standards it was found

necessary to determine the coefficients of expansion of the particular bars on which the graduations were made. In the present case the coefficient was found to be ·0000097 by a process extremely simple and effective. The relations between water and air contact also seem to be well determined by this method of investigation.—Dr. J. J. Putnam showed a *pendulum myograph*, modified mainly for the sake of economy, from that of Wundt. The pendulum itself is made of the thickest plate-glass, and arranged so as to be moved up and down, with the aid of a racket and a counterpoise, together with the stage bearing the movable connections described by Wundt. Since for each position of the pendulum a tracing of given length would have a different significance from that in any other position, enameled cards were prepared with lines upon them diverging from the point of suspension, the intervals between which corresponded to ·01″ when the amplitude of swing was 20°. By means of this apparatus the *reliability of Marey's tambour* had been tested, with a view to its use in time-experiments in physiology. The delay for the tambour used, with a tube about 2 m. long, was found to be nearly ·01″, varying not more than ·002″ to ·003″ under impulses of different character and strength.

Geneva

Society of Physics and Natural History, December 19, 1878.—M. God. Lunel spoke of the variations of colour presented by the squirrel, and cited some cases of albinism of that animal in a special locality of the Valais.—Prof. Brun described observations of the phenomenon known as "rain of blood," made by him on May 14 last, on the Jebel Sekra, a summit of the Rist, at the western extremity of the Atlas, in Morocco. He observed it in the form of spots of a very bright red appearing in the rocks, and one to a mixture of siliceous sand and very fine lime, with abundance of unicellular algæ of the species *Protococcus fluvialis*, and containing especially peroxide of iron.—M. Wm. Barbey informed the Society of the gift recently made by Sir J. Hooker to the Museum of Lausanne of the herbarium of the botanist Gaudin of Nyon.

January 2, 1879.—Prof. Graebe made a communication on the discovery of alizarine in the various colouring matters extracted from it, and particularly on alizarine allies.—M. Alph. de Candolle gave an account of the number of specimens contained in his herbarium, commenced by his father in 1798. At the time of the death of the latter in 1841, the herbarium contained 161,748 specimens; now it contains 287,636 belonging to 80,000 or 90,000 vegetable species.

Paris

Academy of Sciences, March 31.—M. Daubrée in the chair.—The following papers were read:—Conformity of the systems of fractures obtained experimentally with the systems of joints which traverse the cliffs of Normandy, by M. Daubrée. These joints form two systems, and the general effect is like that produced in a plate by weak torsion.—Convenience of special denominations for different orders of fractures of the earth's crust, by M. Daubrée. He proposes the name *diaclase* for a fissure produced by rupture; *paraclase*, to express that the fracture is accompanied by displacement; and *lithoclase*, as a general term including the two large groups now specified.—New process for the gauging of rivers, by M. Boileau. This process is based on the property of water-courses, that at the surface there are two streams whose velocity of translation is equal to the mean velocity of the current. The hydrometric operations are reduced to use of a float.—On the last floods of the Seine, by MM. Lalanne and Lemoine. Last winter was marked by two successive floods reaching (at a short interval) very nearly the same high level (6·21 m. at the Pont Royal on January 8 and 6·05 m. on February 24). Since 1872 M. Lemoine has organised, under M. Belgrand's direction, a system of warnings of flood (three days previous) for the Seine and its larger affluents. They are sent by telegraph or otherwise to seventy four persons in Paris and sixty-seven outside of Paris, and have proved very correct.—On some observations of glazed frost similar to that of January last, and on the mode of formation of hail, by M. Colladon. In large hail-storms, the cumuli producing them are divided into several distinct groups, insulated electrically from each other by sections of dry and cold air, resembling smoke-columns from several chimneys. The columns of hail the author conceives as a huge descending piston; hence the violent whirling movements of wind near the ground, and the descent of cold, dry, highly electrified air from the upper regions, to restore equilibrium; this air divides the clouds into nearly vertical columns; hence the peculiar forms of lightning during those storms.—M. Du Moncel presented a work entitled "L'Eclairage Electrique."—Prof. Lawrence Smith was elected Correspondent in Mineralogy in room of the late Sir Charles Lyell.—Chemical researches on a filamentous matter found in the excavations of Pompeii, by M. de Luca. The substance (which seemed formed of numerous filaments) was black and almost completely carbonised; on simple pressure with the fingers it was reduced to powder. The threads seem to have been flax or hemp, altered by various natural agents underground during eighteen centuries.—On the cost of constructing lightning-conductors, by M. Melsens. His system applied to the large new barracks at Etterbeck-laz-Bruxelles, on buildings occupying 20,000 square metres, will be less than 6,000 francs.—Observations of Planet 193, discovered at Marseilles Observatory, by M. Coggia, February 28, 1879, communicated by M. Stephan.—On two equations with partial derivatives relative to the multiplication of the argument in elliptic functions, by M. Halphen.—On cylindric or logarithmic potential with three variables and its employment in the theory of equilibrium of elasticity, by M. Boussinesq.—Anomaly presented by magnetic observations of Paris, by M. Flammarion. Since 1870-71 the last maximum of sun-spots and of diurnal variation of the declination-needle, the amplitude of this variation has decreased everywhere except at Paris; here it seems stationary; and even the year 1877, which should approach a minimum, presents a maximum. Some like anomalies are observable in previous times.—On the thermal and galvanometric laws of the electric spark produced in gas, by M. Villari. *En résumé*, the thermal and galvanometric deflections produced, the former by the spark, the latter by the discharge of a condenser, are proportional to the quantity of electricity which produces them, and to the length of their active circuits.—Magnetic rotatory power of gases at ordinary temperature and pressure, by M. Becquerel. With improved apparatus he has not only got the rotation-effect but been able to measure it with precision. He gives results for coal-gas, &c.—On the magnetic rotatory power of vapours, by M. Bichat. The experiments were like the Strasburg ones, but with a brass instead of an iron tube (which is objected to as forming a hollow electromagnet).—Pressure exerted by galvanic deposits, by M. Bouty. A cylindrical thermometer bulb covered with gold leaf or silver is made negative electrode in decomposition, *e.g.*, of a salt of copper; the rise of mercury when deposit occurs is noted. All metals, zinc included, exert pressure thus; but the pressure is not necessarily normal nor the same at all points, and cannot serve directly as a measure of the phenomenon; it is the result of a change of volume of the metal in deposition.—On the alkalies of pomegranate, by M. Tauret.—On the formation of carbonic acid, alcohol, and acetic acid by yeast alone, without oxygen, and under influence of this gas, by M. Bechamp.—On glazed frost observed in Florida, by Mr. Collin.

THE AUSTRALIAN AND TASMANIAN RACES

The Aborigines of Victoria, with Notes relating to the Habits of the Natives of other Parts of Australia and Tasmania. Compiled from various sources for the Government of Victoria by R. Brough Smyth, F.L.S., F.G.S., &c. 2 vols. (London: Trübner and Co., 1878.)

IN these two bulky volumes we are for the first time presented with a really comprehensive account of the natives of Australia; and by their timely publication under the auspices of the Victorian Government an emphatic reply is given to the charge often brought against the colonists of indifference to the past history, present condition, and ultimate fate of those races. The work, whose title gives a very imperfect idea of its varied contents, may be best described as a complete encyclopædia of Australian folk-lore, as complete, at least, as a judicious utilisation of all available materials could render it. As such, its appearance may fairly be regarded as an "epoch-making" event in the progress of ethnological studies, performing much the same office for the Australian that the writings of Castren, Uslar, and Bleek, and the Schoolcraft series have done for the Finno-Tartar, Caucasian, South-African, and North-American races. In the character and selection of the subject-matter it bears most resemblance to this last-named compilation, while differing widely from it in the method of its treatment, the confusion and discordant elements inseparable from Schoolcraft's erratic plan being here avoided by a clear arrangement of the materials and a uniform system consistently adhered to throughout.

A large portion of the work, it should be mentioned, has been composed by the distinguished geologist, Mr. R. Brough Smyth, at intervals during the sixteen years he has acted as secretary to the Board for the Protection of the Victorian Aborigines. In this capacity he has had exceptional opportunities of obtaining the most reliable information regarding the natives of that colony, who naturally occupy the largest share of attention. But the others are by no means neglected, and the subject is rendered sufficiently complete by several valuable papers on the tribes of New South Wales, Queensland, South and West Australia, supplied by the Rev. W. Ridley, Philip Channey, J. Moore Davis, and other contributors, all speaking from personal knowledge of the facts.

Besides an able introduction of some fifty pages, surveying the whole field and imparting a certain unity to the work, the first volume is devoted to strictly ethnological subjects. Under twenty separate headings the physical and mental qualities of the aborigines, their social habits, daily life, food, diseases, dress, weapons, implements, manufactures, and myths, are treated in detail. The general impression produced by a careful perusal of the vast array of facts here brought together is, that the "black-fellow" is not nearly so black as he has been painted, a statement which is quite as true in the material as it is in the moral sense of the word. Thus the prevailing colour is represented as not black at all, but rather a "chocolate brown," sometimes inclining to black, sometimes of a lighter hue, and it may be remarked that this is supported by the independent testimony of Richard Oberländer, a most accurate observer, who expressly states that "die Haut ist nicht schwarz, sondern von dunkler Kupferfarbe" ("Der Mensch vormals und heute," Leipzig, 1878, p. 41). The hair also, though in some cases jet black, would appear to be more frequently of a "deep brown," and with boys and girls, "in colour brown, not very dark" (i. p. 5). This, combined with its wavy character ("crisp," "waved," *passim*, but never "woolly" or even "frizzly," like the Papûan), will be regarded by many anthropologists as conclusive of the mixed origin of the aborigines. On this interesting point the compiler unfortunately throws very little light, though he adopts the view held by many, that "there are in Australia two distinct races of men, one of which is clearly of the white variety" (i. 328). By "the white variety" he obviously means what is commonly understood by the "Caucasian" type, and the countenance here and elsewhere given to the belief in the presence of a Caucasian element in Australia is one of the weak points of the work. The curious lists of words adduced, though with some reserve and hesitation, in support of a community of speech carries us back to the days when etymology did duty for science. Thus the native terms *kurrin*, *trippin*, *throkkun*, are compared with the English *inquiring*, *dripping*, *throwing*, leaving the impression that there might possibly be some sort of connection between a native verbal ending *in*, *un*, and the quite recent English verbal ending *ing*—recent, at least, in its modern participial and gerundial senses. Of course, those who bring together such fanciful comparisons have no sense at all of the growth of language, but they might have common sense enough to reflect that it is a growth, and consequently that in the case of idioms assumed to have been originally one, the comparisons must be made not between subsequent historical developments, but between primitive organic elements, if any such exist in common. Then when they have exhausted English, Anglo-Saxon, Greek, Mœso-Gothic, Sanskrit, they rush off to Hebrew, Phœnician, and especially Tamulic and Telugu, without reflecting that, however mixed, the Australian tongues can hardly be made up of such utterly discordant elements as Aryan, Semitic, Dravidian, or that if they are Aryan, they cannot be Dravidian, and so on; hence that their etymological method, proving too much, proves nothing, or, in other words, is unscientific. It is much to be regretted that these simple principles are not more generally understood, and that too many otherwise valuable ethnological works should still continue to be disfigured by linguistic discussions which, a generation or so hence, will be looked upon as amusing anachronisms.

The sections devoted to the native weapons, stone implements, canoes, &c., are of great interest to the anthropologist, who will here find more than one long-cherished doctrine rudely shaken. Thus the argument for a common Australoid race, embracing the Australians, natives of the Deccan, and others, based on the supposed identity of the boomerang with the Indian throwing-stick is shown to be utterly worthless. The question of the resemblance between the *wonguim* or true returning boomerang and other similar weapons met with amongst

other ancient and modern peoples is discussed at considerable length, and the result thus briefly summed up in the introduction:—"Those who have seen such a wonguim thrown by a native accustomed to its use, need not be told that the statements published from time to time in the scientific journals in Europe are founded on imperfect information, or dictated in an unphilosophical spirit by a too great desire to prove that the Dravidian races of the Indian Peninsula and the ancient Egyptians belong to the Australoid stock, and that the boomerang was known to the Egyptians. . . . . There is nothing to show that anything like the wonguim was known to any other people anywhere at any time, and it is at least doubtful whether any weapon resembling the barngeet [*i.e.*, the war boomerang that does not return] was known to the Egyptians. The wonguim and barngeet are altogether different from the saparu, or sickle-shaped sword, which is represented on Babylonian and Assyrian cylinders as the weapon of Merodach or Bel." Thus the boomerang goes the way of the etymologies, though it is but fair to add that the famous passage quoted at p. 327 of vol. i. from St. Isidore of Seville, descriptive of the Gaulish or Teutonic *cateia*, "Genus Gallici teli ex materia quam maxime lenta; quæ, jactu quidem, non longe, propter gravitatem, evolat, sed ubi pervenit vi nimiâ perfringit. *Quod si ab artifice mittatur rursum reddit ad eum qui misit.* Hujus meminit Vergilius dicens. *Teutonico ritu soliti torquêre cateias.* Unde et eas Hispani *Teutones* vocant" ("Origin." xviii. c. vii.), has not been satisfactorily got over. At the same time it may not be superfluous to remember that Gauls and Teutons were not Dravidians, and that, notwithstanding its return motion, the *cateia* was not necessarily a *wonguim*, for other weapons also can be made to behave in the same way. The author regards the boomerang as of native invention, and adds that it is not known in all parts of the Continent, and has not been found in New Guinea or Tasmania.

In the section devoted to the subject of canoes, another popular error is exploded, for it is here abundantly shown that seaworthy boats made of the bark of the gum-tree, and evidently of native invention, were common in the south and east, and not merely on the north coast, where they might have been introduced by the Papûans from New Guinea, or the Malays from the Eastern Archipelago. On the other hand, the practice of cannibalism, about which doubts have always been entertained, is fully confirmed. "It cannot be denied that cannibalism prevailed at one time throughout the whole of Australia. The natives killed and ate little children, and the bodies of warriors slain in battle were eaten. . . . . It is sad to relate that there are only too many well-authenticated instances of cannibalism," &c. (Introd. xxxvii.). It may be added that some years ago the writer received direct evidence of an undoubted case from a lad named Benedict brought to Europe by Dr. Brady, formerly Roman Catholic Bishop of Perth (West Australia), and who assured him that his own little sister had been "speared, roasted, and eaten" by a hostile tribe near New Norcia.

The current views regarding the extremely low mental capacity of the natives, and even regarding their moral qualities, are in other respects shown to be entirely at variance with the truth. In such a wide area there are, of course, great mental as there are great physical differences. But the author's assertion that the estimate commonly entertained of their intellect is, on the whole far too low, seems to be fully borne out by the evidence here accumulated. Though without permanent dwellings, they make provision for the future, construct permanent works of art, have a common property in some things, respect each other's rights, are skilful hunters, have five different ways of catching fish, and are far less cruel and ferocious than many savage races usually regarded as their superiors. They have a keen sense of justice, though their standard of right and wrong, and their notions of political economy may be different from ours, as is evident from the language addressed to Mr. G. F. Moore, Advocate-General of West Australia, by *Yagan*, Chief of the Upper Swan tribe, in the year 1843: "Why do you white people come in ships to our country and shoot down poor black fellows who do not understand you? You listen to me! The wild black fellows do not understand your laws; every living animal that roams the country, and every edible root that grows in the ground, are common property! A black man claims nothing as his own but his cloak, his weapons, and his name! Children are under no restraint from infancy upwards; a little baby boy, as soon as he is old enough, beats his mother, and she always lets him! When he can carry a spear he throws it at any living thing that crosses his path, and when he becomes a man his chief employment is hunting. He does not understand that animals or plants can belong to one person more than to another. Sometimes a party of natives come down from the hills, tired and hungry, and fall in with strange animals you call sheep; of course, away flies the spear, and presently they have a feast! Then you white men come and shoot the poor black fellows! But for every black man you white fellows shoot I will kill a white man! And the poor hungry women have always been accustomed to dig every edible root, and when they come across a potato garden, of course down goes the wanná (yam-stick), and up comes the potato, which is at once put into the bag. Then you white men shoot at poor black fellows. I will take life for life" (ii. p. 228). And so the comedy is played out, until there are no more "black fellows" left on the scene, and when they are gone the white man does them, perhaps, the tardy justice to admit that he never understood them, and that they were not, after all, quite so bad as he had supposed.

At one time the natives were thought to be so stupid that they could not recognise the pictures or other representations even of such familiar objects as kangaroos, emus, or gum-trees. But so far from that being the case, they are here shown to be tolerably expert draughtsmen; and at p. 258, vol. ii. there is given a facsimile of a drawing of some squatters by a native lad, in which the attitudes and expressions are admirably delineated, "clearly indicating the humorous train of thought passing through the mind of the artist, who must have been a close observer and a good mimic."

From the facts adduced in the section devoted to the native myths it is evident that they have some notion of a future state, though their ideas of the deity are often somewhat crude, and their conception of the universe decidedly materialistic. Thus we are told that *Bun-jil*

created all things, but he made no women. Bun-jil has a wife named *Boi-boi*, a son named *Bin-beal*, and a brother named *Pal-ly-yan*, and though the creator of all things, yet he had help from his son and brother. He always goes about with a large knife, and after making the earth he went all over it, cutting and slashing it into creeks and rivers, mountains and valleys. Such, at least, is the belief of the Boonooreng tribe, Coast of Victoria. But, on the other hand, that of the Barwen tribe differs little from the Christian conception; for their account is that *Baiame* (lit., the *builder*, *shaper*, cf. *Schöpfer*) made earth and water and sky, animals and men. "He makes the rain come down and the grass grow;" he has delivered their fathers from evil demons (cf. the mediæval doctrine of demonology); he welcomes good people to the great *warrambool, i.e.*, watercourse and grove, in the sky—the Milky Way—a paradise of peace and plenty; and he destroys the bad" (cf. Revelations, *passim*). Indeed, the parallel is often so striking, that a suspicion sometimes arises whether these myths may not be spurious, mere travesties of the Christian doctrines disseminated by the missionaries amongst the natives, and improved upon by them for the benefit of over-zealous collectors of popular traditions. The doubt is raised in this work, but not always removed. Some, however, are undoubtedly genuine, as, for instance, the account of the River Murray, which was made by a snake. "He travelled from the head of the river to the mouth, and as he went along he formed the valley and the bed of the river." But in doing this he disturbed the crow, which was perched on a tree, became angry, and cut him into small pieces. The pieces are left where the Hindu myth leaves the turtle that supports the elephant upholding the globe.

The second volume is mainly devoted to the native languages, but also contains a series of appendices consisting of a number of papers on incidental subjects supplied by the contributors already referred to. Of these the "Notes on the System of Consanguinity and Kinship of the Brabrolong Tribe," by A. W. Howitt, and the monograph on "The Crania of the Natives," by Prof. Halford, of the Melbourne University, are specially interesting. The latter, which is a very valuable contribution to anthropological studies, is illustrated by a series of carefully made drawings of five skulls, by Major Shepherd, from four different points of view, and is accompanied by complete tables of measurements on the plan recommended by Prof. Cleland, and for the purpose of "obtaining national distinctions of a most exact description." Amongst these skulls is that of "King Jemmy," of the Mordialloc tribe, which presents some very remarkable peculiarities. It is of an extremely brutal type, in the front view showing a mid-rib running along the top, like the crest of a gorilla, and bounded on either side by a temporal ridge, which, with immense orbits, nasal fossæ, and prognathous upper-jaw, give it a most ape-like appearance. Jemmy, lately deceased, is not stated to have been of an abnormal type; and the side view, in which the brutal aspect disappears, conveys rather the impression of a skull of large capacity.

The philological section, occupying altogether 220 pages, does not consist of a systematic treatise on the native languages, but is made up of a number of papers by more or less competent hands, on a large number of Victorian dialects. Some of these papers, as might be expected, are very sketchy and superficial, but others are extremely valuable, containing, besides vocabularies, many grammatical features, short specimens and sentences accompanied by verbatim and free English translations. Ample materials are here supplied for forming at least a general idea of the nature of these idioms, and often of their mutual relations to each other. It is obvious that while all are strictly agglutinating, and so far of uniform structure, they do not stand on the same level, some being much more highly developed than others. They also agree in the general employment of pronominal suffixes instead of prefixes; but this is such a common feature that no conclusions can be drawn from it as to their mutual affinities, still less, as has been argued, for a possible relationship with the Dravidian linguistic group. Owing to their different stages of development, the grammar of some is far more regular and consistent than that of others, and the Lake Hindmarsh dialect, amongst others, is specially interesting, in its present state clearly showing the growth of true inflexion by the gradual absorption of detached pronominal elements. This will be made evident by comparing together the first and second persons singular, present, and future, of the two verbs *woarta* (to come) and *nyä-ngă* (to see) which are as under:—

Present	woartin yan woartin yar	Present	nyangan nyangar
Future	woartin yuan woartin yuar	Future	nyakinyan nyakinyar

Here we see in the first column the full pronouns *yuan yuar* of the future reduced in the present to *yan* and *yar*, while in the second column they become in both cases fused with the root. It is easy to understand from this example how the fusion might, in course of time, become the universal law, and how the language might pass thence rapidly from the agglutinating to the purely inflecting state.

Amongst the arguments here advanced in support of the view that all the Australian languages flow from a common source is one based on their generally defective numeral system. The dialect spoken near Wickliffe, Western Victoria, has distinct words for 1, 2, 3, 5, and 6; but this seems to be almost a solitary case, and it seems safe to say that as a general rule the native arithmetic is limited to the first two numerals, beyond which reckoning becomes a series of sums in addition, which even then scarcely ever gets beyond 10. A typical instance is the Lake Hindmarsh system, which runs thus: (1) Ke-yap; (2) pullet; (3) pullet ke-yap *i.e.*, $2 + 1$); (4) pullet pullet ($2 + 2$); (5) pullet pullet ke-yap ($2 + 2 + 1$), &c. It is also interesting to note the very general prevalence of the word for 2—*pullet*, *bullat*, *pulla*, *bulla*, *bolita*, *polaïl*, &c., occurring in most of the dialects all round the south and east coasts, and reaching far inland, especially in Queensland and New South Wales. This may be accounted for either by supposing that some more advanced tribe at some remote period evolved the idea of *two*, and passed it on to its neighbours, or that it had been evolved before the dispersion. In the first case it would afford no argument for the original unity of the race; in the second we should have to believe that since the dispersion scarcely a single tribe ever got beyond that

low stage of development. But this would seem to be altogether incredible, when we reflect on the immense lapse of time intervening since the dispersion, as shown by the vast accumulations of kitchen middens on many parts of the coast, and by the numerous stone implements that are constantly being turned up, some belonging to an age answering to the Neolithic, some even to the Palæolithic period of Europe. "Chips for cutting and scraping, fragments of tomahawks and pieces of black basalt are found on the low silurian ranges near the rivers and creeks in all parts of Victoria; and wherever the soil is dug or ploughed over any considerable area, old tomahawks are turned up, thus showing the immense period of time that the land has been occupied by the native race." Introd. lvii. Some of the kitchen refuse heaps are over an acre in extent, and "there are also some large shell-mounds on the coast, especially near Cape Otway, where the largest is about 300 feet long, 40 or 50 feet wide, and 16 feet high. It must have taken ages for the fish-eating natives of the coast to build up such heaps" (ii. 234). It seems inconceivable that during all these ages they should never have made a single step in advance of the numeral "two," assuming that this had been inherited from the outset. Hence the first hypothesis appearing to be the most reasonable, the argument for racial unity based on the general currency of the word for "two" falls to the ground. All the reasons for the prevalent belief in the original unity of the Australian languages are briefly resumed at pp. 43 and 44 of Introduction. None of them, except that drawn from their common phonetic system is, perhaps, very cogent; but altogether, taken in connection with other circumstances, go a long way towards justifying the general conclusion arrived at by Threlkeld, Grey, Schürmann, Moore, Bulmer, Hartmann, Hagenauer, and nearly all recent Australian philologists.

The work is rendered still more complete by a final section devoted to the Aborigines of Tasmania. Here nearly everything is brought together that is ever likely to be known regarding the physical and mental characteristics, habits, speech, implements, dress, ornaments, &c., of that extinct race. The difficult question of their origin and affinities is fully discussed, and ethnologists will feel specially thankful for the reprint of Dr. Joseph Milligan's valuable paper "On the Dialects and Language of the Aboriginal Tribes of Tasmania and on their Manners and Customs," which appeared originally in the Journals of the Royal Society of Tasmania. The importance of this contribution to Tasmanian ethnology is due to the fact that the compiler "was for many years Medical Superintendent of the Aborigines' Establishment, first at Flinders Island, and afterwards at Oyster Cove, to which the remnant of the race was removed in the year 1848" (ii. p. 480).

Mr. Smyth evidently regards the Tasmanians as belonging to a different stock from the Australians. They "are darker, shorter, more stoutly built, and generally less pleasing in aspect than the people of the continent. Their hair was woolly and crisp, and some bore a likeness to the African negro. Their aspect was different from that of the Australians. In their form, their colour, and their hair they were rather Papuan than Australian" (Introd.," lxix.). This last sentence probably goes very near the truth, and there can be little doubt that the island was peopled "by some members of the dark-skinned populations of the north" (lxxi.). Their woolly [1] or at least frizzly hair is alone conclusive as to the presence of Papûan blood. But there are, on the other hand, scarcely less clear indications of Australian affinities. The compiler himself admits that "they were not all alike," adding that "there is reason to believe that the members of some tribes were scarcely distinguishable from the Australians" (ii. 379). On the whole, the balance of evidence goes to show that they were a mixed race in which the Papûan element was predominant, and in which special features had been developed by long local seclusion.

This race is generally stated to have become extinct with William Lanney and Truganina ("Lalla Rookh"), the former of whom died in March, 1869, the latter in June, 1876, but some half-castes are still living, "and it is nearly certain that the blood will mix with that of the whites and never be lost. But the race, the traditions of the race, and the language are lost for ever" (ii. 384).

It remains to be stated that the work is well printed and richly illustrated throughout. It is also supplied with an index, which might be fuller, and with two maps on a large scale—the Australian Continent and a tribal map of Victoria. The few misprints that occur will doubtless be corrected in future editions, when the curious English sentence at p. 79, vol. ii., beginning with "However I am inclined," might also be re-cast. There seems to be also something wrong with the paradigm given at p. 30, vol. ii. of the verb *to go*, unless it be made up of three different roots (*Yangan*, *blanga*, and *plapa*); but if so, the fact should be stated. As it stands, the arrangement of tenses is about as intelligent as that of the same verb in popular English and French grammars.

A. H. KEANE

[1] "As woolly as that of any native of Guinea" (Cook); "black and woolly" (R. N. Davies); "woolly hair" (Lieut. Breton); "courts, laineux et crépus" (M. F. Péron).

ON THE MAGNETISM OF ARTIFICIAL MAGNETS

Sur le Magnétisme des Aimants Artificiels. Par V. S. M. van der Willigen. (Haarlem: Les Héritiers Loosges, 1878.)

VISITORS to the Loan Collection of Scientific Apparatus at South Kensington in 1876 will remember a remarkable series of permanent steel magnets contributed from the museum of the Teyler Foundation of Haarlem. Most of these were the work of a famed artificer of the name of van Wetteren, who during a period of thirty years has been occupied in the construction of magnets of excellent quality, under the advice and with the co-operation successively of MM. Logeman, Elias, and van Willigen. The last named of these, whose posthumous monograph lies before us, devoted himself for the last four years of his life to important researches in magnetism.

The memoir, published originally in the *Transactions* of the Teyler Museum, commences by explaining the methods adopted in fusing, tempering, and magnetising the bars of steel. A succeeding chapter describes the

methods employed in measuring the distribution and amount of their magnetism. Then come three long chapters recounting very minutely the details of the dimensions, weight, strength, &c., of no less than forty-six individual magnets, together with particulars of the successive magnetisations imparted to them. The work concludes with a discussion of results and of the formulæ for empirically representing them, and with a brief obituary notice of the author, by Dr. Figee.

It appears from the observations of the constructor, van Wetteren, that bars of steel of apparently equally good qualities in other respects will not make equally good magnets; a point which the author tells us he was unwilling to recognise until he found all the magnets fabricated from one bar inferior to *all* the magnets fabricated from a bar of what appeared to be equally good steel. English bar steel was found inferior by comparison with that manufactured on purpose by M. Wetteren, but the author confesses his inability to assign any reason for the inferiority. Concerning the details of forging and tempering a judicious silence is maintained. The method of magnetisation which was found most efficacious both for bar and horse-shoe magnets, was to place their extremities upon the poles of a powerful electro-magnet of the form constructed by Ruhmkorff for diamagnetic experiments; and then, while thus magnetised above saturation, to remove them after having applied the appropriate keeper. For magnets weighing so much as half a kilogramme an Elias ring was also applied as an auxiliary in the process of magnetisation. The maximum power was not developed until after two or three such magnetisations, the keeper being momentarily removed between each repetition. Reversal of the poles always produced consequent points. The methods of touch, the best of which the author considered to be Hoffer's method of stroking the horse-shoe magnet with a second horse-shoe of soft iron from the poles toward the equator of the magnet, he finally rejects, *in toto*, as being hurtful to the strength and regularity of distribution of the magnetism.

The most important part of the memoir is that devoted to a discussion of the portative force of magnets. Häcker has given the ratio between the portative force of a horse-shoe magnet and that of a bar-magnet of the same weight and length as two to one. M. van Willigen found the ratio with an actual magnet of Häcker to be as three to one; and with van Wetteren's magnets more than four to one. The empirical formula assigned by Bernoulli to express the relation between the weight of a magnet and its portative force is—

$$p = CR^{\frac{2}{3}},$$

where p is the weight which the magnet will sustain, R its own weight, and C a coefficient dependent on the quality of steel and other undetermined conditions. A magnet was adjudged good by the author's standard for which Bernoulli's coefficient had a value of 20 or 21; though 22·5 was occasionally attained. The empirical formula now assigned by van Willigen for the portative force of supersaturated magnetisation is—

$$P = \alpha K \sqrt{S} . \sqrt[4]{\frac{l}{\sqrt{S}}};$$

and for the permanent portative force—

$$p = \beta K \sqrt{S} . \sqrt[4]{\frac{L}{\sqrt{S}}} . \frac{L}{l},$$

where K is the perimeter and S the area of the polar surfaces, l the length of the bar, L the reduced length (or distance between the actual poles or points of maximum free magnetism), and α and β two coefficients depending on temperature, quality of steel, temper, &c. It will be seen that since for magnets of similar form the quantity $K\sqrt{S}$ is proportional to the $R^{\frac{2}{3}}$ of Bernoulli's formula, M. van Willigen has determined that factor of the coefficient which is concerned with the length of the magnet and the position of its poles. It would be interesting, though out of place here, to compare these results with those recently obtained by M. Petrowchevsky in his researches on the distribution of magnetism in magnets.

The author falls into the common error of ascribing to M. Jamin the invention of magnets made of laminæ of steel bound together in bundles. Magnets of this description were employed by Dr. Scoresby in his Arctic explorations at the beginning of the century, and may still be seen in the Whitby Museum, where they are deposited. Similar magnets were in even earlier use by Duhamel and Coulomb; and a magnet almost the counterpart of those of Jamin is described in a memoir on magnets by Geuns published at Venlo, in Holland, in 1768.

SILVANUS P. THOMPSON

OUR BOOK SHELF

Mittheilungen aus dem k. zoologischen Museum zu Dresden, herausgegeben mit Unterstützung der königlichen Sammlungen für Kunst und Wissenschaft. Von Dr. A. B. Meyer. Drittes Heft, mit Tafel XXVI.-XXXV. (Dresden: Baensch, 1878.)

DR. MEYER has now issued the third volume of his "contributions" to science from the well-filled stores of the Dresden Museum—a volume which quite equals its precursors in value and interest. The Director first gives us an account of his new cases for the exhibition of zoological objects, and supplies exact details as to their cost. These particulars may be useful for those engaged on the fittings of several other national museums which are now in process of erection. A contribution from M. Edm. de Selys-Longchamps, which follows, contains a general account of the dragon-flies of New Guinea and the Moluccas, and descriptions of a large number of new species of these insects. We have next an account of the human skeletons and skulls in the Dresden Museum, drawn up by the Director and Herr E. Tungel jointly. The number of skulls in the collection is stated to be 836. We have then an important article by our countryman, Mr. R. Bowdler Sharpe, on the collections of birds belonging to certain groups, made by Dr. Meyer during his expedition to New Guinea and the Moluccas. The groups treated of in this paper are the Accipitres, Dicruridæ, and Campophagidæ, of all of which divisions Dr. Meyer obtained a goodly series of specimens, embracing among the Campophagidæ examples of nine new species.

Dr. Kirsch, the Entomologist of the Dresden Museum, follows Mr. Sharpe with descriptions of some new wasps found in the collection, and the volume is concluded by a second portion of Dr. Meyer's memoir on the Papuan skulls of which he obtained such a splendid series during his Eastern Expedition.

It is quite evident that the present director of the Dresden Museum is not only capable of doing good work

himself, but is likewise able to extract good work out of other people—a task often more hard to be accomplished than the former one.

The Countries of the World. By Robert Brown, M.A., Ph.D. Vol. iii. (London: Cassell.)

THIS volume is devoted to Central and South America, and appears to us to present a fairly full and trustworthy and certainly interesting account of the countries of this most attractive region. Dr. Brown has evidently taken the trouble to search most of the authorities likely to help him. The illustrations to this volume are unusually good and appropriate.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

A Carnivorous Goose

I INCLOSE to you an account of a Golden Eagle, which I have reason to know to be authentic. The possibility of a bird so purely graminivorous as a goose being taught to eat flesh, and acquiring the power of digesting it, is extremely curious. It is well known, however, that cows are largely fed on fish offal in Scandinavia, and I have heard of a Highland cow devouring a salmon which an unwary angler had hid among fern on the banks of a river in Sutherland. ARGYLL

Isola Bella, Cannes, April 7

"March, 1879.—There is in the possession of W. Pike, Esq., at Glendarary, in the Island of Achil, Co. Mayo, a Golden Eagle, now about twenty-five years old, which was taken from the nest and brought up in confinement. This eagle, in the spring of 1877 laid three eggs, which Mr. Pike took away, replacing them with two goose-eggs, upon which the eagle sat, and in due time hatched two goslings. One of these died, and was torn up by the eagle to feed the survivor, who, to the great tribulation of its foster-parent, refused to touch it, together with the other flesh with which the eagle tried to feed it, Mr. Pike providing it with proper food. The eagle, however, in course of time, taught the goose to eat flesh, and (the goose having free exit and ingress to the eagle's cage) always calls it by a sharp bark whenever flesh is given to it, when the goose hastens to the cage and greedily swallows all the flesh, &c., which the eagle, tearing its prey to pieces, gives it.

"I saw them in May, 1878, when, the goose being a year old, had made a nest in the eagle's cage, and laid eleven eggs, and the two birds were sitting side by side on the nest. I hear from Mr. Pike that he did not allow them to hatch out, fearing that it might interfere with their attachment to one another.

"The eagle is very tame and fond of Mr. Pike; he goes into the cage, and it allows him to handle it as he likes, but will not allow any one else near it. It never attempts to get out of the hole made for the goose to go in and out."

Sense of Force and Sense of Temperature

THE sense of force, or of resistance to pressure, and the sense of temperature, have been very commonly confounded under one name, "sense of touch." Indeed, I think they are still imperfectly distinguished in many modern works dealing with the subject of sensation. Nevertheless, there can be no doubt as to these two being sensations altogether distinct. It is even quite probable that they are observed and transmitted by distinct nerve-systems.

An important and interesting question arises as to the kind of information given to us by these two senses; viz., how far it is merely relative, and how far these senses may, by cultivation, be made to give us absolute information.

So far as the sense of force is concerned, it is with most persons chiefly relative. Every one is prepared to say, but generally very roughly, that of two bodies, A and B, A is heavier than B. To test their relative weights we lift first the one and then the other, and decide between them. Sometimes we may go a little farther towards making an absolute estimate by means of the sense of force. I can tell, for example, that a weight is greater than 20 lbs. and less than 30 lbs. by trying to hold it out at arm's length; and most likely with a little practice I could learn to estimate weights to within closer limits than 5 lbs. on each side of 25 lbs. But such testing as this is all that is done in ordinary cases.

There is, however, a very remarkable case in which the sense of force is made absolute to a high degree by practice. It is the case of letter-sorters in the Post Office, who learn to distinguish letters that are over a particular weight with accuracy that is perfectly marvellous. It would be very interesting to try a series of experiments with letters of different weight, some slightly under weight for a particular postage, and some slightly overweighted, and to observe the errors or rather the limits of uncertainty.

The sense of temperature may also be rendered absolute to a certain extent. Several instances might be mentioned, some of which depend, as in the case of testing force by lifting the greatest possible weight in a particular way, on the limit of endurance.

One remarkable case of an absolute determination of temperature by the senses is that of the plumber and tinsmith who are in the habit of holding up the soldering bolt to the face, and judging by feeling whether it is at the proper temperature for a particular piece of work in hand.

Probably there are other cases in the arts in which the sense of temperature is cultivated to a high degree. It is in the hope of getting information on this subject through your readers that I address this note to you. J. T. B.

April 7

Did Flowers Exist During the Carboniferous Epoch?

MR. A. R. WALLACE, in his review of Mr. Allen's, "The Colour Sense" (NATURE, vol. xix. p. 501), has been misled in supposing the fossil insect from the Belgian coal-fields, named *Breyeria borinensis* may be a moth. It was originally described as the hind wing of an orthopterous insect, under the name of *Pachytylopsis borinensis* (*Comptes Rendus*, Soc. Ent. Belg. xviii. p. xli). Subsequently it was transferred to the lepidoptera on bad advice, and re-named *Breyeria borinensis* (same *Comptes Rendus*, p. lx.). Its original location was nearer the truth. I examined the fossil at Brussels in 1877, and have no doubt it belongs to the pseudo-neuroptera, family Ephemeridæ (*vide* my note to this effect in the same *Comptes Rendus* for 1877, xx. p. xxxvi.). The very dense transverse reticulation did not receive sufficient importance when M. de Borre was induced to refer it to the lepidoptera. Thus we remain without any zoological evidence that would tend to prove the existence of flowering plants in the carboniferous age. R. MCLACHLAN

Lewisham, April 4

Water-level Indicators

I OBSERVE in NATURE (vol. xix. p. 518) a description of what is stated to be a new form of water-level indicator which has lately been erected by the India-rubber, Gutta-percha, and Telegraph Works Company, at the Leamington New Waterworks.

So far as mere form goes, it possibly may be considered new, but hardly so in any other sense, as a water-level indicator, fulfilling the purposes you mention, on a very extended scale, has been in action at the Nottingham Waterworks for many months past. It is not only capable of being made to give smaller indications than one foot, but is actually doing so. This apparatus was designed and constructed in the electrical department of the General Post Office, and has given great satisfaction. I may mention that it was under the consideration of Mr. Preece so far back as the latter end of 1877, and but for his determination to have an instrument perfect in every respect before he turned it out, it might have been at work early in 1878. H. ROFE

Nottingham, April 8

Eastern Yucatan

Is there any information to be had about Eastern Yucatan? In 1847 the Maya Indians there rose against Mexico and have become independent. The animosity between them and the Mexicans is so great that there is scarcely any possibility of

penetrating to the Independent Indians of Eastern Yucatan from the western part of the peninsula, which remains Mexican. But should this not be possible from Belize (British Honduras)? I have heard that the coloured people of the colony trade with the Mayas. Would it be possible then to obtain some information in this way?

As to the interest of a visit to the Maya country by an educated traveller it would bear especially (1) on the condition of the people since they are free from their white masters. How does it compare with the condition of the Mayas of Western Yucatan, who live in a *de facto* serfdom to the large landowners? (2) The antiquities, of which we have a description by Stephens, but certainly would know more. Very likely the Mayas will allow a white man who is not a Spanish-American to travel in their country; they have no special reason to hate anybody except the latter.
A. WOEIKOF

Jurschtatskaya, 9, St. Petersburg, March 25

Deltaic Growth

IN reference to the question as to the amount of sediment brought down by Delta Rivers, I had occasion in 1877 to ascertain the amount of sediment carried by the waters of the River Plate, and found it to amount to the $\frac{1}{7762}$nd part by weight. Mr. J. F. Bateman, the well-known hydraulic engineer, in his report on the proposed harbour of Buenos Ayres, fixes the minimum flow of the River Plate at 670,000 cubic feet per second. Assuming its mean volume at 700,000 cubic feet per second (a quantity very much under the mark), it would appear that this river carries seaward some 224,000 tons of sediment every twenty-four hours—or say, in round numbers, 82,000,000 tons every year.

Some portion of this sediment is deposited in the 100 miles of river that intervene between Buenos Ayres and the sea, forming the great banks that render the navigation of the River Plate so troublesome, but a large portion is carried out to sea and deposited beyond the mouth.

I have been informed by captains of steamers trading with Buenos Ayres that the soundings shown on the chart of the coast of Uruguay vary considerably, in many places, from the actual ones now existing, and I have little doubt that a correct re-survey of this coast would show changes as marked as those discovered by Mr. Doyle near Rangoon.

The subject is one of great importance, as the coast of Uruguay is a difficult and dangerous one to make, and from the low character of the coast, the frequency of fogs, and the great uncertainty of the currents, captains have frequently to depend a great deal on the lead to ascertain their position when making this land. During the last few years several fine steamers—French, German, and English—have been lost on this coast near the Castillos, when making the land.
GEORGE HIGGIN

Temperature Equilibrium in the Universe in Relation to the Kinetic Theory

MY attention has been called to an ambiguous phrase in my recent paper[1] on the above subject (NATURE, vol. xix. p. 460) which it is necessary to rectify. On page 461 is the sentence "*Let us suppose now the excessive temperature to fall, or, in other words, the total energy to diminish.*" This is meant as a *supposition*, not as a possible case. The imaginary rise and fall of temperature in the universe are given merely for the sake of aiding the conceptions of the actual facts, by affording *imaginary* cases to show what the effects would be if such cases were possible.
S. TOLVER PRESTON

London, April 15

Transportation of Seeds

THE penetration of seeds of the so-called "flechilla" grasses into the flesh of Australian sheep is too well known to squatters. On some "runs" these grasses are so abundant that the annual loss of stock is a very serious matter. The ripe seed falls upon the wool, and, owing to the re-curved barbules with which it is armed, easily penetrates to the skin, when, its point being as sharp as a needle, every movement of the animal tends to drive it into the flesh. I have found the internal organs so crowded with seeds that they felt like a bag of needles if squeezed in the hand.
ARTHUR NICOLS

[1] "On the Possibility of Explaining the Continuance of Life in the Universe Consistent with the Tendency to Temperature-Equilibrium."

Earthquakes

A SHOCK of earthquake was felt in this neighbourhood on the evening of Tuesday, April 8, at 8·35 (about). We were sitting in the drawing-room of this house, when we heard a sound like the rumbling of a heavy waggon, or distant thunder. It increased in loudness till the room slightly vibrated and the window rattled, as it seemed to pass the house. From the peculiar nature of the sound, and the fact that we are some 50 feet above the road, and 80 or 100 yards from it, I felt certain the disturbance was due to an earthquake and not a passing waggon, but walked to the window to listen, when I heard the sound dying away in the distance. It seemed to come from the south-east, and travel towards the north-west, and to be audible, from first to last, for some seconds, perhaps five or six, because we spoke one to another during the time. I find that the shock was noticed by other people in the neighbourhood, and that in a cottage near Bettws Gormon, a mile or so from here, two glass bottles were thrown down from a high shelf and broken.
T. G. BONNEY

Bron Celyn, near Bettws y Coed, North Wales, April 10

WE were visited by an earthquake of some violence this morning at 2 A.M. (Cadiz mean time). The shock was preceded by a profound subterraneous noise like that of a distant carriage, and it extended to Port St. Mary and Port Royal (six miles). The earthquake travelled from south to north approximately; some clocks stopped.
AUGUSTO T. ARCIMIS

Cadiz, April 3

OUR ASTRONOMICAL COLUMN

BESSEL'S NEBULA IN PERSEUS.—On November 8, 1832, in zone 527, Bessel observed an object, which he recorded as a nebula, distant about one degree from 20 Persei. It is No. 1,063 of Weisse's second Catalogue, where, though called a nebula, it has 9m. attached. D'Arrest, in his "Resultate aus Beobachtungen der Nebelflecken und Sternhaufen," has two observations, in January, 1856, to the first of which he attaches a note that no nebulosity was visible in Bessel's position, and that possibly a comet was observed; the second observation records a star 9·10m., without trace of nebulosity or diameter, the place of which was found to be within a few seconds of arc from Bessel's position, preceded 24·22s. by a star 9m., 76″ to the north. In "Siderum Nebulosorum," &c., D'Arrest remarks: "Star 9m. quæ Besselio quondam nebulosa apparuit . . . Argelandro in Perlustratione ceu fixa 9·3 magn. apparuit; nobis sæpius inspicientibus nunquam nebulosa visa." This refers to the star in the "Durchmusterung," at 2h. 43m. 56·5s. + 36° 54′·2; Argelander has another star of the same magnitude, 9·3, 10′ south. Are we to infer that Bessel's star was surrounded in 1832 by nebulosity so conspicuous that it was caught at once in his zone observations, which had wholly disappeared in 1856, or, as appears the more probable conclusion, that at the time of his meridian observation a comet happened to be centrally over the star? In this case the observation gives its place for 1832 November 8 at 10h. 10m. 25s. G.M.T.; the catalogued position for 1825·0 is in R.A. 2h. 42m. 5·56s., Decl. + 36° 46′ 46″·7.

This observation of Bessel's might at first sight appear of some interest, considering that the comet of the November meteors (1866 I.) must have been near perihelion about November 1832, but upon further examination it will be found that with the elements of 1866 it is not possible to bring the comet near the observed position of the "nebula," upon any assumption as to the time of its arrival in perihelion.

BRORSEN'S COMET.—Comparing the second of the two observations on April 4, in Major Tupman's letter pub-

lished in NATURE, vol. xix. p. 527, with Dr. Schulze's elements, only with the perihelion passage assumed March 30·5716 G.M.T., the differences from observation are $\Delta\alpha = -2''\cdot1$ and $\Delta\delta = +1''\cdot3$. This position, therefore, with others obtained by Prof. Strasser and Dr. Tempel, show that when the mean anomaly is so altered as with the other elements of Dr. Schulze's orbit to bring about an exact agreement between the observed and calculated geocentric longitudes, there is still an outstanding difference between the latitudes of from one to two minutes, which indicates that, notwithstanding the apparently careful computation of the perturbations since the comet's last appearance in 1873, the elements determining the position of the plane of the orbit are susceptible of correction. The ephemeris we gave last week will, however, amply suffice for readily finding the comet, and we shall continue it for May in our next.

Mr. Tebbutt, of Windsor, N.S.W., writes that, aided by Dr. Schulze's ephemeris, he found the comet on February 22, and observed it again in the fading twilight on the following evening. It could hardly be seen with a telescope of less than four inches aperture. It had the appearance of an elliptic nebulosity, the major axis of the ellipse extending in the direction of the parallel of declination.

NEW MINOR PLANETS.—Prof. Peters, of Clinton, New York, notifies his discovery of No. 194, on March 22, in R.A. 12h. 11m., Decl. $+9^\circ\ 31'$, magnitude 10·5. No. 192 was found by M. Palisa at Pola on February 17, and No. 193 by M. Coggia, at Marseilles, on March 1.

GEOGRAPHICAL NOTES

AT the meeting, March 22, of the Russian Geographical Society, Col. Petroussevitch read a very interesting paper on his exploration of the Amu-daria, from Chardjui, in Bokhara, to the delta of the river, and on its former beds. M. Petroussevitch has arrived at the conclusion, based on a thorough levelling of the country, that the turning of the waters of the Amu-daria into the Sara-kamysh depression through one of the former beds, would not meet with great difficulties. This depression being, however, very wide and deep, the waters of the Amu River once arrived there, would form a great lake, and it would be difficult to direct them further to the Caspian. For this last reason it would be better to open a way for the waters of the Amu along one of its former beds which run south-east from the lake Sara-kamysh. All explorations make it very probable that in this way the Amu-daria could easily reach the Caspian. The Russian Trade Society sends, next summer, an expedition for the study of the lower parts of the Amu-daria, of the best direction for a railway to Central Asia, and of the possibility of a canal between the Amu and the Caspian. Several officers of the Russian general staff, with geodesists, a geologist, a botanist, an archæologist, and an artist will be members of this expedition. They will start from the Ural River, passing through Kara-tugay, Tashkent, and Samarkand; further they will go down the Amu to the Uzboi.

UNDER the title of "L'Afrique Centrale en 1522," M. A. J. Wauters, Assistant-Secretary of the Belgian Geographical Society, has drawn up an interesting memoir, in which he has gone with much care into the doctrine of Portuguese geographers respecting the discovery of Central Africa in the sixteenth century. M. Wauters was induced to study the subject by the recent discussions in regard to the geographical data furnished by the great globe in the Lyons Library, and if anything were required to dispose of its claims to originality, this memoir does it most effectually. He traces back the idea of a great central lake, under the name of Saphat or Sachaf, to the days of Martin Hylacomilus and Gerhard Mercator, so that the data on which it was based must have been known previous to the year 1522. M. Wauters's memoir appears in the current number of the *Bulletin* of the Belgian Geographical Society, and is illustrated by a facsimile map.

A LISBON paper gives the text of a letter which Major Serpa Pinto addressed to Sir Theophilus Shepstone from Shoshong, Bamangwato country, on January 2, and which adds some information to that already made public respecting his adventurous journey. He states that he went beyond the Zambesi and purposed proceeding to the east coast through the country of the Choculumbes, when successive obstacles obstructed his passage. Having lost all his resources and being abandoned by his carriers, he found himself in the greatest difficulties, when fortunately he heard of a missionary who had arrived at the Upper Zambesi, and he resolved upon finding him. After a journey of 200 miles he found the missionary, M. F. Coillard, a Frenchman of the Evangelical Mission of Sesuto, Basuto-land, director of the station of Lesibo. His strength being exhausted, Major Pinto was taken seriously ill, but on his recovery succeeded in reaching Shoshong with M. Coillard and accompanied by eight of his followers, the only ones who continued faithful.

THE Danish Government has appointed Lieut. Jensen to explore all the fjords in Greenland from Holsteinborg to the coast facing Disco. The explorations will bear on the moving ice-fields which send so many icebergs into the Polar Ocean.

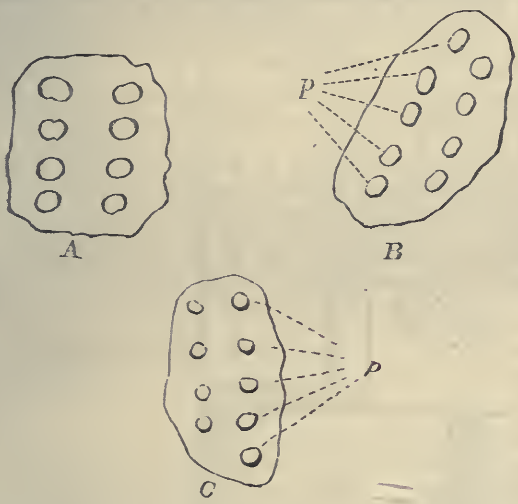
MR. IM THURN paid a second visit to the Kaieteur Falls, on the Potaro River, British Guiana, in February and March last, when the river was in full flood. Referring to our remarks on his previous visit, he states that he by no means intended to depreciate the grandeur of the fall. At his last visit he found it "so infinitely more grand, so infinitely more beautiful, that it is painfully hopeless to try to express in words anything of its beauty and grandeur." Mr. im Thurn's brief account contains several interesting notes on the botany and zoology of the region traversed.

THE WOLF FISH

OF late the wolf fish (*Anarrhichas lupus*) has been somewhat plentiful in the Frith of Forth. A specimen which lived in the Edinburgh Aquarium for a little over a week, came into my possession a few days ago, and I have thought that an account of the dental armature of this curious fish may prove interesting to readers of NATURE. The wolf fish is a near relative of the Blennies. In this fish we see the same elongated dorsal fin, and the same anal fin as in the Blennies; but the dental arrangements of the wolf fish are of a much more specific and unusual kind than are seen in the former group. The specimen dissected measured twenty-five inches from the top of the nose to the extremity of the caudal fin. It was therefore by no means a large specimen, since from six to seven feet is not an unusual length for the sea wolf to attain. Its dark grey body was faintly banded with brown, but the head was beautifully and distinctly marbled with black on a grey ground. The aspect of the mouth, provided with its well marked teeth, partakes somewhat of a feline look, and has suggested the name "sea cat," often applied to it on these northern shores, where the fish is frequently eaten, it somewhat resembling the cod in taste. The appearance of the mouth is highly characteristic. In front of both jaws is found an array of sharp incisor teeth. The upper jaw bears five of these pointed teeth, the two lateral teeth being large, and the central three teeth small. The lower jaw possesses six teeth of similar pattern, the two central teeth being larger than the four lateral ones; and when the jaws are closed

the lower teeth interlock in an exact manner with the upper. The hold or grip of a wolf fish must therefore be of a tenacious kind. Behind these incisor teeth, both above and below, are seen a few small teeth, destined by the ordinary laws of dental succession in the fish-group to replace the incisors in case of injury or loss. These front teeth are firmly anchylosed to the bones on which they are borne.

More interesting are the palatal teeth, and the corresponding teeth of the lower jaw. To these latter, the name of "molars" or "grinders" is frequently applied. Close to the front of the upper jaw we find a series of three tooth-masses, one central and two lateral, arranged in diverging fashion. The central and largest mass resembles the tuberculate molar of a bear in form, and is composed of four firmly united segments, each segment in turn consisting of two pieces. The lateral teeth of the palate, similarly consist of a double series of firmly united segments, but in each of these lateral pieces the outer row of pieces is composed of sharp-pointed segments, resembling miniature incisors. The accompanying diagram will afford an idea of these curious palatal arrangements:



A is the central piece; B and C are the lateral pieces, the outer teeth of which (*p p*) consist of pointed and incisor-like pieces. It follows from this description that the sea wolf possesses in its mouth an apparatus not merely adapted for tearing its food but for exercising a triturating and bruising action as well.

No less characteristic are the dental arrangements of the lower jaw. In the front of this jaw are four incisor teeth, each fully three-quarters of an inch in length; whilst two smaller incisors exist as already mentioned, one at each side of the larger series. Behind these incisors are the rudiments of succeeding teeth, and these rudimentary teeth gradually merge into the main dental arrangement of the lower jaw, which consists of a prominent row of blunt teeth anchylosed to form a common mass, and partially forming a double row on each side of the jaw. Section of the jaw shows that the teeth are imbedded in a common groove, and that complete and thorough ossification of the various dental pieces renders the whole apparatus compact and solid. The arrangement seen in the mouth of the wolf fish suggests the idea of the high specialisation of this type of fish, as indicated by the development of the dental apparatus. In none of the near neighbours of this fish have we at all a near approach to the perfection of teeth thus exhibited; and in respect of its complexity and differentiation of type, we may well be inclined to lend some countenance to the idea of the independent origin in widely removed fishes of structures seen in still greater perfection in such widely-removed fishes as the Elasmobranchiate Skates, Rays, and Cestracion.

The stomach of the specimen I dissected was greatly distended, and contained fully four ounces of digestive *débris*, consisting chiefly of disintegrated Ophiuroids, spider-crabs, broken shells, shrimps and prawns, along with sand and small gravel. The pyloric aperture was firmly contracted and the collection of matter in the stomach clearly pointed to some obstruction of the digestive canal as the cause of death. It was also instructive to find that close to the vent the rectum was largely distended with broken pieces of shells and fine gravel. These matters, along with those in the stomach, had evidently been intussuscepted before the arrival of the fish in the aquarium and probably caused death by the irritation consequent on their non-removal by digestion. ANDREW WILSON

THE ETNA OBSERVATORY

IT will be within the recollection of some of our readers that in September, 1876, Prof. Tacchini, of Palermo, communicated to the Accademia Gioenia of Catania a letter, "Sulla Convenienza ed utilita di erigere sull' Etna una Stazione astronomico-meteorologica" (*vide* NATURE, vol. xv. p. 262). This letter was published in the *Atti* of the Academy, and afterwards appeared in the form of a quarto pamphlet with ground-plan and elevation of the proposed building. The project was at once taken into consideration both by the Italian Government and by the Municipality of Catania; plans were prepared, money was voted, and it was confidently believed that the observatory would be commenced in July, 1878. Owing, however, to certain delays, this was found to be impracticable, and the commencement was postponed till June, 1879. There is every reason to believe that the building will be erected and the instruments in working order by the end of this year. The cost will be borne by the Government, the Municipality of Catania, and the Province of Catania. Merz, of Munich, has offered to construct a 12-inch lens for the great refractor, at the price of a 10-inch lens, and the enterprise has received encouragement and support from various sources both at home and abroad.

The observatory will be erected at the Casa degl' Inglesi, 9,652 feet above the level of the sea. At the present time the Casa is an oblong building constructed of blocks of lava, and containing three rooms (*vide* the accompanying plan). It was built by the English when they occupied Sicily in 1811, and has since been used by those who ascend the mountain as sleeping quarters. A few years ago it had fallen into decay owing to the accumulation of snow in winter and to other causes, but it was put into complete repair in 1862 on the occasion of the visit of the present King of Italy. The observatory will be the property of the University of Catania, and will indeed be a kind of offshoot of the Bellini Observatory of Catania. It is to be devoted not only to astronomical and spectroscopic observations, but it will also be furnished with a complete set of meteorological and seismological instruments. Between the Etna Observatory and Catania three or four meteorological stations will be established at different elevations, as at Nicolosi, and the Casa del Bosco, and observations will be made at the same hour daily at each of these stations, at Catania, and at the Etna Observatory.

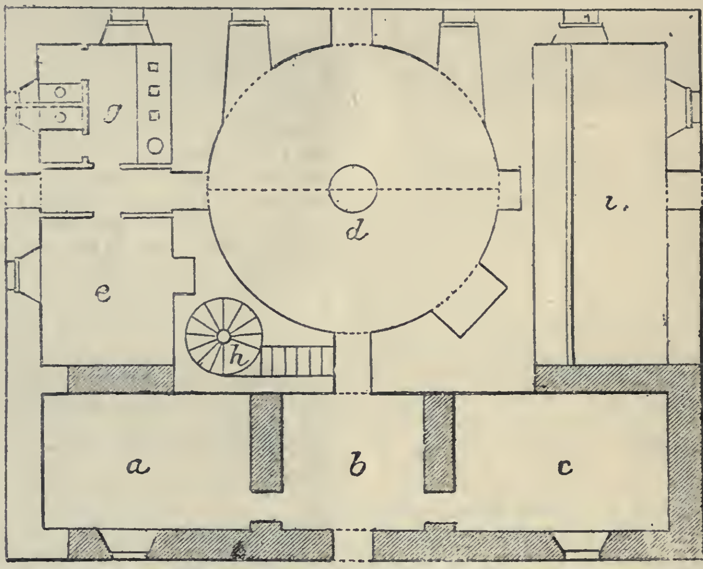
The Merz lens of 12 inches diameter, has a focal distance of $5\frac{1}{2}$ metres. The telescope and clock-work movement are in course of construction by Signor Carignata, the mechanician of the Padua Observatory, who constructed the instruments which were employed by the Italian astronomers who went to India to observe the transit of Venus in 1874. The observatory will only be inhabited during the months of June, July, August, and September, and the large lens will then be transported

to Catania, and fitted to a duplicate mounting in the Bellini Observatory. But a number of self-recording instruments will remain in the observatory, and thus results will be registered during the winter months.

Prof. Tacchini, to whom the whole undertaking owes its existence, specially desires that it should be an International Observatory. With this object in view, the large telescope will be fitted with a second tube, the length and aperture of which can be altered at will, so that astronomers from any part of the world can bring with them their objectives and eye-pieces, and can fit them to the telescope of the observatory. Special arrangements will be made for photographing the sun and moon, and for spectroscopic observations.

The observatory will contain the large telescope covered by the usual dome in the centre; on each side there will be rooms for the other instruments, and below, sleeping quarters, a dining-room, and kitchen for the use of travellers. The following plan, for which, together with many of the above facts, we are indebted to Prof. Tacchini, will show the general arrangement of the observatory.

In his report on the subject Prof. Tacchini commences by pointing out that since the year 1868 the study of the physical constitution of the sun has made very rapid progress. In these studies the spectroscope has played a very important part. But the spectroscopic observations are often hindered, and their exactitude is disturbed by atmospheric causes, and these disturbances are mainly due to the lower layers of the atmosphere. Hence an observatory at a considerable elevation would greatly facilitate such observations. The isolated Mount Etna affords an admirable locality for such an observatory. The blueness of the sky is intense, the stars shine with an extraordinary brightness, Venus casts shadows, spectroscopic lines which cannot be seen at the Palermo Observatory are perfectly distinct when viewed from an elevation of 10,000 feet. "Ora il mio desiderio," says Tacchini, "sarebbe quello di andare sull' Etna per verificare la tanto decantata purezza del cielo e il suo colore speciale, osservare l'aureola del sole, studiarne lo spettro se sarà possibile e fare anche qualche tentativo di fotografia. . . ." He then mentions some of the observations made by Young with a 9-inch refractor at an elevation of 2,800 metres, and describes his own observations made on Etna with a Dollond refractor of 99 mm. aperture,



a, b, c, the three rooms of the already existing Casa Inglesi; *d*, circular chamber, 8 metres in diameter, with a massive pillar in the centre, upon which the great refractor will be placed; *e*, a room for guides who accompany those who ascend the mountain; *g*, kitchen and offices; *i*, stable for mules; *h*, staircase. On the upper floor, *a, b, c*, will be bed-rooms; *e, g, i*, instrument-rooms; and *d*, the circular chamber for the refractor, extending through both floors, and surmounted by a movable dome of iron.

and a spectroscope of great dispersive power constructed by Tauber. "La cromosfera era magnifica e dettagliata abbastanza tenendo conto della piccolezza del magnesio e dello 1474, ciò che non vidi a Palermo collo stesso cannocchiale." Then having made the suggestions which are in part carried out, and which have entirely been adopted, he concludes by a fervid peroration which we heartily endorse:—"Io ritornerò dunque all' Etna, lo spero, e in migliore stagione, e sin d'ora mi figuro coll' immaginazione, la vista della nuova specola, che mi ricorderà l'epoca fortunata e la circonstanza solenne, che qui mi tiene ora unito a voi, e il nome del grande Bellini, che prima ancora di dare alle scene il suo capo lavoro, la Norma, volle in omaggio alla scienza degli astri, suonare all' osservatorio di Palermo la celeste melodia della preghiera alla casta Diva."

While we feel perfectly convinced that important results will accrue to more than one science from the establishment of the new observatory, we must not shut our eyes to the fact that many difficulties will have to be encountered. The observatory on Vesuvius stands upon a projecting spur of rock, and lava-streams of any ordinary magnitude breaking out on this side of the cone would divide, and leave the observatory as on a rocky island. But the Etna Observatory will stand near the upper termination of the Piano del Lago, the plain out of which the great cone of Etna rises. A great eruption, leading to the breaking down of the cone and flow of lava in this direction, could not fail to overwhelm the Observatory. Fortunately the lava usually finds vent by a *bocca del fuoco* on the sides of the mountain below the great cone. The building must be of very great strength; it will be subject to violent shocks of earthquake, to fierce storms of wind, and to the accumulation of great masses of snow upon its dome and roof. Those who have read the history of the mountain know with what tremendous power it scatters its terrors abroad; how hours of loud bellowings and detonations are followed by days of violent earthquake, and weeks during which many square miles of country are inundated by millions of cubic yards of molten lava. That the new Observatory may flourish, unassailed by the fearful forces of the imprisoned Cyclops, will be the wish of all our readers.

G. F. RODWELL

NOTE ON THE SPECTRUM OF BRORSEN'S COMET

On April 1 and 2 I succeeded in determining the position of the green band in the spectrum of Brorsen's comet. The spectrum was so faint that the other bands could not be measured. The instrument was the 9½-inch equatorial of our astronomical laboratory, armed with a one-prism spectroscope. The observations were made by bringing an occulting bar, movable by a micrometer screw, into such a position that the well-defined lower (less refrangible) edge of the band in the comet spectrum should be just visible as a thin line, the rest of the band being hidden by the bar. After the pointing the flame of a Bunsen burner was brought in front of the slit, and the position of the band in the comet-spectrum was thus fixed.

It was found by four independent pointings (which all agreed within about the interval of the *b*-lines) that the central band of the spectrum of the comet coincided precisely (within the limits of perception) with the green band in the flame of the hydrocarbon.

The interest of the observation lies entirely in the fact that it seems irreconcileable with the result obtained by Mr. Huggins in 1868, who found for the same comet a spectrum having bands distinctly different in position and appearance.

According to my observation, the spectrum of Brorsen's comet no longer stands out as exceptional, but agrees with that of other comets.

The comet itself appears in my telescope as a small round nebulosity, about 40″ in diameter, without definite nucleus, but much brighter in the centre, easily visible in the finder of 3 inches aperture, and about equal in brightness to a star of the 7th or 8th magnitude. Before the new moon a straight narrow tail, about half a degree long, was faintly visible with a low power.

C. A. Young

Princeton, N. Jersey, U.S.A., April 5

NOTES

We learn that Congress has sanctioned the scheme for the reorganisation of the American Surveys recently commented upon in these columns. It is understood that the Geological Survey will be placed under the control of Mr. Clarence King, who has so long had charge of the Geological Exploration of the 40th Parallel. But no details have yet reached us.

In the Paris Academy of Sciences, M. Alphonse Milne-Edwards has been elected a member in place of the late M. Gervais, in the Section of Anatomy and Physiology; M. Abich a correspondent in the Section of Mineralogy, in place of M. Damour; and Mr. Lawes a correspondent in the Section of Rural Economy, in place of the late Marquis de Vibraye.

The following are the probable arrangements for the Friday evening meetings at the Royal Institution after Easter:—April 25. Francis Galton, F.R.S.: "Generic Images." May 2. Prof. John G. McKendrick, M.D.: "The Physiological Action of Anæsthetics." May 9. Sir John Lubbock, Bart., M.P., F.R.S.: "The Habits of Ants." May 16. Prof. A. Cornu: "Étude Optique de l'Élasticité" (in French). May 23. W. H. Preece, M.R.I.: "Multiple Telegraphy, or Duplex and Quadruplex Telegraphy." May 30. Grant Allen: "The Colour-Sense in Insects; its Development and Reaction." June 6. Prof. Dewar, F.R.S. June 13. Frederick J. Bramwell, F.R.S.: "The *Thunderer* Gun Explosion."

A catalogue of the library of the Museum of Practical Geology and Geological Survey has been lately published, compiled by Messrs. H. White and T. W. Newton, which cannot fail to be of use beyond the walls of the library of which it is a record. The arrangement is alphabetical, the author's name and important groups of works, as "Geological Surveys" and "Statistics," being printed in black thick type, secondary titles and subdivisions in italics. The pages are clear and easily read and the titles full and accurate. The price, considering that there are over 600 pages, and that only 270 copies appear to have been printed, is somewhat less than that which is generally fixed on the publications of this Department. When the Geological Survey was instituted in 1843, its first Director, Sir Henry De la Beche, C.B., commenced the formation of a museum illustrative not only of the palæontology of the country, but of the economic application of geology to the arts and manufactures. These collections were exhibited in a small building in Craig's Court, and wishing still further to foster geological study, Sir Henry presented to the Survey the whole of his scientific library. This was added to from time to time, until in 1851 these collections were removed to the Museum of Practical Geology, which was built for their reception, and to provide accommodation for the Royal School of Mines, which was then instituted, and to a certain extent associated with the Survey. Since this time, partly by the annual grant from Parliament, partly from the gifts of the various scientific societies of the world, and partly by the bequest of the late Sir Roderick Murchison's library, it now numbers no less than 28,000 works, on the special subjects taught in the School of Mines, geology, mining, chemistry, biology, &c., and it is specially rich in foreign transactions, and the works of reference useful to a mining engineer.

Lord Dufferin, who had accepted the presidency of the Birmingham and Midland Institute, having been compelled to relinquish that office on his appointment to the Embassy at St. Petersburg, Prof. Max Müller was communicated with by the Council, and has signified his acceptance of the post.

The publication of weather warnings in Switzerland will begin on May 1 in Zurich, and on June 15 in Geneva. A telegraphic despatch, containing a description of the weather in Europe, with weather warnings, will be sent from the observatory every day, by telegraph, to any person who will pay quarterly 4*l*. 8*s*., and a shorter bulletin containing only a weather prognostic, will cost 1*l*. for three months.

Swiss papers are much alarmed by a case of infection by birds. Two brothers, merchants at Uster, in the canton of Zurich, who have a large collection of various birds and monkeys, lately received some tropical birds which were sent in a cage from Buda-Pesth. Immediately after the arrival of the birds the two brothers, the wife of one of them, and a shop-girl became sick. A third brother, who is a surgeon, understood the cause of the illness and ordered all suspicious birds to be killed, fifty or sixty in number, the cages to be destroyed, and a strong sanitary cordon around the house to be established. A tinker who had done some repairs to the cages also became sick and died in hospital, as well as an innkeeper and his wife, at whose inn the birds stayed for some days. The number of sick already has reached eight, and their state is very bad. The illness is described as a black typhus.

The third fascicule of the "Pflanzenleben der Schweiz," by M. Christ, has just appeared, and contains a very fine map which illustrates the subdivisions of the Swiss flora.

A committee has been appointed by the Paris Society of Photography to collect funds in order to erect a statue to Nicephore Niepce, who was born at Chalons-sur-Saone in 1765. The subscriptions are to be sent in Paris to M. Pector, 9, rue d'Albe, or M. Koziell, 20, rue Louis-le-grand.

Mr. Clifton Ward's papers on the physical history of the English lake-district have been reprinted in a separate form from the *Geological Magazine*.

M. Marie Davy, the director of Montsouris Meteorological Observatory, has set up a registering Thomson electrometer. The indications are recorded by photography in accordance with the system which has been established at Kew by the British Association. A comparison of readings taken by these two establishments will render essential services to the progress of meteorology. M. Descroix, the observer in charge of this instrument, was assailed before the Meteorological Society by a French *savant* who has invented another electrometer, in which the registration is taken with a pencil and mechanical force. But the discussion proved that such instruments are useless without knowing whether their indications are worth being recorded, as many objections can be raised against their use and have been published by competent electricians.

The French artists are preparing for an Exhibition of Fine Arts, to be held as usual in the Palais de l'Industrie from the beginning of May. When this exhibition is over a scientific exhibition will be organised by M. Nicolle, the successful organiser of the Exposition Maritime et Coloniale held in the same building in 1877. M. Jules Simon, M. du Moncel, and others are taking an active part in the preparations. The chief peculiarity will be the execution of all the scientific experiments capable of being made before an audience and on an unusual scale. The organiser will try to fill the lacuna, which was so much complained of in the last Champ de Mars exhibition.

A correspondent of the *Hiogo News* mentions that in the city of Kioto there are to be seen many semi-foreign buildings which are the Shogakko, or elementary schools. Of these there are 64 in the city, and 445 in the whole *fu*. Kioto is divided into two large districts, called Kami and Shimo Kiyo, which are subdivided respectively into 33 and 32 *ku*. Each *ku* is obliged to establish and maintain one of these schools, except in the case of poor *ku*, when two are allowed to unite and form one school district. Besides the usual Japanese course of studies, the pupils are taught the elements of foreign mathematics, history, geography, and philosophy, and they are also trained in gymnastic exercises. Education is compulsory, only those (who are of age) being exempted who are necessary to the support of their parents.

We learn that the organisation of the captive balloon has been altered by M. Giffard. The aëronautical and scientific staff has been constituted by him into a private company. He has placed at their disposal the funds required for the working of the balloon, and placed the enterprise in their own hands on their own responsibility and care. This arrangement has been agreed to by the public authorities, and will leave a handsome surplus on behalf of the men who spend their lives in the aëronautical career, as a large part of the profits, exclusive of a handsome weekly pay, is to be divided by equal part amongst them. A few important alterations have been made in the car, and ring, and netting. The net ascending power will be enlarged by a ton. A kind of india-rubber gas-meter, containing 100 cubic metres, has been constructed, in order to render inflation instantaneous between two ascents.

The Académie des Ascensions Météorologiques opened its Museum in Paris on April 3. More than 600 persons visited the gallery. It is to remain open every Thursday, and any day admission may be obtained by letter to the General Secretary, 50, rue Rodier. The number of exhibitors exceeds 120. Amongst the collection of aëronautical medals we note some commemorating ascents made in England in the end of the last century. A registering barometer for ascents to 5,000 metres is exhibited by MM. Richard frères; it was purchased by the government for the Meudon aëronautical establishment. M. Egasse exhibits an apparatus for filling balloons with hydrogen extracted by the action of zinc and chlorhydric acid. The result of the reaction is employed in large quantities for destroying miasmatic influence in barracks and other similar establishments. A new paddle has been constructed for ascending and descending without gas or ballast when the balloon has been placed on equilibrium with surrounding air, a new guide rope for diminishing the velocity by friction when the balloon is travelling at sea, a safety-car for these perilous occasions, differential valves, &c. Lectures will be delivered and ascensions executed by the members of the institution.

The *Cologne Gazette* reports, under date the 9th inst., a slight shock of earthquake at Buir and Elsdorf. The shock is stated to have been noticed at five minutes past midnight. It had a rolling noise and took an east-south-easterly direction.

The *Tiflis Messenger* says that a strong earthquake was felt on March 27 in Persia, at the Gulf of Miama.

A general exhibition of the various systems and apparatus used for electric lighting is to be held in the Royal Albert Hall in May. An inaugural lecture, at which the Prince of Wales has promised to be present, will be delivered in the evening of Wednesday, May 7, by Mr. W. H. Preece.

As an agitation prevails in France against the laws proposed by M. Ferry for prohibiting the members of unauthorised bodies from taking any part in public instruction, it is very likely that Government will retain the exclusive right of conferring degrees, but the proposed restrictions will be rejected by Parliament.

The following details (published by Herr Landauer in the *Reports* of the Berlin Chemical Society) regarding the behaviour of safranine when spectroscopically examined, may interest the readers of our recent article on "Absorption Spectra" (vol. xix. p. 495). It is well known that the salts of safranine show the remarkable reaction that the red colour of their solution turns into violet, indigo-blue, bluish green, and finally emerald green, upon addition of concentrated acids, particularly of sulphuric acid. The change of colour takes place in the opposite direction if safranine is dissolved in strong acids and water is gradually added to the solution. If these solutions are examined with the spectroscope, then it appears that each of the colours mentioned shows a separate spectrum. The green solution absorbs the violet, blue, and red rays, the bluish-green one behaves in the same way, but lets a part of the red rays pass; the blue solution absorbs only the yellow rays, and the more the colour of the solution turns violet and red through the addition of water, the more the absorption passes over to the green part of the spectrum. Herr Landauer attempted to determine the cause of these changes of colour in the liquid, and the corresponding alteration of the spectrum. Finding it difficult, however, to isolate the various chemical compounds formed in the liquid, it was only possible to try an explanation from the chemical behaviour of the liquid itself. Finally he arrived at the conclusion that of the two possibilities, formation of different acid salts, or of different hydrates of the same salt, the latter is the more probable one. The change of colour takes place also when the solution is evaporated, and reappears in the opposite direction when water is again added. The sulphate is the most characteristic salt of all; blotting-paper impregnated with a solution of this salt, and dried by heating until it has become green, soon becomes blue by attracting moisture from the atmosphere, and a drop of water thrown upon it instantly gives a red stain with a blue margin. Herr Landauer supposes that there exist three different hydrates (or two hydrates besides an anhydrous salt), which are red, blue, and green respectively, the violet and bluish-green tints resulting from mixtures of these. Herr Vogel's maxim, therefore, that the rule "each body has its own spectrum" can be admitted only with restrictions, may be still further restricted, inasmuch as it may be asserted that

absorption spectra only indicate the component parts of a compound so long as the colour of a given substance is characteristic of its chemical composition.

WE notice an interesting discussion which arose at the last meeting of the Russian Society of Hygiene. M. Malarevsky, pointing out the yearly increasing myopy of scholars, proposed to print books with white letters on a black field, and proved the superiority of this system by experiments he has made with fifty scholars, as well as by experiments on the facility of discernment of black drawings on a white field and of white drawings on a black field, these last always being better seen from a greater distance than the former.

WE have received a very full Catalogue of Official Reports upon Geological Surveys of the United States and Territories and of British North America, by Mr. F. Prime, assistant-geologist of Pennsylvania. It seems to be an enlarged continuation of the Catalogue by Prof. O. C. Marsh, published in the *American Journal* for 1867. The present list covers 50 pp.

AT the last session of the U.S. Congress an appropriation of 250,000 dols. was made for the construction of a fire-proof building for the reception of such collections belonging to the National Museum as cannot be at present accommodated in the Smithsonian Building; and as the plans have already been prepared, it is understood that the work will be begun without delay. The design contemplates a building 301 feet square, with certain projecting corners, the whole covering a space of about 97,000 square feet. Although not quite equal to the area of the Government Building at the Centennial, it is capable of containing a much larger mass of material. The general plan is that of a pavilion, of one story, with brick walls and iron roof, the floor to be of concrete. The corner buildings or projections constitute offices connected with the administration of the Museum, to include a library room, a small lecture-room, and others. It is expected that the entire edifice will be completed and ready for occupation by April 1, 1880.

THE whale whose bones have been so long exposed in the court-yard of the Jardin des Plantes at Paris, is to be demolished in compliance with a report from M. Quatrefages, who shows that the original number of vertebræ has been enlarged, and a series of important alterations have been successively made.

THE publishing office of *Science News*, hitherto published at Salem, Mass., will shortly be removed to New York.

MANY of our readers might like to know of Dr. Karl Möbius' address on March 5 last, on his assumption of the rectorship of the University of Kiel. Its subject is the passage from Goethe—"Leben ist die schönste Erfindung der Natur, und der Tod ist ihr Kunstgriff viel Leben zu haben."

THE Second Annual Report of the Board of Trustees of the Western Pennsylvania Institution for the Instruction of the Deaf and Dumb is one of great interest, and we are sure would be perused with pleasure and profit by all who are interested in the important subject. The Institution seems to be conducted on thoroughly scientific principles, and its success seems very marked. The Report is published by Stevenson, Foster, and Co., Pittsburgh.

WE have received a cheap edition of "The Caves of South Devon and their Teachings," by Mr. J. E. Howard, F.R.S., in which he endeavours to combat the long chronology assigned to the human race by Mr. Pengelly and others. Hardwicke and Bogue are the publishers.

THE *North British Daily Mail* of March 29 contains reports of recent meetings of the Geological and Natural History Societies of Glasgow. In the former Mr. Young gave a descriptive notice of an interesting specimen of *Elephas primigenius* discovered about four years ago when sinking a pit-shaft on Mainbill Farm, near Baillieston, east of Glasgow. In the latter Mr. Harvie-Brown read a paper on the Mammalia of the Outer Hebrides.

"NEW Views in Astronomy, illustrated by Working Models and Diagrams, and Demonstrated by Inductive Philosophy," is the title of a quarto pamphlet by Mr. John Harris, published by Wertheimer, Lea, and Co., of Finsbury Circus.

THE additions to the Zoological Society's Gardens during the past week include a Yak (*Bison grunniens*) from Bhootan, presented by the Hon. Ashley Eden, K.C.S.I.; a Japanese Goat Antelope (*Capricornis crispus*) from Japan, presented by Mr. H. Pryer, C.M.Z.S.; a Rhesus Monkey (*Macacus erythræus*) from India, presented by Mr. J. Roberts; a Grivet Monkey (*Cercopithecus griseo-viridis*) from West Africa, presented by Mr. W. B. Greenfield; a Common Seal (*Phoca vitulina*), British Isles, presented by Capt. Chas. Rawle; a Red-throated Diver (*Colymbus septentrionalis*), British Isles, presented by Mr. J. S. Thompson; a Masked Parrakeet (*Pyrrhulopsis personata*) from Fiji, an Entellus Monkey (*Semnopithecus entellus*), from India, deposited.

THE RESULTS OF RECENT RESEARCHES IN ANIMAL ELECTRICITY[1]

I.—INTRODUCTORY OBSERVATIONS

The State of the Subject Ten Years Ago

UNTIL the year 1867 certain theoretical conceptions based upon the classical investigations of du Bois-Reymond prevailed in the whole department of animal electricity. It may indeed be said that du Bois-Reymond created this branch of modern physiology, for it was he who first struck out the modern method of research and gave the lead to recent investigation. To his individual labours we owe not only the establishment and the orderly arrangement of many facts which had been left ill-defined by his predecessors, but also the actual discovery of a still greater number of fundamental value. These fundamental facts, briefly summarised, were the following:—

1. Muscular fibres and nerve-fibres when cut across exhibit a current directed within them from the transverse to the longitudinal surface, the electromotive force of which may equal one-twelfth of a Daniell's cell.

2. The negative potential of the transverse section also belongs, though in a less degree, to the natural terminations of the fibres of muscle ("natural transverse section"); but in this case it may be wanting, or even be changed to a positive potential. This diminution, absence, or reversal, of the common condition, to which the term "parelectronomic state" is applied, would seem to be favoured by the continued action of cold.

3. If a certain portion of a nerve-fibre be traversed by a galvanic current, the remaining portions, or the extra-polar regions, become the seat of an electromotive force which has the same direction as the traversing current, and which is strongest in the vicinity of the poles (electrotonus). This influence extends only so far as the structural integrity of the fibre is complete.

4. Muscles and nerves with artificial transverse sections exhibit during the period of stimulation a diminution ("negative variation") of their proper current. In uncut muscle the negative value of the diminution or variation becomes algebraically added to whatever current may be already present in the natural termination of the muscle.

Upon these facts du Bois-Reymond had based the following theory:—

1. Muscle- and nerve-fibres contain electromotive molecules suspended in an indifferent conductor, which present positive surfaces to the longitudinal surface or section, and negative surfaces to the transverse surface or section.

2. At the natural terminations of the muscular fibres are arranged particles of a peculiar kind, the presence of which is

[1] A lecture delivered on February 2, 1878, before the Medical Society of Zurich, by Dr. L. Hermann, Professor of Physiology in the University of Zurich, and published in the "Vierteljahrsschrift d. naturf. Ges. in Zurich," 1878. All the papers referred to in this lecture which have no author's name attached are papers of the author himself.

more or less marked, and which present positive instead of negative surfaces towards the ends of the fibres. Cold, according to the theory, favours the development of this "parelectronomic layer."

3. The electrical molecules of a nerve, under the influence of a current which traverses it, assume a new arrangement which consists in their turning negative surfaces towards the positive pole and positive surfaces towards the negative pole. If we conceive these molecules as electrically dipolar in the state of rest, they would be arranged in inseparable pairs, the positive pole of each member of a pair being turned to the positive pole of the other, the negative surfaces of the molecules being all turned to the transverse sections; and the action of the current would consist in an arrangement of all the molecules in the form of a pile. As this rearrangement of the molecules extends in a less degree beyond the portion of nerve traversed by the current, electrotonic forces are developed.

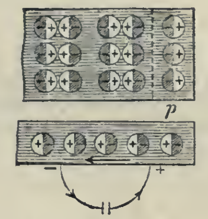


FIG. 1.

In Fig. 1 the upper diagram represents the normal, the lower the electrotonic, arrangement of molecules; above *p* are seen the parelectronomic molecules of the natural termination of the fibres.

4. During stimulation either the electromotive forces of the molecules diminish, or the latter assume a new arrangement, in which they appear less active externally; but the parelectronomic molecules take no share in these changes.

The promulgation of this molecular theory aroused many expectations. It appeared probable that the essence of the condition of activity and of its conduction in muscle and nerve was connected with the electrical properties of certain particles, rotation, oscillation or some other change in one particle leading to similar changes in neighbouring particles. Moreover, it appeared conceivable that even the contraction of muscle might be explicable by the actions of attraction and repulsion among the same particles.

Although speculation upon the origin of these electro-motive forces in muscle and nerve had hardly taken shape, and although the founder of the molecular theory observed a praiseworthy reserve in regard to all such speculation, yet up to the year 1867 it was pretty generally, if tacitly, assumed that the chemical processes occurring in muscles and nerves at rest were essential to the maintenance of the electromotive molecules in constant activity. In a similar way it was taken for granted that excitation depended ultimately upon certain movements of the electromotive molecules which were, of course, associated in some manner or other with increased consumption of oxygen and increased oxidation.

Researches which called forth New Views

Researches which I made upon the exchanges of the gases and other constituents of muscle [1] furnished me with results which differed materially from the then prevailing conceptions of the functional processes occurring in these organs. I found that muscles contain no oxygen capable of being yielded to a vacuum, and nevertheless that they are capable of prolonged exertion in a medium entirely free from oxygen; hence I concluded that the chemical process which underlies muscular work is not a process of oxidation, but a process of decomposition, in which, by the saturation of stronger affinities through the passage of atoms into more stable atomic combinations, energy is set free, just as in the alcoholic fermentation of sugar.[2]

Amongst the products of this decomposition in muscle there occurs carbonic acid. A comparison of the quantities of carbonic acid set free during muscular exertion, and during muscular rigor, showed that in both cases the carbonic acid must spring from the same source, and thus, with the help of an analogous result to which J. Ranke had arrived in the case of lactic acid, a complete analogy between the chemical processes of *contraction* and of *rigor*, was found to hold good. Both processes are processes of decomposition, and as products of the decomposition are known carbonic acid, lactic acid, and in the case of rigor an albuminous coagulum discovered by Brücke and Kühne, which may perhaps in the future be ascertained to be a transitory phenomenon even in the case of contraction. The absorption of oxygen by muscle has nothing to do with this process of decomposition; the former is related to a synthetical process of restitution in which certain of the products of decomposition are perhaps again utilised. In this way was explained the independence (in point of time) between the absorption of oxygen and the production of carbonic acid by muscle.

According to this conception there occurs, during the condition of rest, a perpetual but slow decomposition and a slow process of restitution; the latter is dependent upon a supply of blood containing oxygen. If the supply be intercepted, then the whole store of decomposable matter within the muscle becomes exhausted, and the muscle passes into rigor. During contraction the process of decomposition is suddenly quickened, and the process of restitution can barely keep pace with it: when the latter lags behind the former *fatigue* results.

The analogy between contraction and rigor had attracted attention long before, although, excepting the shortening of muscle, no other feature common to the two processes was known. Rigor had been designated as the last contraction of dying muscle. The new conception reversed the comparison, inasmuch as it assimilated contraction to a momentaneous and transitory rigor; and, since then, the physical analogies between contraction and rigor have been discovered to be more and more numerous. It has been found that in rigor as well as in contraction the volume of the muscle diminishes somewhat, and that in both processes heat is developed; while, to complete the relationship, it has been lately observed that certain evident transitional stages occur between the two.[1] Thus stimuli of excessive intensity, when applied to muscle, lead to a condition in which the state of contraction never perfectly disappears, but leaves behind it a residue of shortening. Fatigue and the process of death favour this condition of persistent, rigor-like contraction (Schiff's "Idiomuscular Contraction"), and a similar condition is induced by many muscular poisons, as veratria, delphinia, digitalin, emetin, caffein, &c.

While pursuing the analogies between the conditions of contraction and rigor I came upon a view of the nature of animal electricity which differed essentially from that which was then in existence.[2]

Fundamental Conceptions of the New Theory

The most important and at that time the most certainly ascertained fact was this, that a transversely divided muscular fibre exhibits, until it has become completely rigid, a negative potential in the plane of the section, and that this difference of potential diminishes or disappears during the state of functional activity. Having regard to the chemical and physical analogy between the processes of activity and of rigor; and considering the fact that when an artificial cross-section is made there is from the very first a portion of matter within the fibre which is passing into rigor, I explained this phenomenon on the assumption that the process of rigor, like the process of contraction, so modifies the protoplasm that it takes on a lower potential than the unchanged inactive protoplasm.

If this be so then an artifical cross-section must preserve a lower potential so long as the fibre has not become rigid throughout its entire extent, and on stimulation of the portion yet alive a diminution of the electrical difference must result.

II.—The Electrical Currents of Organs at Rest

The Absence of Currents in Muscles which are at Rest and Uninjured

In order to sustain the new theory of animal electricity (which, in opposition to the "Pre-existence Theory" of du Bois-Reymond I have designated the "Alteration Theory"), it

[1] Untersuchungen über den Stoffwechsel der Muskeln ausgehend vom Gaswechsel derselben. Berlin, 1867.

[2] Similar views have been more recently expressed, and with a somewhat more general application, by J. Liebig, in the "Sitzungsber. der bayr. Acad.," 1869. ii. 4; and by Pflüger, "Arch. f. d. ges. Physiol.," x. p. 251, 1875. I myself had extended this view to the chemical processes in nerves and glands.

[1] "Arch. f. d. ges. Physiol.," xiii. p. 371, 1876; xvi. p. 252, 1878.

[2] "Untersuchungen zur Physiologie der Muskeln und Nerven," 2 u. 3 Heft. Berlin: 1867, 1868.

was in the first place necessary to determine whether absolutely uninjured muscles are the seat of a muscular current.

Muscles cut out of the body possess almost invariably imperceptible injuries of a mechanical or chemical nature. In the first researches of du Bois-Reymond the muscles were regularly moistened with saturated solutions of common salt, and thereby, to a certain extent, corroded. Hence he was led to ascribe to the natural terminations of muscular fibres the negative potential which is exhibited by artificial transverse sections. This source of error was indeed discovered by du Bois-Reymond himself; but, after he had removed it, there yet remained other electrical phenomena apparently dependent upon the terminations of the fibres, differing, however, entirely from that just mentioned and obeying no strict rule in respect of direction of current. For these phenomena the hypothesis of the parelectronomic layer was introduced.

The more, however, all injuries are avoided in the preparation of muscles about to be used for such observations, the nearer is the approach to complete absence of currents. Chief among the injuries in the case of the frog is that produced by contact with the caustic secretion of the external skin.[1] The gastrocnemius is a muscle which may very readily be defended from such contact during its preparation, and it then exhibits merely weak currents of indefinite direction, such as are found in all circuits containing moist conductors.[2] The muscles of the thigh are, without exception, so connected with one another or with neighbouring parts (skin, bones, &c.) that they cannot be prepared without sustaining *mechanical* injuries in the course of the necessary manipulation.[3]

The statement that cold favours the development of a currentless condition, or of opposing currents, in muscle is not confirmed. The gastrocnemii of freshly-caught frogs do not differ electrically from those of frogs kept for a long time previously in an ice-cellar.[4] It is perhaps as well to observe that muscles which have been actually frozen suffer injury in the subsequent process of thawing, and are therefore to be avoided in these researches.

The most promising method of testing perfectly uninjured muscles appeared to be to examine them in the unskinned animal. Du Bois-Reymond,[5] who was the first to hit upon this method of observation, encountered an unexpected difficulty in the cutaneous currents which almost all animals possess. If it is first attempted to abolish the cutaneous currents by cauterising the skin with salt solutions, the solution rapidly penetrates the skin and attacks the underlying muscles; this is observed to occur by the gradual development of the same current as is induced when the naked muscle is moistened by caustic agents. That the muscles have already been attacked by the time the muscular current is developed[6] may be directly shown by employing silver-nitrate as the cauterising solution, when its action upon the tissues subjacent to the skin is manifested by rendering them opalescent.[7] If the skin is cauterised in places beneath which there are no aponeurotic muscular surfaces, no muscular current can be discovered, or at the most only such weak and irregular currents as count for nothing in the case of a circuit formed of moist conductors; not even the action of caustics, nor abrasion renders the skin absolutely currentless.[8]

Fishes possess no cutaneous current; in their case it suffices to connect any two points on the surface of the skin with the galvanometer in order to ascertain the absence of a muscular current.[9] These animals, like the frogs used in these experiments, must be rendered motionless by the action of curare.

According to the recent researches of Engelmann the heart offers an example in which it is easy to demonstrate the absence of a muscular current.[10] To do so it is merely necessary to remove the pericardium, an operation which can be performed without inflicting any injury upon the muscular substance. The heart is currentless, but every injured spot in it possesses a negative electric potential in reference to the rest. The pre-existence theory can only explain this fact, and the previously mentioned fact of the want of a current in the fish, by the most improbable surmise made expressly to suit the cases, that no muscular fibre has its termination directed towards the surface.

No Electromotive Force pre-existent in Muscle

Another method of deciding whether a current pre-exists in muscle appeared to be to determine whether, immediately after a transverse section is made, the current is present in full force, or whether an interval, however short, is required for the development of it. Were the latter the case it would be impossible for the doctrine to be correct which assumes that electromotive molecules exist ready formed in muscle and are merely laid bare by the knife. The experiments,[1] which were made by me in the years 1875 to 1877, to decide this question, have settled it in opposition to the pre-existence theory. With the help of a special apparatus the galvanometer circuit was closed at the moment when an injury was inflicted upon a previously uninjured muscle and then opened again after a very minute interval of time. The deviation observed was smaller than in a second trial made after the muscular current had already been developed, and in which the current was allowed to act on the galvanometer for the same period of time. The muscular current, therefore, requires time for its development: it does not pre-exist.

The Currents of Nerves, of Glands containing Blood, of Plants, &c.

It was to be surmised that other protoplasmic tissues than muscle would exhibit the phenomenon that portions of the tissue which are in process of dying have a lower potential than the yet living parts. First in importance in this respect is nerve: the current of nerve was discovered by du Bois-Reymond, and, like that of muscle, explained by a molecular hypothesis. Uninjured terminations of nerves are, for many reasons, not available for electrical researches; nevertheless, on the ground of the analogy to muscles, no one doubted the existence of a current in nerves, nor the applicability to them of the molecular scheme. With the discovery of the absence of a current in uninjured muscles, however, the analogy cuts the other way.[2] Henceforward there was not the slightest ground to assume the existence of a current in nerves at rest, except that developed by artificial sections. We shall see that even the phenomena of electrotonus do not in the least justify the molecular hypothesis.

Besides nerves, two other groups of protoplasmic apparatus have been examined by myself; and it has been found that in them, also, artificial sections possess a negative potential when compared with the rest of the organs. In the cases of both groups it afterwards appeared that the observations had previously been made by others. The first case was that of the glandular organs of the frog,[3] in which Matteucci had already found artificial cross-sections to be negative. I made out that this character is only present when the vessels contain uncoagulated blood, to the changes in which at the exposed surface it seems the electromotive force is due. The second case was that of the negative potential of artificial cuts and of cauterised spots in plants,[4] facts first observed by H. Buff.[5] Both phenomena are of such a kind that it is absolutely inconceivable to apply a molecular theory to them; yet notwithstanding the attempt has been seriously made.

The Dependence of Currents upon the Contact of Normal and Injured Protoplasmic Tissue

When examining the artificial cross-sections of plants I observed that the lower potential of the exposed surface quickly disappeared, but that a new section soon restored the original condition. I explained this behaviour by supposing that, according to the fundamental law, the lower potential of the cross-section only persists so long as the cells which are implicated in the section possess a remnant of living protoplasm. If the cells are entirely dead, the current must cease. In this manner we can explain why, in plants with obviously long fibres, artificial longitudinal sections have a higher potential than artificial transverse sections;[6] for the cells which are split up lengthwise die much more rapidly than those which are cut across. The same transitory character of the current which I have discovered in artificial cross-sections through vegetable tissues has lately been observed by Engelmann[7] in the case of the heart and of organs possessed of unstriped muscular fibres, and has been similarly explained. These organs are composed

of independent cellular elements placed one behind the other in rows, and the current of one section can therefore only last until the injured cells have died from end to end.[1] In the last place the same phenomenon was discovered, in the case of nerves, by Engelmann. Here the nodes of Ranvier constitute cellular boundaries which effectually confine the process of death[2] to the internode immediately injured during section, although they offer no greater barrier to the transmission of the excitatory condition than do the cell-boundaries in the heart, intestines, or uterus.[3]

Disappearance of Demarcation Currents (Demarcations-ströme) under the Influence of the Natural Reparative Processes of the Body

It was reserved for Engelmann to discover yet another fact opposed to the doctrine of the pre-existence of electrical forces in muscle.[4] If in a living frog a muscle be divided subcutaneously the negative potential of the artificial section diminishes continually, and ultimately disappears, under the influence of the blood circulating in the part and of the nerves supplying it. As, therefore, nature tends to render artificial sections currentless, it is clear that in the natural condition no muscle can be the seat of currents, but every muscular current observed during rest must spring from injuries.

Inasmuch as all currents exhibited by muscles and nerves in a condition of inactivity (except those caused by inequalities of temperature or by the passage of extraneous currents) depend upon the contact of dying and living matter, and since the electromotive force has its origin in the surfaces which form the boundary between the two, I have called these currents of rest "demarcation currents" (Demarcations-ströme).

Influence of Temperature

If the muscular substance within the same fibre exhibits differences of temperature the warmer spots possess[5] a higher potential than the colder, so long as the temperature does not attain the limits of heat-rigor, and the consequent negative potential ensue. In exactly the same degree as living substance acquires through heat a higher potential than other living substance, is its potential exalted as regards dying substance. Hence, it is not merely that the demarcation-current becomes more powerful by heating the whole muscle, as was in part revealed to du Bois-Reymond, and recently established by Steiner in regard to nerves, but the force of the demarcation-current is dependent only on the temperature of the living substance at the point of application of one galvanometer-electrode, and not on the temperature of the substance lying between the poles. In a word, portions of muscular substance in different conditions form together a voltaic series.[6]

The Currents of Entire Muscles

As has been already remarked, wholly uninjured muscular fibres possess no current. All currents of muscles at rest are, therefore, variations in temperature excepted, the results of injuries. The properties of the current are most simple in the case of a muscle with parallel fibres, and cut transversely at right

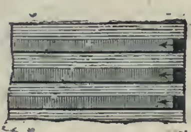

FIG. 2.

angles. In this case all the boundary surfaces between dying and living tissue are parallel to the section, and every point in the transverse surface has a lower potential than any point in the

[1] I made an exactly similar observation in the spring of 1877 on the tissues of young Medusæ which were sent to me through the kindness of Prof. Hensen, of Kiel.

[2] Engelmann, "Arch. f. d. ges. Physiol, xiii., p. 474, 1876.

[3] Gad und Tschiriew (" Verhandl. d. physiol. Ges. zu Berlin," 1877, Nr. 21) deduce the disappearance of the current in nerves from the fact that, after the death of the divided internodes the seat of electromotive force, viz., the ends of the internodes of the next row are no longer in one transverse plane, whence the resulting current is much diminished by partial equalisations. The value of this observation is obvious when it is remembered that the length of the internodes of Ranvier is, generally speaking, only 1—1½ mm.

[4] Engelmann, "Arch. f. d. ges. Physiol.," xv., p. 328, 1877.

[5] "Arch. f. d. ges. Physiol.," iv. p. 163, 1871. [6] *Ibid.*, p. 178.

longitudinal surface.[1] As, however, the muscle possesses between its fibres and on its surface indifferent conducting tissues through which the demarcation-currents can in great part become equalised—such tissues as sarcolemma, perimysium, the dead tissue of the cross-section—two important results follow. In the first place the force of the currents obtained by applying the galvanometer poles to two spots of different potential represents but a fraction of the electromotive force of a single fibre. In the second place the positive potential of the longitudinal surface and the negative potential of the transverse surface are so distributed as to be most marked at the centre of the respective surfaces. Hence arise the so-called "weak currents" when the galvanometer poles are applied to unsymmetrical points on the transverse or longitudinal surface.[2] But the weak currents of longitudinal surfaces may, especially in nerves, be in part due to an electrotonic extension of the demarcation-current which will be the subject of discussion later on.

In oblique sections there occurs a peculiar arrangement of the level-lines[3] (Niveau-linien), inasmuch as there intervenes an electromotive force which is directed from the acute to the obtuse edge of the slanting section: such currents are called "currents of inclination." Du Bois-Reymond explains this force by the step-like arrangement which the terminal molecules form in the slanting section; but it is clear that the same mode of explanation is just as well adapted to the step-like arrangement of the boundary-surfaces between dying and living tissue in the successive sets of fibres (Fig. 3).

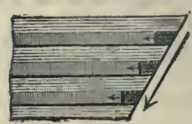

FIG. 3.

The molecular theory, therefore, is not needed to explain the currents of inclination of a *bundle* of fibres; it would only be indispensable in the case of a current of inclination of a *single* obliquely-cut fibre, did such a fibre possess one; but this is precisely what no one has demonstrated or can demonstrate. The circumstance that many muscular fibres present slanting facettes at their terminations in tendons[4] offers no opportunity to support the molecular theory; for such tendons possess no current of inclination in the uninjured condition, while, in the injured condition, the tissue of each fibre invariably dies down to a surface at right angles to the long axis of the fibre, and thus the conditions for the current of inclination arise (Fig. 3).

In all cases of partial injuries to muscle it is only the injured fibres which are the seat of electromotive action; the remainder merely form indifferent conductors which give facilities for local equilibrations. The weak currents of such muscles have, therefore, no regular relation to the surface of the muscle, as all depends upon the situation of the injuries: hence the irregular currents of so-called parelectronomic muscles.

When injuries, of whatever kind, affect the whole surface of a muscle, the probability is that a current will be detected in the muscle flowing from one end of it towards the longitudinal surface; and, in fact, when tested, this is found to be almost always the case. If a slight injury has been inflicted upon the lateral surface of a muscle the death-changes in fibres which have been opened longitudinally will speedily be checked at the boundary of the next fibre, while the death-changes which have been started at the ends or cross-sections will creep along the whole length of the fibres and occasion a lasting current. This has been previously alluded to, when the transitional nature of the demarcation-current in the heart, intestines, &c., was explained.

Local injuries to the external surface of a muscle give rise to local currents; but these currents, when a conductor is stretched from the longitudinal to the transverse surface, produce hardly any effect; whilst the demarcation-currents at the dying end of the muscle are under very favourable conditions for conduction, and

[1] The best method of applying the electrode to an artificial transverse section of muscle; so as to avoid any abduction of current from the living portion, is to produce a heat-rigor of the end of the muscle, and to apply the electrode to the rigid part (" thermal cross-section "); cf. "Arch. f. d. ges. Physiol.," iv. p. 167, 1871.

the forces of the local currents are, on account of the usual oblique application of the muscular fibres to their tendons, generally summed into currents of inclination.

III.—Electrotonus

Considerations opposed to the Molecular Theory of Electronus

The explanation adduced in the Introductory Remarks, in order to elucidate the electrotonic condition of nerves has many theoretical difficulties which cannot be here entered upon. The theory appears, however, to be amenable to an experimental proof. If, namely, the molecules of the portion of a nerve traversed by a current arrange themselves in the direction of the current, the electromotive force of the current should receive a very appreciable increase; or, in other words, the current should become very much greater when it passes through a piece of living nerve than when it traverses a dead piece of similar dimensions. On trying this experiment, however, I find no such difference; or the differences found are far from agreeing with the molecular theory.[1]

Electrotonic Phenomena observed in Conductors with Polarisable Cores

An experiment of Mattencci's[2] gave the clue to an explanation of electrotonic phenomena. He found that a metallic wire which is surrounded by a moist envelope exhibits currents possessing the characters of the electrotonic currents of nerves, whenever a galvanic current is passed, at any point, through the moist envelope. Matteucci discovered, in addition, that the currents cease when the wire is of amalgamated zinc and the envelope is moistened by a saturated solution of zinc sulphate. Hence it follows that the phenomenon depends upon a polarisation between the core and the fluid.

I examined the phenomenon more closely,[3] passing metallic wires through a glass tube filled with fluid and possessing lateral processes for the conduction of currents, and my experiments confirm the fact that electrotonic currents only occur when a polarisable core is present. Further, it was seen that the currents only extended so far as both core and envelope possessed unbroken continuity, whereas continuous contact of the two was not necessary. Lastly, I determined the laws regulating the time of development of these currents, their duration, their cessation on opening, their dependence upon the distance, and the length of the portion of core traversed by the polarising current, their combination and superposition, &c. All the phenomena may be grouped without difficulty under a simple theory.

As the current *a* E *k* (Fig. 4) applied to the envelope endeavours to reach the core K K, it splits up, if no polarisation be present,

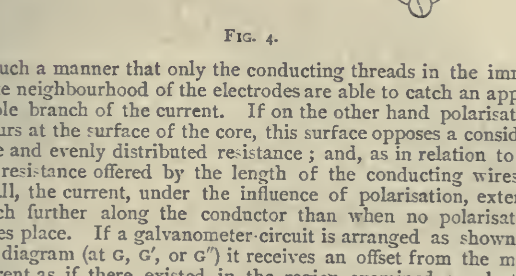

Fig. 4.

in such a manner that only the conducting threads in the immediate neighbourhood of the electrodes are able to catch an appreciable branch of the current. If on the other hand polarisation occurs at the surface of the core, this surface opposes a considerable and evenly distributed resistance; and, as in relation to it, the resistance offered by the length of the conducting wires is small, the current, under the influence of polarisation, extends much further along the conductor than when no polarisation takes place. If a galvanometer-circuit is arranged as shown in the diagram (at G, G′, or G″) it receives an offset from the main current as if there existed in the region examined an electromotive force of like direction with that of the polarising current.

This polarisational extension of the current only continues where both core and sheath are uninterrupted.

The abducted currents are at the same time, on mathematical grounds, a measure of the degree of polarisation at the points touched; and thus afford a means of tracing the extent of polarisation along the core. The curve representing the polarisational values at various points of the core—in general an exponential curve—has at the positive pole a positive maximum and a negative at the negative pole. In the region traversed by

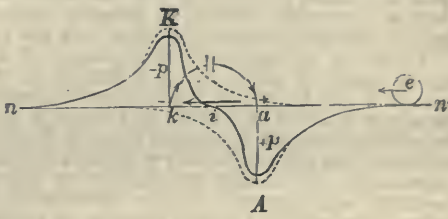

Fig. 5.

the current the curve cuts the axis at the so-called "indifferent point" (Fig. 5, *i*); and in the extra-polar regions it approaches the axes on both sides asymptotically. The curve is represented in Fig. 5, where, as a matter of subsequent convenience, the ordinates of positive polarisation are taken below the axis instead of above.

Internal Transverse Polarisation of Muscles and Nerves

In the year 1871 I discovered that the resistance offered by muscles and nerves to the passage of a current across their fibres was from five to nine times greater than the resistance offered by a current passing in direction of the fibres.[1] In the case of muscle this difference disappears almost entirely when rigor sets in; whilst in dead nerves it certainly persists, though reduced to one half. Further investigation of these facts disclosed their dependence upon a specific internal polarisability, which, in the case of muscle, is entirely associated with the living condition, and, in the case of nerve, in great part so associated. This fitness for polarisation by transversely-directed currents can only be due to a stratification of heterogeneous conductors across the tissue, which is wanting in its longitudinal axis. And since it is common to muscles and nerves, the stratification on which it depends must be sought in the typical structure which is common to the two organs, viz., the tubular nature of the fibres. We may assume, therefore, that polarisation takes place between the peculiar, active, substance of muscle- and nerve-fibres and the indifferent tissue ensheathing it.

Explanation of the Electrotonus of Nerves

As, accordingly, there exist in nerve-fibres all the essential conditions of the electrotonic extension of currents in conductors with polarisable nuclei, it may be assumed that the electrotonus of nerves is fully explained.[2] It is true that the core-substance of nerves is no better a conductor of electricity than the sheath-substance, while in the sheathed wire of Matteucci's experiment the core was of metal. But theory teaches that the electrotonic extension occurs even when the conducting powers of sheath and core are equal, if only polarisation takes place between the two.

This explanation of electrotonus, as I have shown in detail, completely covers all the phenomena. Especially does it account for the facts that the electrotonic state requires no appreciable time for its establishing;[3] and that it cannot extend past a ligatured spot. Whenever a nerve is crushed, the continuity of the core is broken, since, at the crushed spot, the core is killed and converted into indifferent tissue.

As muscle-fibres also possess polarisable cores, they must be endowed with electrotonic properties; nevertheless, neither du Bois-Reymond nor I at first succeeded in demonstrating them by galvanometric means; though, truly, just as little could their absence be distinctly affirmed. But theoretical considerations disclosed the reasons why muscle was less favourable to electrotonic phenomena than nerve;[4] and lately I have suc-

ceeded, by employing better contrivances, in demonstrating with the galvanometer the electrotonus of muscle.

An important addition to our knowledge of the electrotonus of nerves will be discussed at length in the sequel.

IV. The Electrical Currents of Organs in Activity.—A. Muscles

The Fall in Potential accompanying the Excitatory Wave

After Helmholtz had proved in the case of nerves, and Aeby in the case of muscles, that excitation is transmitted along the fibres with a measurable velocity, J. Bernstein undertook to investigate the electrical processes associated with the transmission.[1] To do so, he employed an instrument of his own devising, by means of which he could discover the electrical conditions of a muscle at any period after stimulation. He found in muscle on direct stimulation that a zone or section of negative potential arose which travelled down the fibre from the stimulated point with the same velocity as the wave of contraction. This phenomenon was readily explained by the theory of du Bois-Reymond, according to which the molecules of excited tissue suffer a diminution of activity, whence all excited spots must be electrically negative in relation to the inactive parts of the organ. Accordingly the phenomenon was designated "undulatory propagation of the negative variation."

On the assumption already made that excited tissue has, like dying tissue, a lower potential than the unchanged tissue, the fact is also at once explained, and I have named the currents called into being by the contact of excited with resting tissue, "functional currents" (Actions ströme).[2]

The Phasic and the Tetanic Functional Current

When a single excitatory wave runs over a muscular fibre which is connected at two points with the poles of a galvanometer, that point is of lower potential than the other beneath which the excitatory wave is passing at the time; or, if a wave happens to be passing both points at once, that point has the lower potential where the wave has the greater intensity or the stronger phase. Hence arises what may be called a "phasic functional current," the initial phase of which is a current proceeding *from* the stimulated spot, and the final phase a current in the opposite direction. The two phases are equal when the excitatory wave suffers no diminution in its course.

If a muscular fibre is tetanised, whether excitation travel in an undulatory form down the fibre or seize it as a whole, every galvanometer-pole applied to the muscle will be of higher or lower potential, according to the excitatory value of the points of application.

The Tetanic Functional Currents of Injured and Uninjured Muscles.

The first observations of du Bois-Reymond related to the tetanic functional current of muscles with artificial cross-sections. In such muscles the tetanic functional current is opposed to the demarcation-current, and manifests its influence in a "negative variation or deflection" of the latter. Since I regard the functional current as due to living muscle approximating in a certain degree to the condition of dying muscle, I have denominated such functional currents as diminish a demarcation-current "levelling," or "equalising," currents (ausgleichende).

Subsequently du Bois-Reymond discovered that uninjured muscles also exhibit a tetanic functional current proceeding from the stimulated point towards the end of the muscle. In order to reconcile this with his theory it became necessary to assume that the parelectronomic layer at the extremity of the fibre took part either not at all, or but slightly, in excitation. Finally the latter alternative was adopted, and it proved to be nearer the truth; for it was discovered that the functional current of uninjured muscles is less powerful than that of muscles cut across.[3] In a word, in order to explain the functional current of uninjured muscle, it was found necessary to assume that the extremities of a muscular fibre are less concerned in excitation than the middle.

While du Bois-Reymond was thus confining the limited participation in excitation to the extremities of the fibre, or, in other words, was locating the origin of the functional current in the end of the fibre, it occurred to me that the excitatory wave in its course over a muscular fibre might diminish in intensity;[1] whence it would follow, according to what was said in the foregoing section, that in tetanus an electrode placed near the stimulated point would have a lower potential or be electrically negative, to an electrode more remote. The direction of the diminutional or decremental current so obtained would agree both with observed facts and du Bois-Reymond's theory; but its force, instead of residing in the end of the fibre, is equally distributed over the whole course of the excitatory wave.

[1] J. Bernstein, "Monatsber. d. Berliner Acad." 1867, p. 72; "Arch. f. d. ges. Physiol." i. p. 173, 1868; "Untersuchungen ü. den Erregungsvorgang, &c.," Heidelberg, 1871.

[3] Du Bois-Reymond, "Arch. f. Anat. u. Physiol.," 1873, p. 548.

The Diminution in Intensity of the Excitatory Wave in Excised Muscles

Shortly after I had expressed my belief that the excitatory wave would be found to diminish in intensity in its passage down the muscle, Bernstein actually observed that it was so.[2] But du Bois-Reymond surmised that the phenomenon might be the result of the abnormal conditions of the experiment, and ought, in fact, to be attributed to the moribund state of the excised muscle; and in support of his surmise he stated that perfectly fresh muscle, on direct stimulation, exhibits no decremental functional current between any two points of its substance.[3] He persisted, therefore, in assigning the origin of the functional current to the parelectronomic layer. Moreover, he expressed a doubt whether, on stimulating a muscle through its nerve, excitation is propagated along the muscle in the form of undulations.

Meanwhile, in my own experiments I invariably detected the decrement of excitatory wave in excised muscles, a decrement, it need hardly be observed, which increased with the degree of exhaustion of the muscle.[4] Further, I hit upon the following proof that the force of the functional currents is evenly distributed over the whole fibre. If, while a muscle is being tetanised at one end, the points of application of the galvanometer electrodes be shifted in relation to one another and to the seat of stimulation, a functional current will invariably be discovered proceeding away from the stimulus; and the force of the current will be found to depend solely upon the interval between the galvanometer poles, irrespective of their position in relation to the end of the muscle.[5] The same observations may be made on a muscle which is tetanised through its nerve.[6] A functional current may always be abducted from the muscle, the force of which is exclusively determined by the respective distances of the abducting electrodes from the "nervous equator"[7] of the muscle.

The above experiments prove that excitation, even on nervous stimulation, proceeds in the form of a wave; that in excised muscles it always suffers a decrement; that the tetanic functional current is decremental in its nature; and that its origin is not restricted to the ends of the muscular fibres, but is distributed over the whole course of the excitatory wave.

The Phasic Functional Current developed on Stimulation through Nerve

The first examination of the phasic functional current of a muscle which is excited through its nerve was made by S. Mayer, under the supervision of Prof. Bernstein;[8] in their researches the gastrocnemii of frogs were used. They made out that stimulation was followed by the development of two currents in succession, of which the first to appear was a descending current and the second an ascending current. If the gastrocnemius had been previously injured at its lower end, the second, or ascending, current was less pronounced.

These results were subsequently established by some experiments of du Bois-Reymond,[9] as well as by others which I made with a special non-repeating apparatus adapted to single stimuli.[10] Du Bois-Reymond explained the phasic current as due to the asynchronism of the two forces concurring to produce the

[7] Each constituent fibre of a muscle receives the motorial end-organ of a nerve-fibre. The motorial end organs of all the fibres are not absolutely in the same plane; and by the term "nervous equator" I have designated their *mean level* in a given muscle. The "nervous equator" is that equatorial section of a muscle in relation to which the distances of the various motorial plates, when algebraically summed, amount to nothing. See "Arch. f. d. ges. Physiol.," xvi. pp. 234, 414, 1878.

[8] S. Mayer, "Arch. f. Anat u. Physiol.," 1868, p. 655.

functional current. These forces were assumed to be located in the two extremities of the muscular fibres and to be directed each to the correspondent end of the fibre, on which account they would of necessity overlap. The descending functional current belonging to the lower end was supposed to arise more quickly and to disappear earlier than the ascending current of the upper end; and hence the appearance of phases. Inasmuch as injury to one of the ends of a muscle (or in other words, removal of the parelectronomic layer), according to Du Bois-Reymond, intensifies the functional current proper to that end, it is clear that, when the inferior extremity is injured, the lower (descending) functional current obscures the upper.[1]

My own explanation[2] is essentially different from du Bois-Reymond's. According to my views the muscle must exhibit a descending current when the excitatory wave is at the upper end of the muscle, and an ascending current when at the lower end. Hence it is not the first, but the second phase, which is proper to the lower end of the muscle. The former, as I have shown, pertains to the moment when the excitatory wave is in the neighbourhood of the upper electrode—a condition most advantageously secured, owing to the peculiar structure of the gastrocnemius, by placing the electrode so as to abduct a current from the mid point of the fibres rather than from their upper end.

According to this theory it is clear that the descending phase must precede the ascending: for every excitatory wave is started at the middle point of the muscular fibre where the nerve enters, and only reaches the ends of the fibres at a later period. If, however, the lower end of the fibre have suffered injury, the excitatory wave running towards the injured part will be powerless to cause a current, owing to the constant negative potential of the injured end, and hence the second, ascending phase comes to nothing.

The fitness of this explanation was placed beyond doubt by experiments on the phasic functional current of regularly-constructed muscles.[3] In such muscles there invariably appeared in each half first an atterminal and then an abterminal phase

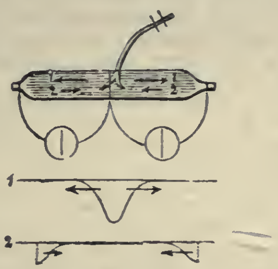

FIG. 6.

(Fig. 6). The atterminal phases in both halves (1 in Fig. 6) coincide in time, arising, as they both do, in the mid-point of the fibre at the starting of the excitatory wave; in other words, the middle point of the fibre becomes negative in comparison with either end.

In like manner the abterminal phases of both halves coincide (2 in Fig. 6), being produced by the arrival of the excitatory waves at the extremities of the fibre: in other words, either end of the fibre becomes negative in comparison with the mid-point.

In this manner the wave-like propagation of the excitatory condition in muscle was established for the case of muscle stimulated through nerves, and, at the same time, another proof was afforded that the force of the functional current does not exclusively reside in the ends of the fibres.

Furthermore, it was directly shown in these experiments that the excitatory-wave in excised muscles, while traversing the fibres, experiences a diminution; for the second, abterminal phase was invariably much weaker than the atterminal, as is indicated in Fig. 6 by the length of the arrows and the height of the representative curve, and it invariably further diminished in the course of an experiment.

The Functional Current in wholly Uninjured Muscle in Man

In the case of man the currents of normal resting muscle were secured from investigation by the obstacle of the skin. But Du Bois-Reymond found, during the violent voluntary contraction of the muscles of an arm or a leg, that the limb exhibited an ascending current. This he took to be the algebraical sum of the tetanic functional currents of all the muscles exerted, although such an explanation only became very probable by the exclusion of certain other experiments designed to elucidate the matter.[1] But the current could never be demonstrated under the most favourable conditions of abduction, viz., by the application of the galvanometer wires to individual groups of muscles.[2]

[1] Du Bois-Reymond, *loc. cit.*, 1873-76.
[2] "Arch. f. d. ges. Physiol.," xvi. p. 236.
[3] *Ibid.*, p. 239.

The question whether the diminution of the excitatory wave only occurs in excised muscles as a result of death changes, could, of course, only be settled by experiments on living human beings. And since the manifold disturbances inseparable from the method of experiment rendered the tetanic functional current almost useless for this investigation, I undertook to examine the *phasic* current in the muscles of the fore-arm.[3] I found that the same relationship held for the muscles of man as had before been shown to exist in the case of the frog. The first phase is an atterminal current in which the region of the nervous equator—about 10 cm. below the elbow—becomes negative in comparison with the two ends; the second phase is abterminal, *i.e.*, the ends of the muscles become negative in comparison with the equator (Fig. 7). But in the perfectly

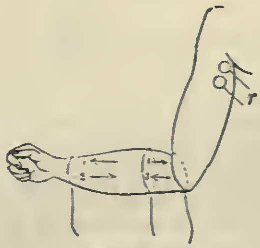

FIG. 7.

normal muscles of man the second phase was *not* weaker than the first—a relation which was constant in the excised muscles of the frog. And hence we may conclude that in absolutely normal muscles the excitatory wave does not diminish in intensity. These experiments, which constitute the first regular examination of muscular action in living man, further taught approximately the rate of propagation of the excitatory wave in human muscles, viz., from 10 to 13 metres per second.

The Absence of the Functional Current when none of the above Conditions of Electrical Inequality exist in Muscle

If an uninjured, currentless muscle be thrown into the active condition by a stimulus affecting its whole mass at once, it never exhibits any functional current,[4] whether the stimulus be single or tetanic. The explanation of this is obvious. In such a totally excited muscle the whole substance passes at the same moment into the same degree of excitation; and, hence, is nowhere the opportunity given for the contact of excited with non-excited or imperfectly excited tissue.

If, on the other hand, the muscle possesses an artificial transverse section with the associated boundary current, then indeed a levelling or equalising functional current arises on total excitation and diminishes the current of injury.[5]

When muscles are tetanised through their nerves, functional currents only appear where the excitatory wave has not the same intensity throughout the tetanised mass. Hence in man, whose muscles when under absolutely normal conditions exhibit no diminution or decrement of wave, it is impossible to demonstrate a tetanic functional current. I have, indeed, when using very powerful and fatiguing stimulation, now and then succeeded in getting indications of such a decremental functional current, but from some cause or other, we cannot depend upon this experiment to lead to a constant result, perhaps for the reason that the conductivity of human muscles is but slightly hampered by fatigue, or possibly because the collateral effects of stimulation mar the experiment.[6] I may be allowed to remark here that certain experiments now in course of publication show very clearly that stimulation of human muscles causes a secretory cutaneous current directed from without inwards. This current is the true

cause of the negative potential exhibited by the voluntarily contracted muscles of one limb when compared with the opposite but unexerted limb, and is therefore the current which du Bois-Reymond took for the muscular functional current of man.[1]

B.—Nerves

The Functional Current of Nerves remote from all Transverse Sections

In the nerves of the frog, according to Helmholtz, excitatory waves are propagated at the rate of twenty-eight metres per second. Hence, if the two ends of a galvanometer circuit were laid upon two points of a nerve a functional current should be manifest on stimulation of the nerve, and should consist of two phases according as the excitatory wave was passing one or the other of the electrodes. Nevertheless the functional current of nerves, owing doubtless to its exceedingly fleeting character, has hitherto escaped detection.[2] Since the excitatory wave of nerves does not diminish in its course, it is to be expected that the two phases of the nervous functional current will be equal; and hence also it is that in tetanic stimulation, where we have to do with the algebraical sum of these two equal and opposite phases, we obtain no functional current whatever in uninjured nerves.

The Functional Current of Nerves at a Transverse Section

The functional current of nerves bounded by an artificial transverse section was discovered by du Bois-Reymond; it is an equalising current, and consists, therefore, in a diminution of the constant demarcation current. Du Bois-Reymond only found this current in nerves tetanically stimulated, but Bernstein, by means of his apparatus already referred to, succeeded in demonstrating its presence in the case of single excitatory waves.[3] If the poles of the galvanometer circuit are applied, one to the artificial cross-section, and the other to a point in the longitudinal surface, the diminution of the demarcation current occurs in the instant that the excitatory wave passes the latter, or longitudinal pole. By altering the position of this pole, the progress and the course in time of the excitatory wave may be examined. The rate of progression so deduced was found to agree with that determined in other experiments by varying the distance between the point of the nerve at which a stimulus was applied and the fixed point at which the result of stimulation was manifested, viz., the dependent muscle, or the pole applied to an artificial cross-section. And this similarity of result established the identity of the process occurring during excitation, and the wave of negative deflection.[4] The way in which the wave comports itself on approaching the artificial cross-section will be explained below.

The Functional Current of Polarised Nerves: the Polarisational Increment of Excitation

In 1866 Bernstein found [5] that the electrotonic currents of nerve, on stimulation of the nerve, suffer diminution like the demarcation-currents. As a disciple of the molecular theory he explained this phenomenon in the following way: Since the electrotonic currents depend upon an altered arrangement of the molecules, and since the force of each molecule diminishes on stimulation of the nerve, therefore the electrotonic currents must also be lessened during excitation. And so the new phenomenon seemed to be completely covered by the molecular theory. In my view, however, the electrotonic currents are merely offsets diverted from the main polarising current owing to the internal polarisation of the nerve itself. Since these offsets could not be supposed to be modified during excitation, I concluded that every apparent diminution depended upon a functional current which arises owing to the polarised condition of the nerve, and which is opposite to the polarising current in direction. I assumed, as the cause of this functional current, that the excitatory wave failed of maintaining its magnitude while passing through the polarised portions of nerve; it increased as it reached more positively or less negatively polarised areas, and diminished under the opposite conditions. This is called the doctrine of the "polarisational increment of excitation,"[1] and it is clearly competent to explain Bernstein's observations.

If this assumption be reasonable, the excitatory condition travelling along the nerve should be most intense at the anode of the polarising current, and least intense at the cathode; and hence there should be present in the intrapolar region a powerful functional current of like-direction with the polarising current and reinforcing it. Such an intrapolar current I did, in fact, discover to be constantly present;[2] though afterwards it appeared that a similar observation had previously been made by Grünhagen, by whom, however, the current was otherwise explained as the effect of a diminished resistance in the nerve during excitation, leading to an increase in the polarising current.[3] Before I had any knowledge of this early observation of Grünhagen, the probability of the explanation which he assigned to it had been tested by me, and numerous indications had been found that the intrapolar increase of current was indeed an electromotive phenomenon and not due to a diminished resistance.[4] But later I was enabled to settle the question in the most direct manner, by the discovery that the transverse resistance of nerves is *not* diminished during excitation—excitation having in general no manner of influence upon the resistance offered by the nerve.[5]

Further Physiological Support of the Doctrine of Polarisational Increment

In order to grasp the doctrine of polarisational increment, let us regard the axis *n n'* in Fig. 5 as representing a nerve, the conditions of polarisation of which are indicated by the vertical ordinates, positive polarisation being exceptionally represented by descending lines, and negative by ascending lines. With these ordinates we can trace out the polarisation curve, *n* K *i* A *n'* (already spoken of in describing Fig. 5, which see), the lowest point of which corresponds to the anode, and the highest to the cathode. Let us now suppose a ball, *e*, devoid of friction, and travelling through space with a certain horizontal initial velocity, to be set rolling along this curve. The *vis viva* of the ball will then represent the magnitude of excitation. It is at once evident that the initial velocity is increased in the part of the curve below the line *n n'*, *i.e.*, in the anelectrotonic region, but is diminished in the upper portions of the curve, *i.e.*, in the catelectrotonic region. If the initial velocity is too small, the ball will not be able to reach the summit of the catelectrotonic portion of the curve, or, in other words, the excitation becomes dissipated in the corresponding region of nerve, and never succeeds in passing the cathode. Moreover, if the ball, with a certain initial velocity, were to be set going at some point of the inferior (anelectrotonic) portion of the curve, it would reach the outlying parts beyond the polarised region with a diminished velocity; while, if it were set going upon a part of the curve (catelectrotonic) superior to the line *n n'*, it would reach the outlying parts with an increased velocity.

All these deductions from the doctrine under discussion have been verified, in part by already established facts and in part by recent observations. The experiments by Eckhard and Pflüger have shown that a certain stimulus applied to a nerve produces a greater effect in the catelectrotonic region than in the anelectrotonic. And it is clear that these phenomena are as intelligible under my theory as under the assumption usually made to explain them, viz., that the irritability of the nerve itself is diminished during anelectrotonus and increased during catelectrotonus.[6]

Moreover, certain facts are known which seem to imply that, with a sufficient degree of polarisation, or with a sufficiently slight stimulus, the excitatory wave becomes blocked at the cathode.[7] If to this we add that excitation does not indefinitely increase with the stimulus, but soon reaches a maximum, we may further conclude that, under certain conditions, a diminution of excitation must take place even during the passage of the wave through the anodic area.[8]

In the last place it is to be noticed, that the artificial section of a nerve induces a negative polarisation or catelectrotonus of

[1] These experiments have been recently published; cf. Hermann and Zuchsinger, "Arch. f. d. ges. Physiol.," xvii. p. 310, 1878.

[2] I have succeeded in detecting these currents by extending the rate of propagation in the nerve by cold; and by using a bundle of four or six nerves together. Cf. "Arch. f. d. ges. Physiol.," xviii., p. 574, 1878.

[3] J. Bernstein, *loc. cit.*

[4] The new experiments referred to in the last note confirm this indirect conclusion in a more direct manner.

the fibres in the neighbourhood of the section, owing to the extension of the demarcation-current along the nerve.[1]

By this electrotonic extension we can explain—or for the most part explain—the so-called "weak currents" of the longitudinal section.[2] A stimulus applied to the nerve near the line of sec-

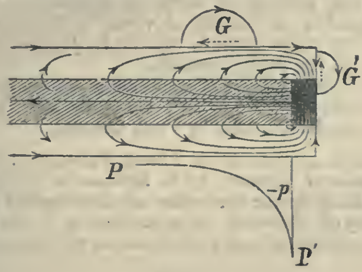

FIG. 8.

tion, according to the law of polarisational increment, should have a greater effect than when applied to points more remote, and this experiment shows to be the case. Finally, an excitatory wave travelling along the nerve towards the cut end of it must, according to the same law, gradually diminish before it disappears entirely in the area of section itself.

V. CONCLUDING REMARKS

The whole of the electrical phenomena of muscle and nerve, therefore, may be readily deduced from a few very simple propositions. Irritable protoplasm responds both to destructive and to exciting influences by an electromotive sign. The altered substance takes on a negative potential with respect to the unaltered. This, together with the doctrines of internal transverse polarisation and of the polarisational increment of excitation, appears fully competent to explain all the facts hitherto observed.

That these fundamental doctrines have the closest reference to the whole life of irritable tissues no one will be disposed to doubt. Yet much examination will be needed to disclose the exact nature of the interdependence.

Although it must now be confessed that the theories which were based upon facts discovered more than thirty years ago, have failed to withstand the criticism of a wider experience, the domain of animal electricity has not lost, but rather gained in interest. And the services of the man who not only discovered this region of physiology, but created the means of conquering it, and who made himself master of its most important fundamental features, are in no danger of becoming dimmed in our estimation by the theoretical changes we have been compelled to accept.

BAROMETRIC PRESSURE

IN a work of great importance,[3] recently published by Prof. Bert, on the physiological effects of barometrical pressure, the author sums up the conclusions to be drawn from his researches as follows:—

A. The diminution of barometric pressure acts on living beings only by diminishing the tension of the oxygen in the air which they breathe, in the blood which animates their tissues (*anoxytienne* of M. Jourdanet), and by thus exposing them to the dangers of asphyxia.

B. The increase of barometric pressure acts only by increasing the tension of the oxygen in the air and the blood. Up to about three atmospheres this increase of tension gives rise to intra-organic oxidations a little more active. Beyond five atmospheres the oxidations diminish in intensity, probably change in their nature, and, when the pressure rises sufficiently, are completely arrested. It follows that all living beings, aërial or aquatic, animal or vegetable, complex or mono-cellular—that all the anatomical elements, isolated (blood-globules, &c.) or grouped in tissues, perish more or less rapidly in air sufficiently compressed. This rule appears only to suffer exception for the reproductive corpuscles of some microscopic beings. For the higher animals death is preceded by tonic and clonic convulsions of extreme violence. Among vertebrates the rapid accidents due to the too great tension of oxygen only commence to manifest themselves at the moment when the hæmoglobin, being saturated with oxygen, that gas enters into the state of simple dissolution in contact with the tissues.

C. Diastases, poisons, and true virus resist the action of oxygen at high tension.

D. The inconvenient effects of diminution of pressure may be efficaciously combatted by the respiration of an air sufficiently rich in oxygen to maintain the tension of that gas at its normal value (20·9). Those of the increase of pressure may be combatted by employing air sufficiently poor in oxygen to arrive at the same result.

E. Generally the favourable or noxious gases (oxygen, carbonic acid, &c.) act only on living beings in accordance with the tension which they possess in the surrounding atmosphere, a tension which is measured by multiplying their centesimal proportion by the barometric pressure; the increase of one of the factors may be compensated by the diminution of the other.

F. When animals possess reservoirs of air either completely closed (swimming bladder of acanthopterygians, &c.) or in communication with the air during decompression alone (swimming vessel of the Cyprini, intestines of aërial vertebrates, &c.), or in communication with the air during both compression and decompression, but by very small orifices (lungs of aërial vertebrates, &c.), the diminution or increase of pressure may have physico-mechanical effects.

G. Sudden decompression from several atmospheres has only the effect (except for some cases comprised under conclusion F) of allowing to return to the free state the nitrogen which was, under favour of pressure, dissolved in the blood and the tissues.

H. The beings actually existing in a wild state on the surface of the globe are accommodated to the degree of oxygenated tension under which they live; all diminution, all increase, appears to be unfavourable to them when they are in a state of health. Therapeutics might make something out of these modifications in various patholgical conditions.

I. Barometric pressure and the proportion per cent. of oxygen have not always been the same on our globe. The tension of that gas has apparently been, and will without doubt continue to go on, diminishing. There is here a factor which we have not yet taken into account in biogenetic speculations. The power of reaction against these various modifications leads to the supposition that microscopic beings must have appeared first, and that they will be extinguished by the insufficient tension of oxygen.

K. It is inaccurate to teach, as is ordinarily done, that vegetables must have appeared in the earth before animals, in order to purify the air of the great quantity of CO_2 which it contained. In fact, germination, even that of mildew, does not take place in air sufficiently charged with CO_2 to be fatal to warm-blooded animals. It is quite as inaccurate, as I have observed long ago, to explain the anteriority of reptiles with warm-blooded animals by the impurity of the air tainted with too much CO_2; reptiles, in fact, are more injured by this gas than birds, and still more so than mammals.

SCIENTIFIC SERIALS

THE *Sitzungsberichte* of the Vienna Imperial Academy of Sciences (Natural History Section, vol. lxxvi. parts 1–5, and vol. lxxvii. parts 1–4) contain the following more important papers:—Addenda to our knowledge of annelids, by Dr. Aug. v. Mojsisovics.—On the orthoptera of the Senegal River, by Dr. H. Kraus.—On the fauna of the Cypris slates of the Eger tertiary strata, by O. Novák.—On the natural history of glimmer, by G. Tschermak.—Researches on cystolithes and some similar formations in the vegetable kingdom, by K. Richter.—On the genesis of salt deposits, particularly of those in western North America, by F. Pošepny.—On the fresh-water fish of South-Eastern Brazil, by Dr. F. Steindachner.—On the "Salse di Sassuolo"

[1] "Arch. f. d. ges. Physiol.," vii., p. 363, 1873. This polarisation, of course, still occurs even when the demarcation-current is not abducted, or when the abducted portion is counterbalanced by an opposite current. In the latter case, according to Bosscha's law, the nerve behaves just as if no abducting circuit were applied to it. "Arch. f. d. ges. Physiol.," ix., p. 29, 1874; x., p. 237, 1875.

[2] In Fig. 8 the core of the nerve-fibre is obliquely shaded. Even in the absence of polarisation of the core the boundary current would become distributed after the manner shown in the figure, and would pass into the galvanometer circuits G and G' as the so-called weak longitudinal and transverse currents of du Bois-Reymond. But, with polarisation, the extension along the core is very much greater than without it, and at the same time the polarisational curve pp' is produced.

Jahrbuch der k.k. geologischen Reichsanstalt (vol. xxviii. part 4, October—December, 1878) contains several highly interesting treatises, viz. :—On Alpine phosphates, by J. Gamper.—On the production of common salt from the Russian steppe lakes, by Dr. C. O. Cech.—Observations on the Jurassic formation in the Carpathian cliffs, by Victor Uhlig.—On the artesian well in the Stadtwäldchen near Budapest, by Wilhelm Zsigmondy.—On Emanuel Kaiser's views on the hercynian fauna, and the limit between the Silurian and Devonian formations, by Dr. E. Tietze.

Reale Istituto Lombardo di Scienze e Lettere. Rendiconti. Vol. xii. fasc. iii. We note the following papers in this number :—New phenomena observed in treatment of wine and must, with lime (continued), by Prof. Pollacci.—New physio-pathological researches on pulmonary phthisis (continued), by Prof. Giovanni.—Project of an electrical indicator of the level of water in a flood, by Prof. Ferrini.—Amplitude of oscillations of the declination-needle during 1877 and 1878, at the observatory of Brera, in Milan, communicated by S. Schiaparelli.—Determition of the difference of longitude between Milan Observatory and those of Padua, Monaco, and Vienna, by Prof. Celoria.

Fasc. iv.—First lines of introduction to the study of Italian bacteria (continued), by S. Trevisan.—Composition of butters in Lombardy, and analysis of butter in general, by Dr. Menozzi.—New researches on the rot of vines, by Prof. Garovaglio.—Researches on polar systems, by Prof. Jung.—On provision against trichina, by Prof. Bizzozero.

Fasc. v.—A new process of microscopic art, by Prof. Golgi.—Fruitful copulation of a dog with a cat, by Prof. Lemoigne.—On the intestinal anguillula, by Prof. Cantoni.

Atti della R. Accademia dei Lincei, February, 1879.—Necrological memoir of Gastaldi, by S. Sella.—On the expression of one of the limits in the correction of the elliptical co-ordinates in the theory of planetary perturbations, by S. De Gasparis.—On the composition of rocks of the mines of Montecortini, by S. Cossa.

Rivista Scientifico-Industriale, Nos. 4 and 5, 1879.—We note in these numbers a memoir by Prof. Perotti, on governing combination of the elements of gaseous mixtures.

No. 6.—On a baricentric property of the triangle, by Prof. E. Cavalli.—On a new experiment on electrolysis with weak electromotors, by Prof. A. Bartoli.—On the telephone and microphone as musical instruments, by G. Mocenigo.—Description of some new plants recently introduced into horticulture, by E. O. Fenzi. There plants are *Gentiana algida*, *Primula capitata*, and *P. stuartii*, *Nicotiana acutifolia* and *N. suaveolens*, *Eremurus robustus*.—On two new species of Myriapoda, *Polydesmus siculus* and *Atractosoma nigrum*, by Prof. F. Fanzago.—On a new reagent for cobalt, by Mr. Tattersall.—On poisonous colours, by the editor.

Archives des Sciences physiques et naturelles, March.—From this part we notice the following papers of interest :—On the influence of coloured light upon the development and growth of animals, by Emile Yung.—On the effects of induction coils upon the nervous system, by M. Schiff.—On an acceleration of the process of tanning by means of phosphoric acid, by E. Ador.—On methyl-aniline and toluidine and the colouring-matters derived from these compounds, by MM. Reverdin, Monnet, and Nölting.—On alizarine blue, by M. Graebe.—The other papers contained in the part have been noticed by us elsewhere.

SOCIETIES AND ACADEMIES

London

Mathematical Society, April 10.—C. W. Merrifield, F.R.S., president, in the chair.—Mr. Donald McAlister was elected a Member, and Messrs. A. J. C. Allen and E. Anthony were proposed for election.—The following communications were made :—Notes on quantics of alternate numbers, used as a means for determining the invariants and covariants of quantics in general, by the late Prof. Clifford, F.R.S. (communicated by Dr. Spottiswoode, P.R.S.).—Note on geometrical maxima and minima, Mr. J. Hammond.—On a class of fractions, Mr. R. Tucker.

Linnean Society, April 3.—William Carruthers, F.R.S., vice-president, in the chair.—Mr. W. T. Thiselton Dyer exhibited the inflorescence of *Gynerium saccharoides*, grown at Kew, but which had died during the winter severe weather. Excepting through Mr. Spruce's researches on the Amazons, little is known respecting this handsome plant, which differs from the Pampas grass in habit, and is tropical like maize, &c.—Dr. H. Trimen, in dealing with the subject of the myrrhs of commerce and pharmacy, showed the unique *Balsamodendron myrrha*, Nees. It was gathered by Hildebrandt in Somali Land, 1873, and possesses but few leaves and a single fruit; the traveller, however, saw the myrrh exuding from the tree itself. The original type specimens of *B. myrrha*, collected by Prof. Ehrenberg in Arabia, were also exhibited, and, according to Dr. Trimen, Hildebrandt's late statement of their identity with the foregoing seems well founded. Ehrenberg's other myrrh plant, the *B. Ehrenbergianum*, Berg., with his notes attached, and the *B. Playfairii*, Hook. fil., from Somali Land, with its gum called "Hotai," and other examples of varieties of myrrh and bdellium were placed before the Society and commented on by Dr. Trimen. He specially adverted to the liberality of the authorities

of the Royal Berlin Herbarium and of the Hanbury Collection for being enabled to study the rare valuable specimens laid before the Fellows of the Linnean Society.—The account of a remarkable peat flood in the Falkland Islands, by Mr. Arthur Bailey, was communicated by Mr. W. T. Thiselton Dyer. About midnight, November 29, 1878, it was discovered that a black moving mass of peat, several feet high, was making its way towards the settlement at the rate of between four and five miles an hour. The next morning (30th) it was found that the town of Stanley was cut in two, intercourse between its east and west ends alone being possible by boats. Fortunately no lives were lost, and by the energy and activity of the inhabitants in the formation of a trench, much injury and destruction were considerably arrested.—The Secretary read in abstract some notes on Moquilea, with a description of a new species by Mr. John Miers. The author specially compares and marks the differences between the genera Moquilea and Licania, they having often been confounded, and he afterwards points out the distinctive characters constituting his new species, *Moquilea organensis.*

Chemical Society, April 3.—Mr. Warren De La Rue, president, in the chair.—The following papers were read:—On terpin and terpinol, by Dr. Tilden. The author has continued his previous researches, and has succeeded in obtaining crystals of terpin hydrate from essence of lemon; the author considers terpinol to have the constitution of an alcohol. Oil of lemon cajeputol, oil of coriander, and citronella contain bodies closely resembling terpinol.—On a gold nugget from South America, by Mr. G. Attwood. These nuggets are found in alluvial soil in Venezuela. Numerous gold-bearing quartz-veins are found in the neighbouring hills. About one-half of the nuggets are covered with a dark brown substance resembling a silicate of iron. When this is dissolved much finely divided gold separates, and the nugget is partly covered with dull fine gold. The gold obtained from the quartz is less pure than that of the nuggets. The author concludes that gold nuggets gradually increase in size owing to the accumulation of fresh particles of finely-precipitated gold.—On lead tetrachloride, by Mr. W. W. Fisher. The author has not isolated this compound, but has obtained it in solution by dissolving lead dioxide in hydrochloric acid; the yellow solution thus formed precipitates brown hydrated peroxide of lead when treated with solutions of alkalis, &c. The author also suggests the use of chlorine or bromine in the presence of sodium acetate as a means of quantitatively determining lead by precipitation as a peroxide.—On the transformation of aurin into trimethyl pararosanilin, by Messrs. Dale and Schorlemmer. This is effected by the action of an aqueous solution of methylamine at 125° on aurin.—On the solution of aluminium hydrate by ammonia and a physical isomeride of alumina, by C. F. Cross. By boiling the ammoniacal solution of aluminia hydrate a precipitate is obtained, which on drying and ignition furnishes alumina which is extremely hygroscopic, absorbing 35 per cent. of water.—Researches on dyeing, Part ii. Note on the emission of colouring matter, by Dr. Mills and Mr. Campbell. The experiments were made with silk and a dilute solution of Nicholson's blue. The authors affirm that a real and uniform dyeing effect can always be obtained with silk and Nicholson's blue, the heat and souring used by dyers being unadvisable. The authors recommend the addition of common salt to the vat.

Geological Society, March 26.—Henry Clifton Sorby, F.R.S., president, in the chair.—William Adamson Barron, Gregory Dent, Julian John Leverson, and Rear-Admiral Francisco Sangro Tremlett, R.N., were elected Fellows of the Society.—The following communications were read:—Results of a systematic survey (in 1878) of the directions and limits of dispersion, mode of occurrence, and relation to drift-deposits of the erratic blocks or boulders of the west of England and east of Wales, including a revision of many years' previous observations, by D. Mackintosh, F.G.S. The author's researches lead him to the following conclusions:—Boulders from the North-Criffel range and Lake-district can be traced from the Solway Firth to near Bromsgrove (about 200 miles), and over an area in greatest breadth (from near Macclesfield to Beaumaris) of 90 miles, those from Criffel being particularly abundant near Wolverhampton. Boulders from the Arenig occupy a triangular area, limited by a line drawn northward from Chirk to the Dee estuary, and to the south-east of that town are found as far as Birmingham and Bromsgrove. The dispersion of the more distant Criffel boulders would require submergences of from 400 to 1,400 feet; of the Lake-district a little deeper; while the distant dispersion of the Arenig boulders took place at submergences between 800 and 2,000 feet. The author describes several of the more local drifts, and correlates the lower boulder-clay of the north-west with the chalky boulder-clay of the east of England. He considers floating ice, not land ice, to have been the agent of dispersion.—On the glaciation of the Shetland Isles, by B. N. Peach, F.G.S., and John Horne, F.G.S. After an account of previous opinion on the subject, the authors proceeded to describe the different islands, reviewing in succession the physical features, geological structure, the direction of glaciation, and the various superficial deposits. From an examination of the numerous striated surfaces, as well as from the distribution of boulder-clay and the dispersal of stones in that deposit, they inferred that during the period of extreme cold Shetland must have been glaciated by the Scandinavian Mer de Glace, crossing the islands from the North Sea towards the Atlantic. The authors described the order of succession in the Old Red Sandstone formation in Shetland, and referred to the discovery of an abundant series of plant-remains in rocks which have hitherto been regarded as forming part of the series of ancient crystalline rocks. The plant-remains are identical with those found in the Old Red Sandstone rocks in Caithness, Orkney, and Shetland, from which it was inferred that the quartzites and shales in which the fossils are imbedded must be classed with this formation. The authors also described the great series of contemporaneous and intrusive igneous rocks of Old Red Sandstone age, adducing evidence in proof of the great denudation which has taken place in the members of this formation in Shetland.—On the southerly extension of the Hessle boulder-clay in Lincolnshire, by A. J. Jukes-Browne, B.A., F.G.S.

Manchester

Literary and Philosophical Society, January 8.—Charles Bailey, F.L.S., in the chair.—Mr. Thomas Rogers read a paper on, and exhibited many specimens of, ballast plants collected at Cardiff in September, 1878.

February 25.—E. W. Binney, F.R.S., in the chair.—On the mean temperatures of the winters of the last twenty-nine years, by the Rev. Thomas Mackereth, F.R.A.S., &c.

March 4.—J. P. Joule, F.R.S., president, in the chair.—On a modification of Bunsen's calorimeter, by Prof. Balfour Stewart, LL.D., F.R.S.—The poisonous qualities of the yew, by William E. A. Axon, M.R.S.L., F.S.S.

March 18.—J. P. Joule, F.R.S., president, in the chair.—On siliceous fossilisation, part 2, by J. B. Hannay, F.R.S.E., F.C.S., Assistant Lecturer on Chemistry in the Owens College.

Edinburgh

Royal Society, March 17.—Prof. Kelland, president, in the chair.—Sir William Thomson communicated a paper on vortex motion, gravitational oscillations in rotating water. This paper contained an investigation of oscillations under the influence of gravity, of a mass of rotating liquid; former communications having been chiefly directed to the discovery of the vortex theory of atoms. In Laplace's great work on the theory of the gravitational oscillations of a mass of water spread over an approximately spherical body, he takes account of the fact that the earth is rotating and of the effects produced thereby on the motions of the ocean, and how these motions are affected by the great continents. Sir William Thomson finds that vortex motion due to the rotation of the earth affects the tides very considerably, even in such comparatively small areas as those of the English Channel and the North Sea. He shows that in a limited basin without an aperture, covering from, say, one to ten degrees of latitude, any tidal phenomenon which there may be, due to the gravitation attraction of the moon, is greatly affected by the rotation of the earth, if the greatest period of free oscillation of liquid in the basin is comparable with the period of rotation of the earth. It is to this fact that the peculiar phenomenon of the tides in the English Channel is due. The peculiarity is this, that for instance when it is high water at Dover, there is low water at the other end of the channel, and simultaneously a nodal line at St. Alban's Head, *i.e.*, no rise or fall there; moreover, there are currents across this nodal line towards the end of the channel at which the tide is rising, *i.e.*, water is flowing east across this line when tide is rising at Dover, and west when it is rising at the other extremity. This phenomenon holds true only for ten or twenty miles on the English side of the Channel. On the French side there is nothing of this kind but a gradual transition of the time of high tide along the coast. On the English coast, within a comparatively short distance, not more

than thirty miles, on either side of the nodal line referred to, there will be high tide on the east simultaneously with low tide on the west. He explains this by showing that in a canal of uniform breadth and depth, along which a wave is travelling, the effect of the rotation of the earth is to make the wave cling to the right hand side in whichever direction the wave is travelling. This manifests itself by the crest of the wave not being of equal amplitude all across the canal, but falling off from the right side down to nothing on the other side if the breadth of the canal is great enough. Where y is the distance of a point from the right bank and x the distance along the bank, the expression for the height of the crest is $e^{-my} \sin (px - qt)$. In a canal which has non-parallel sides, *i.e.*, in which the sides converge, the effect is more marked. This is true of the English Channel or of any other where the time of an oscillation running across from one side to the other and back, is comparable with the period of rotation of the earth. He has worked out the problem in the case of the canal mentioned above, and also for forced and free oscillations in a circular basin.—The next paper was one by Dr. Joseph Coats, Dr. Wm. Ramsay, and Prof. McKendrick, on the action of anæsthetics on the blood pressure. The question they originally wished to solve was whether, in cases where the use of chloroform destroyed life, the result is due to its effect on the respiration or to the action on the heart. They found that at first sight it affected the respiration, but by keeping up artificial respiration they found that it also had an action upon the heart. They experimented both on rabbits and on dogs with the following results:—Chloroform and ethydene chloride reduce the blood pressure, while ether has no appreciable effect. Chloroform reduces the blood pressure much more and much more rapidly than ethydene. It has also an apparently capricious effect on the heart's action, the blood pressure being reduced to nothing and pulsation being very rapid. Sometimes the heart's action was affected as much as a minute or more after the chloroform had ceased to be administered and after the blood pressure had recovered nearly its normal state. The effect of ethydene was to reduce gradually the blood pressure. Chloroform causes death in dogs primarily by paralysing either the heart's action or the respiration according to the individual's peculiarities. The respiration generally stops before the heart's action ceases. They found that artificial respiration was very effective in restoring animals in danger of dying from the effects of chloroform. Ethydene never produces absolute cessation either of the heart's action or of respiration. The results obtained confirm and amplify those of the Committee of the Royal Medical Chirurgical Society of 1864.—Prof. McKendrick showed some experiments by Mr. Aitken on the physiological action of rotating disks on the retina.—Mr. Thomas Muir gave some general theorems on determinants, viz., an expression for the product of a determinant by one of its minors; a theorem for the reduction of the order of a determinant, another for the multiplication of a determinant by an expression of a number of terms equal to the order of the determinant. He laid on the table a note on alterants.

PARIS

Academy of Sciences, April 7.—M. Daubrée in the chair.—The following papers were read:—On the iodides of stannpropyls, by M. Cahours.—On complementary pirouettes, by M. Chevreul. A disk having one half painted with colour a, and the other half white, and being rotated not more than 160 times a minute, nor less than 60, the complementary c of a appears on the white half.—Consequences of experiments made to imitate terrestrial fractures, with regard to various characters of exterior forms of the ground, by M. Daubrée. He points out several examples of the influence of diaclases and paraclases in determining the form of land, their directive influence on erosion, &c.—M. de Lesseps presented a *brochure* of the International African Association, containing a recent lecture by him, and a catalogue of African products at the recent exhibition.—The following elections were made:—M. Alphonse Milne Edwards, member in anatomy and zoology, in place of the late M. Gervais; M. Abich, Correspondent in Mineralogy, in place of M. Damour, elected Free Academician; Mr. Lawes, correspondent in rural economy, in place of the late Marquis de Vibraye.—Analysis of the physiological action of sulphates of magnesia and soda, by M. Moreau. This describes an experiment wherein, some time after ingestion of magnesian sulphate into the intestine, he introduced yellow cyanide of potassium as a test of absorption. The urine afterwards showed no trace of cyanide. The sulphate causes afflux of liquid in the intestinal cavity; so that this occurred in the present case without manifest absorption.—On the summation of a particular species of series, by M. André.—On displacements produced in the interior of an elastic ground by normal pressure exercised at a point of its surface, by M. Boussinesq.—Heat-centre produced by molecular shocks, by Mr. Crookes.—Reply to M. Flammarion's note on the declination of the magnetic needle, by M. Marié-Davy. The reason of the alleged different action of the needle at Paris he finds in the dissimilarity of the methods employed in calculation of the averages grouped in M. Flammarion's tables.—On the gravivolumeter, by M. Houzeau. In this instrument liquid is forced up out of a vessel into a siphon by blowing through a caoutchouc tube, which is then closed with a spring pincer; on pressing the latter, air enters, and the liquid comes from the siphon drop by drop, with great regularity; the numeration of the drops gives precisely the weight of the liquid.—On determination of the presence of fire-damp in the atmosphere of mines, by MM. Mallard and Le Chatelier. They use a lit jet of hydrogen, which gives a larger and more distinct blue aureola than the flame of a common safety-lamp in presence of fire-damp, and reveals the presence of even 0·25 per cent. of the latter gas. The flame, within a cylinder of copper, is viewed through a lens closing a lateral orifice.—On some conditions of alcoholic fermentation, by M. Richet. Oxygen renders more rapid lactic fermentation of milk. Boiling, by coagulating an albuminoid matter originally soluble, diminishes by one-half the activity of the fermentation. Digestive juices which give soluble albumen and peptones increase the rapidity of lactic fermentation.—On the amylaceous and amyloid granules of the egg, by M. Dastre. He opposes M. Dareste's affirmation of the presence of *amyloid* bodies in eggs, maintaining that they are certainly not starch, and have not even the appearance of it.—Determination of sugar in the blood, by M. d'Arsonval. He defends a method of the late Claude Bernard's against recent objections by M. Cazeneuve.—On the method used by Claude Bernard for determination of reducing sugars in the blood, by M. Picard. If there are some animal substances which have the same action on cupric liquors as glucosic solutions, there are a very large number which have rotatory power.—On the distribution of phosphates in the different elements of the blood, by M. Jolly. Alkaline phosphates predominate in the aqueous part of the blood. All the elements contain a variable quantity of phosphate of iron, but it is chiefly accumulated in the corpuscles.—On the formation of a peculiar amyloid matter in the asci of some Pyrenomycetes, by M. Crié. What distinguishes this essentially is (1) its formation in profound darkness by a protoplasm without chlorophyll, and (2) its insolubility in the cellular liquids. This amyloid matter, the physiological *rôle* of which is not yet known, M. Crié calls amylomucine.—On ancient glaciers in the Maritime Alps, by M. Desor.

THURSDAY, APRIL 24, 1879

SCIENTIFIC WORTHIES

XIV.—JEAN LOUIS RODOLPHE AGASSIZ, BORN MAY 28, 1807; DIED DECEMBER 14, 1873

LOUIS AGASSIZ, by which names he was everywhere known, was born at Motier, in the canton of Freiberg, Switzerland, on May 28, 1807. He belonged to an old French Protestant family, who had been compelled to quit their native country by the revocation of the Edict of Nantes, we are told by Dr. Steindachner, in his paper on Agassiz, contributed to the Vienna Academy, to which we are largely indebted for what follows. His father was pastor at Motier, where his forefathers for six generations had filled the same office. Agassiz received his earliest education at home under the care of his mother, a woman of high endowments and rare culture. At the age of eleven years he betook himself with his younger brothers to the Gymnasium at Biel, in the canton of Bern, where he was mainly occupied with the study of ancient and modern languages, the knowledge of which proved of important service to him in his later biological investigations. His play-hours he devoted to fishing and the collecting of insects. Thus early did his leaning towards ichthyological researches show itself, and his knowledge of the habits of fish often astonished even experienced fishermen.

In the meantime Agassiz's father was transferred from Motier to the little town of Orbe at the foot of the Jura, and here young Agassiz became intimate during the holidays with a young clergyman named Fivaz, who first introduced him to the study of natural history, and especially botany. After four years' stay at Biel he entered the Academy of Lausanne, and in 1824 betook himself to Zurich to study medicine, in accordance with the earnest desire of his parents. Soon after, Agassiz left Switzerland to continue his medical studies at Heidelberg, where, at that time, the celebrated anatomist, Tidemann, carried on his work. After a year's stay Agassiz exchanged Heidelberg for Munich, where Schelling, Oken, Martius, Döllinger, Wagler, Zuccarini, Fuchs, von Kobell, &c., were lecturing; and these soon became not only the kind teachers, but also the friends of young Agassiz. Döllinger, especially, the great master in physiology and embryology soon recognised the high talent of his pupil, and ripened in Agassiz a long-cherished plan of devoting himself to zoology in the widest sense of the term.

It was here in Munich that the young Agassiz, who occupied a small room in Döllinger's house, soon gathered around him a circle of young and talented students, to talk over and discuss matters of scientific interest. Agassiz's room was the meeting-place of this club, which soon assumed the title of the Little Academy, and of which Agassiz acted as president. Before this society did Michaelis lay the results of his researches in the Adriatic Sea, Born exhibited his beautiful preparations of the anatomy of the lamprey, Rudolphi lectured to the students on the Bavarian Alps and the coasts of the Baltic, and Schimper and Braun here first expounded the laws of phyllotaxis. Döllinger himself did not disdain to initiate his disciples and friends of this Little Academy in his newest discoveries and ideas, ere he made them known to the scientific world, and here he taught them the use of the microscope in embryological research.

Meantime the Bavarian members of a great scientific expedition to Brazil, under the leadership of Spix and Martius, returned to Munich, bringing with them rich collections; and after the death of Spix, the celebrated botanist, Martius entrusted Agassiz with the working out of the ichthyological material. Agassiz had scarcely reached his twenty-first year when he concluded this task in so brilliant a fashion that with this, his first-born work, on the Fishes of Brazil, he gained a reputation as one of the first ichthyologists. This work was published in Latin at Munich in the year 1829, and was dedicated to Cuvier. About the same time Agassiz began his investigations on fossil fishes. The immediate occasion of this step was a short notice by Prof. Rud. Wagner on the fossils of the Munich Museum, in which he praised the number and beauty of the unnoticed fossil fishes. Agassiz immediately applied to Prof. Fuchs, who had the care of the palæontological collection, for permission to investigate the ichthyolites in detail; Professors Wagler and Schubert placed freely at his disposal the collection of recent fishes and their skeletons, and Döllinger, Oken, and Martius in various ways encouraged him in this difficult undertaking.

From this time Agassiz devoted all the spare time left him by his medical studies to the investigation of fossil fishes, which naturally implied an adequate knowledge of the most nearly related living forms; in the holiday months he made short visits to the museums of the larger towns of Central Germany, to examine their palæontological treasures. In 1830 Agassiz went to Vienna, where he stayed a year, attending at the hospitals, and studying in the Imperial Museum the splendid collection of sturgeons of the Danube region, as well as the fossil fishes of Monte Balca. Moreover, he was so interested in the Cyprinoids of the Danube, which were already partly known to him from those of the Isar, that he concluded a work on the Freshwater Fishes of Central Europe; on account of the revolution of July, 1830, this work was not published.

The years 1831 and 1832 Agassiz spent in France, and in Paris had much pleasant intercourse with Cuvier and Alex. von Humboldt. Cuvier was then giving a course of lectures on the history of natural science, and combated with all the power of his science and his detailed knowledge of the organic structure of the whole animal world the development theory of Geoffroy based on the variability of species, which the latter defended in the sittings of the Paris Academy. From this time Agassiz adhered to Cuvier's ideas on the classification of the animal kingdom and on creation catastrophes especially, and with but little modification, defended them in his teaching and writing to the end of his life.

In Humboldt, again, Agassiz found an attached and powerful patron, whose support at a later time essentially facilitated the publication of many of his costly works, and to whose recommendation he in part owed the brilliant reception he met with in America, which he chose as his second home.

The Paris Museum was then in the zenith of its reputation; its zoological, palæontological, and anatomical collections were then the richest and most celebrated of

Europe, and Cuvier granted to the young Agassiz with genuine disinterestedness and liberality the complete use of its rich material. With untiring diligence and rare perseverance, Agassiz here continued his researches on fossil fishes, and anew worked thoroughly through the rich palæontological collection of Conte Gazzola, which contained the originals of Volta's celebrated treatise "L' Ittiologia Veronese."

In 1833 Agassiz again visited the great museums of Germany and Switzerland, and had already distinguished 500 species of fossil fishes, when, in August, 1834, he sailed for England, in order to study there the exceptionally rich public and private collections, in which he found 300 new species. In the year 1835 and 1840, he extended his journeys into Wales, Scotland, and Ireland, visiting London again and again, in order there to test the notes collected for many years for the completion of his work, and to make himself acquainted with the newest discoveries in the department of palæontology.

In 1844 Agassiz concluded the publication of his gigantic work on the Fossil Fishes, which appeared at Neuchâtel in five quarto volumes, with 311 folio plates. Eighty of the greatest museums of Europe had furnished the material for it, and the number of described species amounted to 1,700 in about 20,000 examples. The "Recherches sur les Poissons Fossiles" is undoubtedly Agassiz's most important work, and forms, with Cuvier's and Valenciennes' "Histoire Naturelle des Poissons" and Johann Müller's treatises, the foundation of our present knowledge of fishes, while it does not confine itself to the region of ichthyolites, but extends over the entire wide field of the anatomy and classification of fishes, essentially modifying the latter. Agassiz considered, and with justice, that the separation of the ganoids from the other fishes into the rank of a special order, as the greatest step towards progress for which science was indebted to him; and, on the basis of the comparison of the fossil fishes of all formations with living forms, he enunciated several generally valid laws, which have had an important bearing on the development theory of the whole organic world.

As a special fruit of Agassiz's stay in England appeared in 1844 and 1845, a monograph on the Fossil Fishes of the Devonian System and a smaller treatise on the Fishes of the London Clay.

As early as 1832 was Agassiz called to be professor at Neuchâtel, and in a short time raised the little town to be a chief seat of science in Switzerland. He created a Natural History Museum, and was the chief founder of the Scientific Society, which issued the first volume of its *Memoirs* in 1835. From all parts of Switzerland came young and talented pupils and friends of nature thither, and gathered round Agassiz, who understood how to inspire them with his great ideas. They followed him in his frequent zoological and geological excursions in the Jura and the Alps, and assisted him in procuring scientific material and helping him in the time-consuming preliminaries of those numerous works which date mainly from the years 1835 to 1845. Along with his friends Desor and Valentin, Agassiz published the great monograph on living and fossil Echinoderms.

The rich collection of fossil conchifera of Switzerland, which a young and able geologist of the name of Gressly had brought back from his travels, led Agassiz to work out the fossil conchifera of the Jura and the chalk, the result being published under the title of "Études Critiques sur les Mollusques fossiles du Jura et de la Craie," in four parts with 100 plates. This was followed by several similar supplementary publications on fossil conchifera, of which the "Iconographie des Coquilles tertiares, reputées identiques avec les espèces vivantes ou dans différens Terrains de l'Époque tertiaire," and "Mémoire sur les Moules de Mollusques vivans et fossiles," are the most important.

In spite of these numerous and comprehensive works, Agassiz found time to devote to the study of living fishes. Thus may be mentioned his treatise on the cyprinoids (1834); the great work brought out in conjunction with Carl Vogt between 1839 and 1845, on the freshwater fishes of Central Europe; in 1842 he brought out his most important "Nomenclator Zoologicus," the result of many years' gatherings, and which contained an alphabetical arrangement of the specific names of the entire animal kingdom, their etymology, information as to the authors who had proposed these names, as well as the year of their appearance. The "Nomenclator" found a magnificent conclusion in the "Bibliographie générale d' Histoire Naturelle," printed at the cost of the Ray Society, unfortunately not without some ugly mutilations on the part of the editor.

While Agassiz no doubt exercised a considerable influence on geology by means of his palæontological researches, still it is as a glacealist that his name will always be prominently associated with that science. Venetz', Schimper's, and especially Charpentier's observations and theories on the greater extension of glaciers, and their relations to erratic blocks attracted the attention of Agassiz in 1836 to the glacial phenomena of Switzerland. Charpentier's theories on the former extension of glaciers and other points especially interested Agassiz, who gave himself with his peculiar energy and fertility of idea to the study of glaciers. With Gyot, Desor, Studer, and other young friends, did Agassiz during several years visit most of the glaciers of Switzerland, and examined them in their entire extent, from their origin to their lowest margins. In 1841 was the ascent of the Jungfrau undertaken. In the middle of the Aar glacier, at a height of 8,000 feet above the sea, twelve miles from any human habitation, protected by a huge block, was a station erected, which latterly obtained a European celebrity, under the name of "Hôtel des Neuchâtelois." Here for fully eight years were researches carried out on the origin of glaciers, the forward and backward oscillations, the structure and thickness of the ice, as well as its formation, the origin of moraines, &c. In 1840 appeared Agassiz's first great work, "Études sur les Glaciers," in which he thoroughly discussed the chief phenomena of glaciers, and developed his views on their earlier extension. In a second work, "Système glacial," he gave a satisfactory account of the observations made in the years 1841–45, especially on the progress of glaciers in various years and under the influence of conditions of temperature. The adoption of a special glacial period was the final result of Agassiz's research among the glaciers of Switzerland, as well as those of Scotland and Wales. An immense ice-bed, the

result of a depression of temperature toward the end of the tertiary covered North and Central Europe, Asia, and North America, and a similar phenomenon was also found to have occurred in South America, from the South Pole to Monte Video and Chile, as Agassiz ascertained during the *Hassler* Expedition of 1872. The immense importance of this theory, both in geology and biology, was soon recognised, and its discussion has engaged the earnest attention of the ablest men in all departments of science. In the autumn of 1846 Agassiz went to America, partly on a commission from the Prussian Government and partly to fulfil an engagement to give a series of lectures on Comparative Embryology at the Sewell Institute of Boston. This course of lectures led to important results; it aroused an enthusiasm for the study of nature in the widest circles, and Agassiz understood how to make the scientific development of North America in this direction a matter of honour for the whole nation. The offer of the use of the steamers of the Coast Survey led to a scientific cruise in the summer of 1847 along the coast of Massachusetts, followed a few years later by a second larger cruise to the coral reefs of Florida.

After Agassiz had been released from his scientific mission by the Prussian Government, he accepted with pleasure the Chair of Zoology and Geology in the Lawrence Scientific School of Harvard College, Cambridge, created specially for Agassiz by the founder of the school, Mr. Abbot Lawrence. Agassiz thus gave up all thought of returning to Europe; he placed his activity, his science, and his talents, at the disposal of the nation that showed itself so anxious to keep him, and where he would enjoy a social power and a liberty which were hardly possible to the *savans* of the Old World.

As in Neuchâtel, so in Cambridge, Agassiz in a very short time attracted around him a circle of young men, enterprising lovers of natural science. With these, in June, 1848, he undertook a journey to the then little-known region of Lake Superior. In 1850 appeared his well-known work, "Lake Superior: its Physical Character, Vegetation, and Animals," in which Agassiz discussed in detail the erratic phenomena of the lake, its future form and extent, the character of its ichthyological and reptilian fauna, while Cabot, Harris, Gould, and J. Leconte worked out the rest of the collections. In succeeding years he made similar expeditions with his pupils into the interior of the United States, and with the collections brought back laid the foundation of a natural history museum, which, until then, had no existence at Harvard University.

In 1852 Agassiz went to Charleston as Professor of Zoology and Comparative Anatomy, but returned to Cambridge after two years, the warmer climate of the south not agreeing with him. Soon after he visited all the great towns of North America, lecturing in all departments of zoology and geology. Everywhere he was received with enthusiasm, for his expositions were remarkably clear and full of suggestive thought, his language noble and fluent, his knowledge of human science of the widest, his manner so charming and his conversation so full of the highest instruction, that every one felt it a privilege to be near him. From that time Agassiz became the declared pet of the Americans; he was the most popular man in the whole broad land, and in intellectual matters became its greatest benefactor, exercising his influence in improving education and increasing educational establishments.

In 1855 Agassiz began to prepare for the publication of a magnificent work, "Contributions to the Natural History of the United States," he having already published several papers on the subject in American journals. In a short time the necessary means were obtained by subscription, and in 1857 the first volume appeared, dedicated to Döllinger and his generous friend Francis Calley Gray. Unfortunately this work only reached the fourth volume. The first volume contained as introduction the universally-known and much-discussed "Essay on Classification," which latter, as a separate work, was published in London in 1859, and in an enlarged French translation in Paris, 1869. Agassiz treated in this work the questions of the origin, development, and systematic arrangement of the organic world, and developed from these his philosophical views which he had obtained from his own studies and observations, and which stand in direct opposition to the Theory of Descent.

Agassiz's collections had grown so enormously that the accommodation at his disposal was quite inadequate. By the liberality of Mr. F. C. Gray and the State of Massachusetts, as well as Cambridge University, a great Natural History Museum was begun in June 1859, and by December was so far advanced, that the greater part of Agassiz's collections could be transferred to it. From this time the improvement and completion of this museum became the chief object of Agassiz's activity. He aimed at making it in comprehensiveness and suitability for its purpose, a pattern institution for the whole world, and fitted to give the friends of natural history all possible help in their researches. The Museum of Zoology and Comparative Anatomy is much better known to the public of Cambridge and Boston as "Agassiz's Museum."

In 1864-65, Agassiz somewhat broke down from his continued labours, and he was advised to travel. He decided to visit Brazil, the fish of which furnished him with the subject of his first work. With six assistants he left New York in April, 1865, for Rio Janeiro. The party divided to work in various directions, Agassiz, himself, selecting the Amazon as his sphere, sailed up the river to Manaos, at the Mouth of the Rio Negro, and thence to Tabatinga. During the journey from Pará to Manaos 300 species of fish were collected, of which one half were drawn from life by Burkhardt. His headquarters were at Teffe and Manaos, where he studied the habits of the fish in their migrations in the main stream, and several of its tributaries. While he stayed here, his assistants explored some of the other tributaries of the Amazon, while others explored the regions on the Rio Francisco, Rio Doce, Paranahyba, &c. In July of the following year Agassiz returned to the United States with such a collection of booty as would have filled another Museum. With the co-operation of Agassiz, his wife, the true companion of her husband, and full of sympathy for his ideas, brought out the journal of these remarkable travels, which in a short time reached a sixth edition in America, and was translated into French in 1869.

Again, in the end of 1871, Agassiz left for South America, on board the war-ship *Hassler*. Count Pour-

tales, in this well-known expedition, had charge of the deep-sea researches, while Dr. Steindachner with Agassiz, was responsible for the other zoological collections. The results of this expedition are well known to naturalists. The leisurely cruise along the coast of Patagonia and Chili gave Agassiz an opportunity of studying the glacial phenomena of South America. His stay in San Francisco and Sacramento gave an impulse of the greatest importance to education and science in these towns, and in the latter led to the creation of a Natural History Society, which was named after him, the Agassiz Institute.

The history of the Penikese School of Natural History must be so fresh in the memory of our readers that we need not here repeat the details. The success of the school, modelled somewhat after that of Dohrn, at Naples, exceeded all expectation, the accommodation being quite inadequate for the number of students who appeared. At the end of the first summer his pupils bade him a long good-bye in the hope of meeting their much-loved master next year. But the additional burden seems to have been too great for the strength of the never-resting devotee of science. After scarcely eight days' illness, he died at Cambridge, December 14, 1873, in his sixty-third year, in the height of his fame. He has been justly named by his fellow-citizens of the States the "Humboldt of America." Ever amiable and open in intercourse, stimulating and instructive, clear and concise in exposition, was Agassiz; and his numerous pupils, of whom several have developed into important workers in science, as Alex. Agassiz, Stimpson, Putnam, Shaler, Wilder, Morse, &c., clung to him with truly child-like love and respect. The news of his unexpectedly sudden death shocked the whole population deeply, for America had lost in him one of her citizens of whom she had the best right to be proud.

Besides Dr. Steindachner's paper, we would refer the reader who desires further details to a paper in the *Revue des Deux Mondes* for July and August, 1875.

WATERTON'S LIFE AND TRAVELS

Wanderings in South America, the North-West of the United States, and the Antilles, in the Years 1812, 1816, 1820, *and* 1824. With Original Instructions for the Perfect Preservation of Birds, &c., for Cabinets of Natural History. By Charles Waterton. New Edition. Edited, with Biographical Introduction and Explanatory Index, by the Rev. J. G. Wood. With 100 Illustrations. (London: Macmillan and Co., 1879.)

THE reading world will feel grateful to both author and publisher for this handsome edition of one of our classical books of travel and natural history; while those who are already familiar with the work will read with interest and pleasure the excellent biographical notice of Waterton here given. We have first a sketch of his school and college life, when his taste for natural history got him into many scrapes; but we learn that the Jesuit fathers at Stonyhurst wisely utilised his irrepressible love of animals by making him rat-catcher and general vermin-killer to the establishment. We next find him travelling on the Continent, where he had a narrow escape of dying of the plague at Malaga. He visited Gibraltar, and saw a whole colony of the well-known apes which were then far more abundant than now. He speculates on the "tremendous convulsion of nature" which had opened the channel of the Straits, observing that—"if apes had been on Gibraltar when the sudden shock occurred, these unlucky mimickers of man would have seen their late intercourse with Africa quite at an end"—a passage which recalls to us those extreme catastrophist doctrines in geology which are now happily extinct.

When his wanderings in South America were at an end he settled down in his ancestral Yorkshire home, Walton Hall, devoting himself to the management of his estate and the study of nature, and living a life of the most Spartan simplicity. His single room had neither bed nor carpet. He always lay on the bare boards with a blanket wrapped round him, and with an oaken block by way of pillow. He went to bed at eight, and was up, dressed and clean shaven every morning at four, having himself lit a fire and boiled water to shave with. His devotions and reading occupied him till six; his bailiff's report, writing and business till eight, his breakfast hour; so that he had done a fair day's work before most people are out of bed. His room was at the very top of the house; he never touched fermented liquors, and took very little meat.

His great delight was in studying the habits of birds and other wild animals; and he devoted his park of over 250 acres to this purpose. He had moats, and ponds, and swamps, woods and trees of all kinds; and he spent 10,000*l*. in surrounding the whole with a wall nowhere less than eight feet high, in order to keep out poachers and animal intruders. In this domain no gun was ever fired or anything done to disturb the feathered inhabitants. The very year after the wall was finished the herons came and established themselves in the park, where they had never bred before; and, as Mr. Wood remarks, it is strange that they should have known that the wall, which they themselves could so easily pass, would be any protection to them. He constructed a yew fortress for pheasants, built a cat-proof tower for starlings, and a lofty dovecot to secure his pigeons from poachers. Owls and titmice and many other birds had special haunts constructed for them, while rats and other bird-enemies were carefully trapped or poisoned.

Waterton was one of the kindest and most humane of men. He studied the comforts of his horses, his dogs, and even of his pigs, as if they had been human beings. He had his gates specially constructed so that his horses and cows could lean over them and converse together, without inconvenience to themselves or injury to the gates. When he took possession of a deserted country house in Demerara, tenanted by frogs and snakes, owls and vampires, he tells us in his quaint language,—"The frogs, and here and there a snake, received that attention which the weak in this world generally experience from the strong, and which the law commonly denominates an ejectment. But here neither the frogs nor serpents were ill-treated; they sallied forth, without buffet or rebuke, to choose their place of residence; the world was all before them. The owls went away of their own accord, preferring to retire to a hollow tree rather than to associate with their new landlord. The bats and vampires stayed with me, and went in and out as usual." Even when, going down the St. Lawrence, he caught, crawling on his neck, the only bug he saw in North America, he "thought of my uncle Toby and the fly;" and so, instead of killing it, he "quietly chucked it among some baggage that was

close by, and recommended it to get ashore by the first opportunity."

Any wild animals that he does not actually want for specimens he treats in the same way, and it is therefore not surprising that he looks favourably on the Indian and his mode of life. Ignorant travellers and colonists call the Indians a lazy race; "but," he remarks, "man in general will not be active without an object. When an Indian has got plenty to eat, what need has he to work? He has no idea of making pleasure-grounds. Money is of no use to him as there are no markets for him to go to, nor milliners' shops for his wife and daughters. He has no taxes to pay, no highways to keep up, no poor to maintain, no army nor navy to supply. He lies in his hammock both night and day (for he has no chair nor bed, neither does he want them), and in it he forms his bow, and makes his arrows, and repairs his fishing-tackle. But when his provisions are gone he rouses himself, and scours the forest in quest of food. He plunges into the river after the deer and tapir, or passes through swamps and quagmires, and never fails to obtain food. Should the approach of night check him while hunting, he lays him down in the forest and continues the chase the next morning till he is successful. With us the poor or needy man has to work every day and all day long for a maintenance, but should this man acquire a fortune he usually changes his habits." Waterton then amusingly sketches for us the life of an idle man for a single day, and concludes:—"Now, could the Indian in his turn see this, he would call the white men a lazy, indolent set. Perhaps, then, upon due reflection, you would draw this conclusion: that men will always be indolent when there is no object to rouse them."

Not even Gilbert White was a closer or more accurate observer of the habits of animals than was Waterton, and had he recorded all his observations during the forty years he lived at Walton Hall we should have had a work in no way inferior to White's "Selborne." There is one curious observation of his which throws some light on the origin of one of the superstitions of natural history, but which seems to have been entirely overlooked. The name *Caprimulgus*, or "goat-sucker," has its equivalent in many European languages; and the belief that this bird sucked goats or cows has been prevalent since the time of Aristotle. The only foundation for this wide-spread belief, suggested in any ornithological book to which I have access, is, that the goat-sucker is often found near sheep-folds and cattle-pens on account of the abundance of insects in such places. Pliny however says that they enter the folds and fly to the udders of the goats in order to suck the milk. This is a much more definite statement, and, strange to say, Waterton supports the *fact* thus stated by his own observation, and at the same time shows how the erroneous *inference* arose from this fact. At p. 233 of this volume we find the following:—"I am fully persuaded that these innocent little birds never suck the herds; for when they approach them, *and jump up at their udders*, it is to catch the flies and insects there. When the moon shone bright I would frequently go and stand within three yards of a cow, *and distinctly see the caprimulgus catch the flies on its udder*." The passages marked in italics are most remarkable, since they directly confirm Pliny's statement that the birds "fly to the udders of the goats." It is not quite clear by the context whether Waterton made this observation in Demerara or in England. He is describing the habits of the Demerara goat-suckers at the time, but as he has said nothing about there being any cows on the deserted estate where he was staying, he may in this passage be referring to his observations at home.

In another passage at p. 198 this is certainly the case. He says (according to his custom addressing his reader as if speaking to him):—

"When the moon shines bright you may have a fair opportunity of examining the goat-sucker. You will see it close by the cows, goats, and sheep, jumping up every now and then under their bellies. Approach a little nearer,—see how the nocturnal flies are tormenting the herd, and with what dexterity he springs up and catches them, as fast as they alight on the belly, legs, and udder of the animals. Observe how quiet they stand, and how sensible they seem of his good offices, for they neither strike him, nor hit him with their tail, nor tread on him, nor try to drive him away as an uncivil intruder."

There can be no doubt that these are Waterton's own observations at home, though expressed rather generally; but the other passage, at all events, written in the first person, is far too definite a statement to be doubted, coming from such an observer; and it is curious that no modern writer on the subject appears to have referred to it.

As a capturer of snakes Waterton was pre-eminent, his fight with the great boa constrictor, and his capture single-handed of a smaller one, which he allowed to coil round his body while he held its neck in his two hands, are well-known incidents in his "Wanderings;" but Mr. Wood tells us how he coolly manipulated live rattlesnakes in the presence of a number of friends at Leeds, transferring them from one box to another with his bare hands. His secret was, simply, that if a snake is not frightened by noise or sudden movements, its natural sluggishness prevents it from resenting cautious handling.

We quite agree with the editor that few books have ever been written so thoroughly truthful and accurate, and so entirely free from exaggeration as those of Waterton; yet his veracity was often doubted by his reviewers, and he was classed among travellers of the Munchausen type. This however he little cared for, but he did not like to be called eccentric. He thought himself the most ordinary of human beings, though he climbed trees barefoot and never in his life wore a black coat. "Yet," as Mr. Wood well says of him, "had he not been eccentric he would not have been the Charles Waterton so long known and loved. . . . It was eccentric to come into a large estate as a young man, and to have lived to extreme old age without having wasted an hour or a shilling. It was eccentric to give bountifully and never allow his name to appear in a subscription list. It was eccentric to be saturated with the love of nature. It might be eccentric never to give dinner-parties, preferring to keep an always open house for his friends; but it was a very agreeable kind of eccentricity. It was eccentric to be ever childlike but never childish. We might multiply instances of his eccentricity to any extent, and may safely say that the world would be much better than it is if such eccentricity were more common."

So far we have had only praise for this book, and

though we have said nothing yet about the illustrations, they are also worthy of commendation as really illustrating the matter in hand, and being for the most part of excellent quality. But now we have the less pleasant duty of finding fault. Waterton had a strong prejudice against the use of scientific names. He tells us that the Salempenta is excellent eating; that you hear the voice of the Hannaquoi at early dawn; while such words as Conanacouchi, Labarri, and Karabimiti are continually used without any explanation of their meaning. In pursuance of his duty as editor Mr. Wood undertakes to clear up all these points, and to make the path easy both for the general reader and the scientific naturalist; and he does this by means of an "Explanatory Index," which occupies nearly one-third of the volume, and of which he says in his preface that he believes "there is not a single living creature or tree mentioned by Waterton concerning which more or less information cannot be found in this Index."

The index referred to does undoubtedly contain a great deal of useful and interesting information, but it is also full of the most extraordinary and misleading errors, which seem to show that Mr. Wood participates in his old friend's contempt for scientific names, since he evidently thinks accuracy in these names of little importance. First we have several completely obsolete names given, which the reader would in vain look for in any modern book on natural history; such as Champsa for Alligator, and Arapunga instead of Chasmorhynchus as the name of the bell-bird. Then we find misspelt or misplaced names; as *Derotypus coronatus* instead of *Deroptyus accipitrinus* for the name of the sun-parrot, and *Helias eurypyga* instead of *Eurypyga helias* for the sun-bittern. More important are the completely wrong identifications of species, or the mixing together of two quite different animals. The ant-thrushes are said to belong to the genus Pitta, which is eastern, whereas they form a peculiar American family, Formicariidæ. The feathers of the "wild turkey," a bird which does not exist in South America, are said to be used by the Indians of Demerara. The "hannaquoi," or motmot, is said to be named *Ortalida motmot*, and the description mixes up the real motmot (Momotus) and the gallinaceous Ortalida, saying that the eggs are blue and that the bird can be easily tamed and feeds with the poultry; which is certainly not true of the motmot, of which a figure is given, and which is a solitary forest bird whose eggs are white and which never walks on the ground. The "kurumanni" wax is said to be produced by a wild bee named *Ceroxylon audicola*, which is the name of the wax-palm of the Andes. The name of the "coral-snake" is given as *Tortrix scytale*, whereas the species belongs to a quite distinct family, being either an *Elaps* or a *Pliocerus*; while the deadly "labarri" snake is named *Elaps lemniscatus*, though, from the description Waterton gives, it is almost certainly a Craspedocephalus. The red grosbeak, which Waterton mentions as a rarity he was long in search for and gives a recognisable description of, is called *Cardinalis virginianus*, a bird not found in Demerara; whereas it is almost certainly the *Pitylus erythromelas*. The little tiger-bird is said to be a Tigrisoma or tiger-bittern; but Waterton's description shows it to be *Capito cayanensis*, a fruit-eating bird of a totally distinct family. The "yawaraciris" are said to be manakins of the genus Pipra; but the description in the text clearly points to the well-known "blue creepers" of the genus Cœreba. The jay of Guiana described by Waterton, and which Mr. Wood could not determine, is the *Cyanocorax cayanus*, while the "grand gobe-mouche," which is omitted from the index, is easily recognisable as the *Querula rubricollis*. Of the plant identifications I am not prepared to speak, except to remark that the cultivated pineapple is certainly not a species of *Pitcairnea*.

It is to be hoped that this delightful work will come to a second edition, and admit of these blemishes being removed. It would also be a great convenience if references were added to the explanatory index, to avoid the trouble of first going to the index proper and then back to the body of the work. These, however, are matters which, though important to the student who keeps the book for reference, will not much affect the enjoyment of the general reader; and I can therefore cordially recommend all who have not made the acquaintance of the "Wanderer" to do so in the pages of the present volume.

A. R. W.

OUR BOOK SHELF

Ueber ehemalige Strandlinien in anstehendem Fels in Norwegen. Dr. R. Lehmann. (Halle, 1879.)

PROBABLY no feature of Scandinavian geology has been more frequently discussed than the remarkable lines of terrace which have been traced along the slopes of the coast, even up into the far northern fjords. Certainly no stranger, even if ignorant of geology, can visit these regions without being impressed by the freshness and persistence of these "parallel roads," which wind in and out among the intricate navigation of strait and sound, islet and archipelago. From the time of Celsius downwards a continually increasing literature has been devoted to this subject, and now Dr. Lehmann, of the Realschule, in Halle, adds another essay to the pile. He discusses at length and rejects the theories of erosion by glaciers and by floating ice, and adopts that of breaker-action. But probably no exclusive theory is correct. Unquestionably Norway has been overridden by land-ice, scarped and notched by coast-ice, as well as cut into by tides and breakers. That the terraces mark lines of former sea-level seems so self-evident that it hardly deserves more than a simple mention of the fact. But when these lines were cut out of the rock and the land was a hundred feet or more lower than it is now, the coasts were doubtless cumbered with ice, and while the breakers were grinding out a platform from the solid rock, their work was probably expedited by drifting masses of floe-ice. Dr. Lehmann's pamphlet is useful for the collected references it contains to recent literature on the subject. But it is needlessly voluminous.

Die Lust an der Musik. Erklärt von H. Berg. B. Behr's Buchhandlung. (Berlin, 1879.)

THIS is a little pamphlet which we have perused with no small amount of disappointment. After a short chapter treating of the origin of music, in which the author merely recapitulates the theory expounded by Darwin long ago, we come to Chapter II., on the development of music, in which the author states very little that has not before been stated by Darwin, and particularly by Helmholtz, in his "Lehre von den Tonempfindungen." The principal chapter, viz., that on the effects of music, in which we expected to find the explanation promised in the title of the pamphlet, or at least the expression of some new ideas on the subject, occupies but four small

pages, and contains merely a few illustrations of the capacity inherent in music of modulating the pleasant sensation it produces in the mind of man in a number of various ways. An appendix treats of the pleasure man derives from the aspect of colours, certain forms, and the beauty of the human body.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.*]

On the Spectrum of Brorsen's Comet

THE observations of Prof. Young on the present appearance of the spectrum of Brorsen's comet are of great interest, from the circumstance to which he refers in his letter in NATURE, vol. xix. p. 559, namely, that in 1868 I found the positions of the three bright bands of this comet not to agree with those of other comets which I showed to be coincident with the bright bands in the spectrum of flames containing carbon.

The care I bestowed upon the determination of the apparently anomalous character of the spectrum of Brorsen's comet in 1868 gives me great confidence in its approximate accuracy. I wish now to call attention to the fact that a spectrum apparently essentially similar to the peculiar one exhibited by Brorsen's comet in 1868, was observed at Dunecht by Lord Lindsay in the case of Comet C 1877 (Borelly's). It is remarkable that another comet, Comet B (Winnecke's) 1877, observed by Lord Lindsay on the same evening (May 6) presented the ordinary cometary spectrum.

Lord Lindsay's diagram in the *Monthly Notices* R.A.S. (vol. xxxvii. p. 431) of these two spectra agrees as nearly as can be expected in such observations with my diagram in the *Phil. Trans.*, 1868 (Pl. xxxiii.), contrasting the spectrum of Comet B, 1868, with that of Brorsen's comet.

It may be accepted, therefore, as beyond doubt that the unusual form of spectrum of Brorsen's comet in 1868 is occasionally presented by comets. The great interest of Prof. Young's observation lies in the information which it gives us that the *same comet* may present on one occasion one spectrum, and on another the other spectrum.

I regret that the special arrangement of my telescope for photographic work does not permit me to observe the spectrum of Brorsen's comet at its present appearance.

Upper Tulse Hill WILLIAM HUGGINS

The Migration of Birds

IN NATURE, vol. xix. p. 433, there is a notice of my paper "Ueber das Wandern der Vögel," to which I have somewhat to reply.

However agreeable it is to me that my views should be communicated to your readers, and however little I object to their being submitted to rigorous criticism, I must still also desire that this criticism be fair.

I believe it is due to differences of national customs that your reviewer has not quite satisfied this desire. We make, perhaps, in Germany a sharper distinction between a *scientific* treatise and a *popular* work than in England. Of the latter we do not require that it bring forth what is *new*, but only that it should give what it has to give in a clear and easily intelligible manner. Nor do we require completeness of such a work, or even a criticism of the scientific works on which it is based; indeed, it is generally left to the author how far to cite his sources of information and how far not. In the *scientific* treatise it is quite otherwise; here only that is of value which is new; the theme must be treated *exhaustively*; the sources must always be named and dealt with critically, &c.

Now my publication is a lecture, which was delivered *before a company of educated ladies and gentlemen, and so before mere laics*, and a year and a half afterwards was printed in Virchow and Holtzendorff's Collection of Popular Lectures. *It thus belongs unquestionably to the category of popular writings.*

For this reason your severe critic had no occasion to point out that in my lecture there is much that had been long known, that sources are named but rarely, and that no scientific criticism is exercised. That is quite a matter of course in a popular work, at least in Germany. Mr. Newton would have had much better right to feel surprised *that even any new ideas were contained in it.*

My original aim in this lecture was merely to make my hearers acquainted with the new facts and views on the migration of birds, as they have been established by Wallace, Middendorff, and especially by Palmén. As I followed the new facts theoretically to their consequences, there arose perhaps some new ideas, which I should be glad to find verified in the future.

It is further a matter of course that, notwithstanding the *popular* form of my work, I stand by all that I have said; but I must protest against being made responsible *for what I have not said!*

Thus, *e.g.*, I have nowhere said that I hold Palmén's routes of flight for "absolute truths." I am rather quite of Mr. Newton's opinion, that these routes are merely *inferred*, not *directly* observed, and therefore that they are to a certain extent "conjectural." In this sense, however, the routes of birds must ever remain comparatively "conjectural," unless one were to follow the birds in a balloon. But while "conjectural," Palmén's routes are yet inferred by a purely scientific method, and I doubt not that most of them will in the main be confirmed by further observations. Precisely in the application of this method lies Palmén's great merit, and it is only to be hoped that ornithologists will follow further in his footsteps, and correct his mistakes by accumulation of new facts. That Palmén's routes contain some errors I do not doubt; I should rather wonder if it were not so.

Little, however, comes of this with reference to the questions which are treated with special fulness in my lecture, *the origination of the instinct of migration, and the powers by which the bird reaches its distant goal.*

I have, further, nowhere said that birds fly over the sea at a height of 20,000 feet, but have merely cited the fact that birds have been seen at such height; with reference, of course, to explanation of their flight over the sea. I believe that birds, in flight over the sea, do not close their eyes, but exercise their keen eyesight as far as possible. Therewith, however, it is not said (as Mr. Newton imputes to me) that in *all* flights over the sea they always keep the land in sight.

I desist from adducing further misunderstandings by Mr. Newton, and come to what *I have actually said* and am minded to maintain.

In agreement with Palmén, I have expressed the opinion, *that migratory birds have no special sixth sense*, as Middendorff has assumed, but that *they find their way only with the help of their ordinary five senses.*

Mr. Newton seems to be of a different opinion. He does not say, indeed, whether he agrees with Middendorff, but he brings forward observations which appear incapable of harmony with my view.

First, there appear in New Zealand two species of cuckoo (*Chrysococcyx lucidus* and *Eudynamis taitensis*) which regularly fly some 1,000 miles' distance over the ocean. I believe with Mr. Newton that the birds cannot fly so high as to see at once New Zealand and the Norfolk or Kermadec Islands, though on the former is a hill of 1,000 feet. Likewise I will accept the case of *Charadrius pluvialis* as a regular guest of the Bermuda Islands, and a doubtful *Charadrius* species as regular guest of the Sandwich Islands. *All these observations are, indeed, still very imperfect*, inasmuch as it is not known whence the birds come nor whither they go; but so much seems certain, that they do *regularly* fly over large stretches of ocean in which are almost no islands or rocks, and which are so great that they must of course also fly by night.

What then? Are we therefore compelled to make the assumption, with Middendorff, of a sixth sense, which informs the bird which direction is north? Is there no simpler explanation of the fact? Obviously, we should only be warranted in accepting such a purely hypothetical sense, if it were clearly proved, that we could never get to understand the facts without it.

The question had already occupied me, before I knew of Mr. Newton's examples. I omitted it in my lecture, because it seemed to lead me further into the region of hypotheses than I considered I could answer for before my audience.

I do not believe that we are necessitated by the far sea flight of birds, to assume a sixth sense. Is it not conceivable that birds are capable of keeping exactly the same direction of flight for many hours together, and so to fly somewhat like a shot ball or a steamship with rudder bound fast? From the physiological side, it might of course be objected that a very slight difference in the strength of the right and left wing-beats must cause a deflection from the original course, just as in the case of rowing without a steersman, a constant control by sight is necessary, if the right direction is not to be lost. To this might be replied, however, that birds are so accomplished in flight, and that we may assume they have *an extremely fine muscular sense.* Besides, they migrate mostly in company, and an error in flight of one bird will be easily corrected by the others.

But how do they hit the direction in flying away from the coast? They must be able to exactly measure the angle at which they ought to leave the land. Therein, of course, a quite small error would involve great deflections from the proper course, *but do we know that this does not actually occur often enough? and may it not be supposed that in many cases corrections are made in the flight, as soon as any point of orientation again emerges in the circle of vision? So* much we at least know, that even on land birds wander not infrequently. And it is at least not demonstrated *in any one of the cases cited by Mr. Newton,* that the birds referred to appeared on those islands *every year,* nearly *at the same time and in the same number.*

Mr. Newton adduces a second series of "facts" which seem to be against the sufficiency of the five senses; *but are these really facts?*

The young, scarcely three months old, of many of our birds, are said to pursue their flight southwards in autumn *alone.* Is that certain? and have we not here, perhaps, a too ready deduction of general rules from a few well-observed cases? Mr. Newton even says: "This seems to happen with nearly all the accipitres," &c. He quotes a letter from M. Gätke, stating that in July "Young starlings pass over Heligoland by hundreds of thousands *without a single old bird* accompanying them." I confess that I cannot regard this as a *fact*, but as a more or less probable *conjecture;* for M. Gätke, though an excellent ornithologist, could not possibly have inspected a hundredth part of these "hundreds of thousands" of starlings flying about.

I do not mean to assert that these or the other data are false; they may well be correct. I merely hold that we must guard against building far-reaching theoretical inferences on observations the general validity of which is not in the least demonstrated.

But even supposing that all these data are correct; further, supposing it certain, that these young birds, which go forth alone, also actually find the route of the species with the same certainty as if they had known it long before, would these facts be explained by the supposition of a magnetic sense? I think not. For in that case, what must have been born with the young bird? Merely this magnetic sense? *i.e.*, the power of directly perceiving external direction in its own body? By no means. There must also be born with the young bird the consciousness of what angle to the magnetic meridian it must shape its flight at.

But much more than this. It has been long known that birds, so long as they are migrating over land, frequently alter their direction; hence, supposing the young bird to be guided by a magnetic sense, there must be born with it the tendency to fly (say) twenty miles at an angle of 45° to the magnetic meridian, then 100 miles at an angle of 27°, and so on. That this is a physiological absurdity, no one would deny.

For these reasons I hold that *a special sense for direction does not exist in birds*, and that the phenomena of migration, however wonderful they appear, yet cannot ultimately depend on magic (*Zauberei*), and in this Mr. Newton no doubt agrees with me. Hence, nothing remains but to try to explain these phenomena by the known physical and mental properties of birds; *for there is no third course.*

I shall be rejoiced if Mr. Newton succeed with this better than I. AUGUST WEISMANN

Freiburg im Breisgau, March 31

THE editor having afforded me the opportunity of seeing the foregoing remarks, it will, perhaps, be convenient to the readers of NATURE that I should here add the comments I have to make upon them.

I deeply regret if my criticism of Dr. Weismann's treatise or lecture be open to the charge of unfairness. I had no wish to misrepresent him, and I cannot see that I have been guilty of such an act—indeed, the wide publication of his theory would render any attempt to do so futile. As to his acceptance of Dr. Palmén's conjecture for "absolute truths," I must urge that he took no exception to any of them, while, in the case of his Bernacle or Brent Goose, he especially adopted (p. 27) that route X which I had particular reason to consider unfounded. I did not assert that Dr. Weismann spoke of birds flying over the sea at the height of 20,000 feet, though there seems no reason why some might not, if they can do so over the land; nor did I impute to him that they always keep land in sight. I had no need to declare my disbelief in Dr. von Middendorff's magnetic hypothesis, for I never met with any man that held it. I had spoken of it already elsewhere (*Encycl. Brit.* Ed. 9, iii., p. 769), and I considered it had been set at rest for ever by Prof. Baird in the article I cited. In like manner it seemed useless to disclaim any belief in the possession by birds of a "sixth sense" which is not common to ourselves and other animals. My only object was to show that Dr. Weismann's theory was inconsistent with certain facts, and nothing he has since adduced makes me think it otherwise. As to some of these "facts" he is incredulous, and I have no fault to find with his caution in this respect, but I am sure that the more he investigates them, the less he will be inclined to demur to them. I shall leave to the ornithologists of New Zealand the defence of those that relate to their cuckoos. Dr. Weismann will find in Mr. Jones's "Naturalist in Bermuda" (London, 1859) more than enough to justify my allegations in regard to the passage of *Charadrius virginicus* (not *pluvialis*) over those islands; indeed it has long been notorious; and as to the plovers of the Sandwich group, I have not only to thank Capt. Long, R.N., for his confirmation (*suprà*, p. 460) of my statements, but also Prof. George Forbes, who kindly informs me that when there, on the occasion of the transit of Venus, he shot scores of these birds, and that his friend Capt. Cator, R.N., of H.M.S. *Scout*, having sailed thence, was overtaken in mid-ocean by them, flying in a direct line for Vancouver's Island, on arriving at which he found they had already reached it. Concerning the "facts" relating to some young birds preceding their parents in migration, the more inquiries I make of well-placed observers the more satisfactory are the answers. For want of space I cannot here give the details, but I may just say that Mr. Cordeaux, who has been for many years a watchful observer of migratory birds on the Lincolnshire coast, has named to me nine species of *Limicolæ*, of which he has personally assured himself that the young migrate apart from, and invariably arrive earlier than, the old—thus fully bearing out Temminck's assertion, made nearly forty years ago. The case of our cuckoos, which I cited, is incontestable, and M. Gätke, I doubt not, will satisfy any scruples about his starlings in that book which we are expecting from his hands.

I will also take this opportunity of replying to Mr. Pringle's note (*suprà*, p. 481). My chief reason for not referring to the matter of temperature was that we know too little of the power of birds to resist extreme cold to depend much upon it, and I thought I would not take up room by bringing in that question. Doubtless there is something in what he says touching the loom of land, but I fail to see how it will help very far, and especially in nocturnal flights. ALFRED NEWTON

Magdalene College, Cambridge, April 20

Colour in Nature

I WISH to offer a few remarks upon Mr. Wallace's kind and appreciative review of my work on the "Colour-Sense" in NATURE, vol. xix. p. 501. Mr. Wallace attributes to me "many errors" and inaccuracy as to matters of fact; but I do not think the instances he alleges are sufficient to justify the statement. Had I said in every case what Mr. Wallace makes me say, I should, doubtless, have been misrepresenting facts; but it seems to me that in most of the passages to which he refers he has slightly misconceived my meaning. I should not attempt to oppose so distinguished a naturalist on points of biological inference, but I venture to defend the accuracy of my statements of fact.

1. "*Scissirostrum Pagei* does not 'belong to a family generally dull,' while it is itself decidedly dull-coloured." The first statement will be correct if we place *Scissirostrum* among the brilliant starlings; but Mr. Wallace himself, following Prince

Lucien Bonaparte, puts it next to the West African *Buphagæ*. Now the *Buphagæ* are certainly dull birds, while *Scissirostrum* is described in the "Malay Archipelago" as "almost entirely of a slaty colour, with yellow bill and feet, but the feathers of the rump and upper tail-coverts each terminate in a rigid glossy pencil or tuft of a vivid crimson" (i. 430). I wrote with this passage of Mr. Wallace's under my eyes, and refer in a footnote to his volume for the vivid crimson. I did not say the bird was brilliant, I merely noticed the colour of its tail and beak. The case really stands thus: If *Scissirostrum* was differentiated from a generic ancestor generally resembling *Buphaga*, we have to inquire, why did it develop these ornamental adjuncts? and my answer is, because while *Buphaga* pecks the parasites of the backs of mammals, *Scissirostrum* feeds off "grains and fruits."

2. "Santarem, of which it is said 'the pastures are destitute of flowers, and also of animal life, with the exception of a few small plain-coloured birds,' is one of the richest localities for flowering shrubs in South America." Now, this passage to which Mr. Wallace takes exception is not mine, but is a textual quotation from Mr. Bates ("Naturalist on the Amazons," p. 183). It is given in inverted commas in my text, with reference to the original in a footnote. I was, of course, aware that the Brazilian woods generally were full of brilliant birds, and that "the butterflies in the adjacent forests were gorgeous in the extreme." What I wished to point out was that in particular spots like these meadows, where the general aspect of the flora was not bright, the purely local fauna was likewise dull. We may find great varieties in this respect nearer home in a meadow, an adjacent warren, and a moor or swamp behind it. Moreover, the passage was professedly quoted, simply as showing the general impression left upon my mind by reading various books of travel. May I add a sentence from a private letter of Mr. Darwin's, which helps out the same view on a larger scale? "The contrast," he says, "in the colour of the birds in Patagonia" (where he had just noticed "the sombre aspect of nature"), "and on the bright green flower-decked plains of La Plata is very striking."

3. About a certain squirrel, described in the "Malay Archipelago" as having a tail "ringed with gray, yellow, and brown," and as looking "exceedingly pretty," Mr. Wallace now says it "is one of the dullest of the group," while he did not "say a word about its feeding on 'bright-coloured fruits.'" But he *did* say that it would eat "any fruit" (i. 192), and I presume, therefore, that it sometimes eats "bright-coloured food."

4. "So far from the colours of caterpillars being 'mostly protective,' every entomologist knows that a large number of caterpillars in every part of the world are conspicuously coloured." True; but Mr. Wallace himself was the first to suggest that these conspicuous colours were themselves protective by giving warning of inedibility; and I am at a loss to understand what he means by thus going back upon his own words. I took my statement from Sir John Lubbock's lecture "On Certain Relations between Plants and Insects," pp. 23–24, where this fact of universal protective colouring in larvæ is very clearly brought out.

5. "Again, the ground-feeding pheasant family are passed over as containing only one brilliant bird, the peacock, whereas it abounds in species of the most gorgeous colour." But my words are very different from this—"Even among the pheasants themselves," I say on p. 176, "many species are far from brilliant; and when we come to compare the whole family with that of the parrots or the humming-birds, we shall find that the peacock alone can fairly come into competition with the typical fruit-eaters and flower-feeders." Mr. Wallace goes on to mention (amongst others) the "Impeyan pheasant of the Himalayas," and "the intensely-brilliant fire-backed pheasants of the Malay countries," as among the most brightly-coloured species. Any one would suppose from his review that I had totally overlooked these cases; but in the very same paragraph with the sentence which Mr. Wallace blames the following passage occurs:—"The forests of the Himalayas and the Malay Archipelago, with their great brilliant fruits and flowers, and their exquisite insects, form the haunts of the most beautiful species of pheasants" (p. 177). As a matter of fact, before writing that paragraph I had carefully compared all the living *phasianidæ* in the Zoological Gardens, and all the preserved specimens in the British and Oxford Museums; and I feel sure that any one who does the same will agree with me that the peacock alone can be placed in the very first rank of brilliant colouration.

6. How much the subjective element enters into these questions may be seen from the following remark of Mr. Wallace:—"The tigers, the zebras, the beautifully-marked antelopes, and the spotted deer and giraffes, *which are really among the most brightly-coloured of all mammals*, are passed over as less beautifully coloured than the squirrels and monkeys." Now I confess myself simply astounded at the statement that the zebra, of all animals in the world, is brightly coloured—a creature without a tinge of anything but creamy white and black about its body. Quite apart from the nature of food or surroundings, I call a panda a brightly-coloured mammal; or a mandrill; or a Rhesus monkey; or a Canadian chipmonk; but certainly not a tiger, a zebra, or a giraffe, none of which has a single tinge of scarlet, blue, green, or bright yellow.

No one who knows anything of Mr. Wallace could for one moment imagine him capable of intentionally misrepresenting the humblest opponent in the smallest particular; and I owe him many thanks for much kind and appreciative criticism both on this and several previous occasions. Yet I cannot help thinking that in these instances, and others with which I will not burden your space, he has unconsciously permitted mere differences of opinion unduly to assume the appearance of positive errors in fact. GRANT ALLEN

Remarks by the Reviewer

1. *Scissirostrum Pagei* is universally placed in the starling family. Its affinity to *Buphaga* is very doubtful, while its *crimson-tipped tail-coverts* are very different from "*a tail of vivid crimson*" which Mr. Allen gives it (p. 184).

2. I object altogether to founding theories on chance expressions of travellers. It is curious, that in my "Travels on the Amazon" (p. 157) I refer to these same Santarem pastures as follows:—"There were some boggy meadows here, more like those of Europe than one often sees so near the equator, on which were growing pretty, small *Melastomas* and other flowers. The paths and campos were covered with flowering myrtles, tall *Melastomas*, and numbers of passion-flowers, convolvuluses, and bignonias." These open meadows and campos really exhibited more conspicuous flowers than the woods and forests which swarmed with brilliant butterflies and birds.

3. I referred to the squirrel, because it was the only example given by Mr. Allen which I could at the moment test.

4. My argument is, that the colours of caterpillars are often as varied, as vivid, and as beautifully arranged as in birds and winged insects. This is not necessary for protection by *conspicuousness*, for which purpose any tint contrasted with foliage, such as black, or white, or ringed with black-and-white, would have sufficed.

5. The "pheasant" question I leave, as Mr. Allen has placed it, for the consideration of naturalists.

6. Here it seems to me Mr. Allen is himself changing his ground. His main argument is that the æsthetic tastes of the higher animals are the same as ours, yet he objects to the elegantly-marked and intensely-contrasted zebra and tiger being called "brightly-coloured." Surely they are more beautiful than the mandrill or the Rhesus; while among animals *white* is as much a colour as among flowers. ALFRED R. WALLACE

Nitric Acid Batteries

I INCLOSE the results of some experiments I have lately made to ascertain if the cost of working the nitric acid batteries of Grove and Bunsen could be reduced. I find that the nitric acid can be replaced by a mixture of half nitric and half dilute sulphuric. And the latter gives a higher force for nearly three hours. The experiments were made with a large-surface voltameter, and the gases were collected during one minute every half-hour; four pint-size cells were used. The experiments were repeated, and every care taken to avoid any error. I have also used the mixed acids very successfully with twenty-eight cells for the electric light. I presume the increased power is due to the internal resistance of the battery being slightly lowered by the addition of the dilute sulphuric acid in the porous cell. I may add that the fumes were much less than when nitric acid alone is used. JOHN HENRY KNIGHT

Farnham, April 19

The Black Rat

IN regard to the distribubution of the black rat (*Mus rattus*), your correspondent may be glad to know that this animal, spread

over the States in early days, but has since been supplanted, as in England, by the brown rat (*M. decumanus*). Forty years ago the black rat was the only rat in South-west Ohio. About thirty years ago the brown rat drove him out. Some years later the same occurred in Illinois. I have been informed by one of my students living in Minnesota, that neither rat is known in and about the town of St. Cloud in that state, only one having ever been seen there, and that was killed on landing from a steamer. I have seen it stated that the black rat is still to be found in some localities in England, among them the Whitechapel Docks. E. W. CLAYPOLE

Antioch College, Ohio, April 7

Did Flowers Exist during the Carboniferous Epoch?

I CANNOT accept Mr. McLachlan's reference of the interesting *Breyeria borinensis* to the Ephemeridæ, even though he has "examined the fossil," and "has no doubt" about it. The photograph which I possess is so beautifully sharp that it brings out the minutest details, and a careful examination and comparison of it with specimens and drawings leads me to the conclusion, that in the general character of the wing-neuration it is strictly lepidopterous and of the Bombycine type, having the costal, subcostal, and median nervures, with their branches and bifurcations, arranged precisely as in that group, but differing in the much greater length of the wing and the increased number of the branches of the subcostal vein—seven instead of four. In some of the Chalcosiidæ, however, there are often six branches to this vein, but crowded together and sometimes anastomosing, owing to the much shorter apical portion of the wing. In this family also we often have an intermediate false vein, which is distinctly visible in the fossil. Until, therefore, I am referred to some group of insects with which it more nearly agrees, I must believe it to be an ancestral moth, even though, according to Prof. Haeckel and Mr. Scudder, moths ought not to have existed in the carboniferous epoch.

After a careful comparison of the photograph with specimens and figures of Ephemeridæ, I can see *no resemblance whatever* to the neuration of the family with which Mr. McLachlan so confidently associates it; while the "dense transverse reticulation" to which he refers seems to me to be merely due to crumpling of the membrane, and certainly bears no close resemblance to the strong reticulation of the veining of the Ephemeridæ, and it is, moreover, only visible at all at the base of the wing. The general form of the wing and arrangement of the veins are, however, so different, as, to me, to be conclusive against this view. ALFRED R. WALLACE

Blue Flame from Common Salt

At the present time any spectroscopic observations of coloured flames are peculiarly interesting, and I am glad to see the origin of the blue or violet flame produced by common salt and other chlorides again discussed in your pages.

In the letter of Mr. Percy Smith (NATURE, vol. xix. p. 483), he considers the only feasible explanation to be "that it is due simply to hydrochloric acid," but he gives no proof, and admits that a spark between carbon points in a bottle of this gas does not give the violet bands. In a short paper on the subject in the *Philosophical Magazine* of December, 1862, I considered "this supposition is negatived by the fact that anhydrous chloride of copper emits these rays equally whether it be placed in a flame of hydrogen or of pure bisulphide of carbon." Neither does this characteristic flame seem due to any carbon compound, inasmuch as several chlorides will give it in a hydrogen flame. I also found that "a stream of chlorine or hydrochloric acid passed into a flame never gives the violet light, nor does Dutch liquid, muriatic ether, or chloroform mixed with alcohol and burnt in a spirit lamp," though chloride of platinum or gold give a flash of it at that temperature.

Would Mr. Smith favour us with any details of his experiments which may support his conclusion?

17, Pembridge Square, April 10 J. H. GLADSTONE

Cape Diamonds

AT the Croydon County Court a lady sought to recover 36*l*. 15*s*. paid for a ring, the stone in which had been represented to be *a diamond*, and which was indeed admitted to be a Cape diamond.

Judgment was given for the plaintiff, because several diamond *dealers* gave evidence which, the judge stated, clearly showed that what were described as "Cape diamonds" were not at all *to be regarded as* ordinary diamonds, and the receipt showed that the ring was sold *as a diamond* ring. The "several diamond dealers" stated that so-called Cape diamonds were comparatively valueless and lacked the essential qualities of the Brazilian stones, viz., lustre, hardness, and colour.

Now all this is beside the question, which was not as to the value of Cape diamonds, nor yet what they lacked of the qualities of the Brazilian stone, but simply whether this stone was a diamond or not, not even whether it was or was not an ordinary diamond, and I am surprised that any judge could be thus led away from the legal point.

I see that notice of appeal has been given, and it is to be hoped for the credit of elementary science that the court above will require some *scientific* evidence, such as specific gravity or chemical composition, about Cape diamonds. If, for instance, it can be shown that they are a form of carbon, the point is settled.

It would be just as absurd for a person to object to Derby coal as not coal because it lacked the good qualities of Wallsend. The ring was sold as a diamond ring; the question is: Is the stone a diamond?

I have no personal interest whatever in the matter. I know nothing of the case except as it appears in the report. I possess no diamonds, not even a "Cape"; but I am interested in seeing justice administered with some regard to the scientific knowledge of the day. B. G. JENKINS

April 14

Sense of Temperature

YOUR correspondent J. T. B. asks for further instances of the cultivation of the sense of temperature. None can be more striking than that of the caste of egg-hatchers in Egypt, who determine the temperature in their ovens entirely without the aid of instruments, and maintain it at 100° to 103° Fahr. during the requisite three weeks. How successful they are is shown by the official return for 1831, given by Lane ("Modern Egyptians," London, 1842, vol. 2, p. 5, *et seq.*) from whom I take these particulars. Out of a total of 26,204,500 eggs artificially incubated, 17,418,973 were successfully hatched.

April 19 ALFRED H. HUTH

Tides at Chepstow

THE highest tides in the Wye and in the Severn for the present year were on Tuesday, April 8. On that day, up the Wye, at Llandogo, the tidal rise was 13 feet; at Tintern Abbey, 21 feet 5 inches; at Chepstow Railway Bridge, 44 feet. Up the Severn, at Newnham, the tidal rise was 20 feet; at Portskewitt, 46 feet 6 inches; at Cardiff, 44 feet; at Clevedon Pier, 52 feet.

Reference to Coxe's "Historical Tour in Monmouthshire," 4to Edition, 1801, p. 358, containing his own *soundings* at high tide, on September 4, proves that there has been no perceptible change in the depth of the Wye at high tide this century.

The Severn has been confined within narrower limits by the South Wales Railway embankment, on the Monmouthshire side, since 1850, and by Lord Fitzhardinge's breast-works on the Gloucestershire side, from about same date, but the height of the tide and the depth of the river have not been sensibly affected by these slight alterations. One fact further may be worth mention, however: a gun-boat or armed sloop, commanded by Capt. White, came up the "Pill," below St. Pierre, in 1827, on a surveying expedition, remained at anchor some days, and re-entered the Severn without difficulty, piloted by W. Wheeler, a thing that would now be impossible on account of the embankments. The Pill is a mere creek—the "anchorage," dry ground. JOHN YEATS

OUR ASTRONOMICAL COLUMN

BRORSEN'S COMET.—The following ephemeris of this comet for May is deduced from Dr. Schulze's elements, with the time of perihelion passage corrected so as to accord better with the observations in March at Florence and Kremsmunster. The heliocentric co-ordinates, referred to apparent equinox of May 1, for combination

with the X, Y, Z of the *Nautical Almanac*, have been found from—

$$x = r[9{\cdot}94281], \text{ sin. } (v + 207^\circ\ 51'{\cdot}8),$$
$$y = r[9{\cdot}98498], \text{ sin. } (v + 126\ 18{\cdot}6),$$
$$z = r[9{\cdot}73737], \text{ sin. } (v + 60\ 32{\cdot}2).$$

THE DOUBLE-STAR, SOUTH 190.—Interest attaches to this object for more than one reason. The principal star possesses a large proper motion in which the companion participates, while there is a much slower change of relative position in the same way that we observe in 61 Cygni. Further, there would appear to be some evidence of variability of light in the principal star. Argelander in his memoir on the proper motions of 250 stars, assigns +0·0691s. in right ascension, and – 1″·766 in declination, or 2″·015 annually in arc of great circle, in the direction 151° 14′. If we compare Lalande's observation on May 22, 1798, with the observations made at Bonn in 1864, and at Washington 1867–69, almost identical values with those given by Argelander will result. The following figures will sufficiently indicate the variation in relative position that has occurred since Piazzi observed the star early in he present century:—

Piazzi	1806·7	Position	251°·4	Distance	9′·4c
Herschel and South	1823·32	,,	270·1	,,	10·82
Herschel (Cape Obs.).	1836·46	,,	277·4	,,	12·08
Jacob	1856·37	,,	284·0	,,	13·35
Stone (Cincinnati)	1877·37	,,	290·3	,,	14·92

The star forms one of Sir W. Herschel's catalogue of 145 new double stars, where the duplicity is stated to have been discovered in 1785; at the epoch 1791·39 the angle was estimated 270° —, distance IV.; an observation not easily reconciled with more recent ones.

As regards variability the principal star was rated 4m. in Argelander's zone No. 295, on May 20, 1850; it is 5·9m. in the second Radcliffe catalogue, while the Washington observers call it 6·6m.; Lalande and Piazzi estimated it 6m. Argelander calls the companion 8·4. The position of South 190 for 1880 is in R.A. 14h. 50m. 27s., N.P.D. 110° 52′·3. It is No. 1186 in the Greenwich catalogue for 1860.

THE MINOR PLANET HILDA.—This small planet, the most distant member of the group, which approaches the orbit of Jupiter within 0·85 of the earth's mean distance from the sun, has been sought for unsuccessfully at Berlin, near the calculated position; there may now probably be a difficulty in recovering it.

GEOGRAPHICAL NOTES

WE hear that Sir Walter C. Trevelyan, who died lately at Wallington, Northumberland, has bequeathed to the Royal Geographical Society, of which he had been for many years a trustee in conjunction with Lord Houghton, the sum of 500*l.*, in addition to a valuable collection of books relating to the Faroe Islands, maps, &c.

THE geographical haze in which some of our daily contemporaries persist in enveloping themselves, appears to be growing denser. The "War at the *Cape*" is bad enough, but the telegram received last week from a special correspondent at Baku, informing a wondering public that "Krasnovodsk has returned with General Lazareff, and Lomakine's reconnaissance to the confluence of the Attrek and Sumbir [*sic*], &c.," fills the cup to overflowing. Krasnovodsk, we thought, was the name of a town and bay on the eastern shore of the Caspian, but the tangle is above our powers to unravel.

THE new part of the *Transactions* of the Asiatic Society of Japan is wholly occupied with Mr. John Milne's narrative of his journey across Europe and Asia to the Land of the Rising Sun. From some singular statements which he makes, we suspect that Mr. Milne was not sufficiently careful in making himself acquainted with the literature of Chinese travel before leaving; otherwise he would hardly venture to assert that the journey from Peking to Tientsin and overland to Shanghai has but seldom been made by Europeans. Mr. Milne's views on the subject of the rendering Chinese sounds are very remarkable.

THE Paris Society of Geography held its annual meeting for the election of officials on Friday, April 18. Admiral Laroncière le Nourry was returned president almost without opposition. The great gold medallist is Lieut. de Brazza, the Ogowé explorer. A gold medal was also awarded to Lieut. Wyse, of the French Navy, for his exploration of the Isthmus of Darien, for the construction of an inter-oceanic canal. The gold medal for Polar exploration was awarded to Sir George Nares, Commander of the last English Arctic Expedition. The Cross of the Legion of Honour was also given to M. Brazza and his fellow-explorer, Dr. Ballay. Lieut. Wyse and Lieut. Reeks received a similar honour for the Darien explorations. An address was given by Commander Perrier on the determination of longitudes by electricity. A map was distributed amongst members showing all the European and African towns whose longitudes have been determined by that process. They number about one hundred, extending from Oural to Valentia, and from Lapland to Sahara.

NO. 3 of this year's *Mittheilungen* of the Vienna Geographical Society contains an important paper, with map, on the sources of the Dniester and the valley-structure of the region of the Upper Dniester and Strwcaz. The first number of this year's *Boletin* of the Madrid Geographical Society contains, among other things, the first part of an account of an excursion in the La Plata Republics, by Capt. Carrasco y Guisasola.

THE just published *Bulletin* of the Antwerp Geographical Society contains, amidst a considerable variety of matter, a paper by Mme. Dumas de Baiglie, entitled "Les Voyageuses illustres." The Society about a year ago resolved to admit ladies, and the author of this paper is a *membre associé*, who seems very grateful for this recognition of the rights of women.

AMONG the new bills introduced into the first session of the Forty-sixth U.S. Congress is one authorising the president to establish a temporary colony at some point north

of the eighty-first degree of north latitude, on or near the shore of Lady Franklin Bay, for the purpose of scientific observation and exploration, and to develop or discover new whaling grounds; such officers as may be necessary to be detailed to take part in the same, and with permission to use any public vessel or vessels in connection therewith. This is essentially Capt. Howgate's plan, and probably introduced by his request.

THE last number of the *Indian Antiquary* contains a note by Major J. S. F. Mackenzie on some curious customs current among the Komti caste in regard to marriage, &c. "A Folklore Parallel," by Prof. C. H. Tawney, of Calcutta, is also worthy of notice.

MGR. LAVIGERIE, Archbishop of Algiers, communicates to *Les Missions Catholiques* intelligence respecting the portion of the French missionary expedition in East Africa, which, under the leadership of Père Livinhac, was gradually making its way towards Lake Victoria. At the date of the letter (December) the five Europeans were all in good health, and were then in Mirambo's country, on the way to Uganda. Père Livinhac writes that they had been three months in Unyanyembe, and that they were then twenty or thirty days' march from the lake. In the same number of *Les Missions Catholiques* Mgr. Ridel continues the account of his recent captivity in Corea, in which he gives a terrible picture of the prisons of the country.

A TELEGRAM from Malmö states that the steamer *Nordenskjöld*, built for M. Sibiriakoff, to go to the assistance of Prof. Nordenskjöld's expedition, was launched on the 17th inst.

A VERY interesting narrative of travel has just been commenced in the *Tour du Monde*, entitled "Voyage en Nouvelle Guinée," by M. Achille Raffray. The first instalment deals with the Moluccas, which M. Raffray visited *en route*, but in the second he commences his work in New Guinea. The illustrations are unusually good.

BIOLOGICAL NOTES

THE EARLY TYPES OF INSECTS.—Samuel H. Scudder has published a memoir on the early types of insects (*Memoirs* of the Boston Society of Natural History, vol. iii. Part i. No. 11, March, 1879). He concludes that the hexapods, arachnids, and myriapods appeared together in the carboniferous strata. That the hexapod insects may be divided into a higher group (Metabola), and a lower group (Heterometabola), that the latter are Devonian and carboniferous, the former just appearing in the Jurassic period. The Devonian forms were in the early stages of their life, undoubtedly aquatic. Nearly all the palæozoic orthoptera belong to the lower Saltatorial families. It would seem that the earlier types were of inferior organisation, and that the general type of wing structure in insects has remained unaltered from the earliest times.

HALOSPHÆRA, A NEW GENUS OF UNICELLULAR ALGÆ.—Under this name Dr. F. Schmitz describes, in the first "Heft" of the first volume of the *Mittheilungen aus der zoologischen Station zu Neapel*, an organism which is found abundantly between the middle of January and the middle of April, floating on the surface of the water in the Bay of Naples. Hitherto known to collectors simply as *punti verdi*, Dr. Schmitz gives it the name *Halosphæra viridis*. It presents to the naked eye the appearance of minute just visible pale green globules, the largest having a diameter of from 0·5 to 0·6 mm., but with no independent power of motion like that of *Volvox*. Each globule consists of a tolerably thick perfectly smooth and colourless cell-wall, coated on the inside with a thin layer of pale green protoplasm, which incloses a single very large central vacuole filled with a colourless cell-sap. The green colour of the protoplasm is due to its being interspersed with a small number of minute grains of chlorophyll; and there is also, at an early stage, a single globular nucleus with a somewhat darker nucleolus. As the cell increases somewhat slowly in size, the process of cell-division commences. The single nucleus divides into two nuclei, which gradually separate from one another; and this process is repeated time after time, until a very large number of nuclei, which the author reckons to average from 200 to 300, come to be tolerably regularly distributed through the parietal protoplasm of the mother-cell, which has by this time attained its full size. The layer of protoplasm then breaks up into a number of primordial daughter-cells, each surrounding one of the nuclei, and having the form of a hemispherical ball, the flat surface of which is in contact with the cell-wall of the mother-cell. They are of a uniform bright green colour, without apparently containing any distinct grains of chlorophyll. The external cell-wall of the mother-cell has now become differentiated into two distinct layers, the outer one of which bursts into two nearly equal halves, and becomes completely detached from the inner one, which now itself consists distinctly of two layers. The hemispherical green daughter-cells then become transformed into zoospores of a very peculiar shape. They begin gradually to detach themselves from the outer cell-wall, and to take up positions in the interior of the cell. In most cases each of them contracts in the centre into somewhat the shape of an hour-glass, but pointed at the two ends, ultimately dividing in the middle into two zoospores of conical shape, with a nearly flat base, but toothed at the edges, and a pointed apex. To a colourless protuberance in the centre of the nearly flat base are attached two very long vibratile cilia. Sometimes only a single zoospore is formed from each of the primordial cells, and occasionally more than two. The remaining cell-wall of the mother-cell has, in the meantime, been gradually swelling up and deliquescing, and has now become completely converted into mucilage, so that the zoospores escape free into the surrounding water. After moving about for some time with a rather slow swarming motion, they fall to the bottom; but their further development has not been followed up. Until its complete life-history is known, it is impossible to assign a systematic position to *Halosphæra*. It may possibly come near *Eremosphæra*, a genus of Conjugatæ; its resemblance to *Volvox* is clearly only superficial.

A NEW ALGA.—In the first Heft of the 1st vol. of the *Mittheilungen aus der zool. Station zu Neapel*, Dr. Falkenberg describes a new genus of Phæosporeæ under the name *Discosporangium*, with the following characters:—Thallus, an irregularly branched filament, consisting of a single row of cells, and growing by an apical cell. Reproduction by zoospores, which are formed singly in the compartments of multilocular zoosporangia. The zoosporangia are placed singly near the middle of the cells of the thallus, forming a square unilamellar plate, the compartments of which open separately when ripe on the upper side of the sporangium.

IN the second Heft of the same publication Dr. Falkenberg gives a complete list of the marine Algæ of the Bay of Naples.

MARINE FLOWERING PLANTS.—Dr. I. B. Balfour has just published (*Transactions* Bot. Soc. Edinburgh, Session 1877-78) a most valuable and interesting memoir on two species of the genus Halophila, found very abundantly in widely extended patches on the reefs surrounding the island of Rodriguez. The island was visited in 1874 by Dr. I. Balfour as naturalist accompanying the "Transit of Venus" expedition. Of the two species one, *H. ovalis*, grows on spots which are just uncovered at low tides. The other, *H. stipulacea*, grows in places where it is always submerged. Specimens

collected both in flower and fruit were preserved in alcohol, and were most painstakingly investigated at Prof. de Bary's botanical laboratory at Strassburg. The only portion of the life-history of these plants left for future investigators is the germination of their seeds, which, probably, does not take place until the first quarter of the year. The stem structure is simple. Of the presence of sieve-tubes in the bundles there appears to be no doubt. The mode of the tissue formation at the tips of the roots is peculiar; from an initial group of cells underneath the root-cap, there issues three distinct tissues. This corresponds to the third type of Janczewski, who, among the monocotyledons, found it only in Elodea. The scale and foliage leaves are described in detail. The epidermal layer is peculiar; stomates are to be found in neither of the species. The floral axis is short and axillary; there is a double-leaved spathe. The author is inclined with Ascherson to consider the plants diœcious. The anther cavities are filled with a mass of confervoid pollen. These pollen cells are found to be united in long strings, each string apparently continuous through the greater part of the length of the cylinder. The partition walls between adjacent cells in a string are transverse. The ovary is inferior and contains many ovules. The author suggests the morphological identity of the stamens and carpels, "the same phyllomes (or the phyllomes from the same nodal regions), which, in the male form stamens, in the female form carpels." A technical and emended character to the genus and of the two species concludes this paper.

AMERICAN APHIDES.—Dr. Riley gives a detailed account of the life-history of some species of gall-making Pemphiginæ (Art. 1, vol. v. *Bulletin* of the United States Geological and Geographical Survey of the Territories, 1879). The facts concerning these Aphides have a special interest on account of the close relationship between the insects of this group and the now notorious grape vine Phylloxera. The special history of *Schizoneura americana*, n. sp., is given. It is to be found curling and gnarling the leaves of the White Elm (*Ulmus americana*), and passes from the egg state through no less than seven stages, in some winged, in some wingless, but in all agamic until the seventh, when, as the result of fertilisation, the true egg state is again reached. Another very common gall described is that formed by *Colopha ulmicola*, and the diagnoses of five new species of Pemphigus are given. In a second part of this paper Mr. Monell describes several new species, and gives detailed synonymy of several already described. Two excellent plates accompany Dr. Riley's notes on the gall-making forms.

NEW BIRDS FROM THE PORTUGUESE POSSESSIONS IN WESTERN AFRICA.—Prof. Barboza du Bocage publishes (*Journ. de Scien. Math. Phys. Natur.*, Nos. xxiii. and xxiv., Lisboa, 1878) his sixteenth and seventeenth lists of birds from Angola. A new genus and species (*Hylypsornis salvadori*) is established for a creeper, and a pretty sun-bird is called after M. d'Anchieta, who has added so much to our knowledge of the birds of Angola (*Nectarinia anchietæ*). Several other new species are described in the sixteenth list. In the seventeenth list a new genus and many additional new species are also established, the more remarkable being a sun-bird (*Nectarinia oustaleti*) and a unique bird from Caconda (*Sharpia angolensis*), called after Mr. Sharpe, of the British Museum, and having affinities with Hyphantornis.

A UNIVERSAL CATALOGUE

THE Council of the Society of Arts, probably the most practically useful body in the kingdom, has taken a positive step towards the accomplishment of a task which certainly deserves to be called gigantic. We need not moralise once more on the extent to which the making of books has been carried; many a modern Solomon has no doubt been appalled into silence in the effort even to realise, far less to express, the extent of this manufacture. To attempt to begin *ab initio* to catalogue the works published during the past century, or even since the beginning of the present century, would be a task which to us would seem to be hopelessly endless. Any one whose business it is to work with books, and even the most thorough-going scientific worker must refer to them occasionally, must recognise the immense advantage, however, of having in one properly arranged catalogue, as complete a list as possible of printed books, and the farther back it went, the more valuable it would be. It is, then, certainly a fortunate thing that there exists ready to hand, though unprinted, a catalogue which for all practical purposes may be regarded as a universal catalogue of printed books, and that not only for the past century, but the past four centuries and more; for the British Museum Catalogue begins as far back as 1450. Some time ago the Society of Arts considered the advisability and practicability of constructing a catalogue coming down to the year 1600. The Council addressed a series of questions to them likely to give useful answers, and afterwards met to hear evidence on the subject. Mr. Bullen and other authorities were thus examined, and it seems to have been Mr. Bullen who happily suggested that the best and only sure method of laying a solid foundation for the Universal Catalogue of English printed literature would be to print the Catalogue of the Printed Books in the British Museum, from A.D. 1450 to the present time, say, the end of the year 1878, representing about 1,250,000 vols., and comprising between 2,000,000 and 3,000,000 entries, *i.e.*, main titles and cross references. He considered the work might be ready for printing, "in a rough and ready way," in two years, and in less time if more force were employed, and that it would take five years to print. All the witnesses agreed that the printing of the British Museum Catalogue would be highly desirable, and the Committee are of the same opinion.

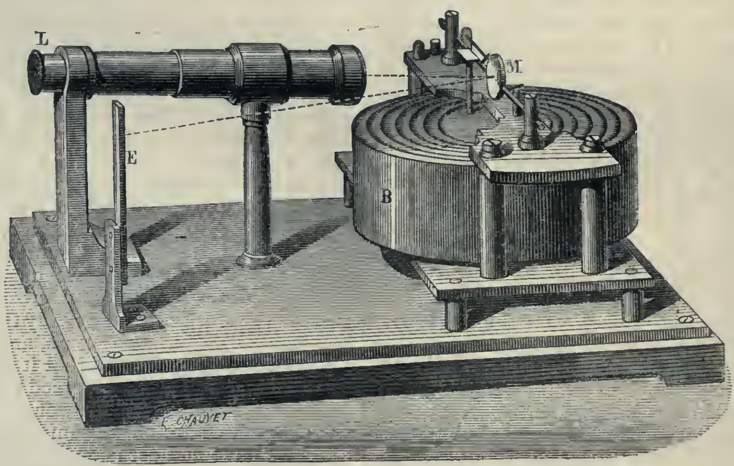
As we have had occasion to point out in these pages, the British Museum Catalogue is by no means perfect, and it is specially difficult for a man in search of a scientific serial or paper to get at it without much roundabout hunting from one cross reference to another, much waste of time, and loss of temper. Still considering all the difficulties in the way of constructing a perfectly new catalogue, we do not think a better course could be followed than that suggested by the Society of Arts' Council. It might be possible to introduce some improvement in arrangement during the process of printing, and especially with reference to the arrangement of the publications of scientific societies, which at present is so completely unscientific. It must also be borne in mind that the Catalogue is only one of authors, and that for many purposes of research such a catalogue is of little use without an equally complete one of subjects. Still the want of the latter is no argument against the publication of the former, though we should hope that the one would be followed by the other.

Of course such a stupendous, and, at its cheapest, costly undertaking could hardly be accomplished by any private body, and it is natural that the Society of Arts should look to government for help in the matter. As the scheme has the approval of the President of the Society, the Prince of Wales, we should think that the Government is not likely to hesitate in granting such aid as might be required. Of course the printing and paper need not be luxurious nor expensive, and the specimen-page issued by the Society seems to us satisfactory. It is calculated that the British Museum Catalogue would thus occupy about forty-five volumes of 1,000 pages each, and could be issued through the Stationery Office at about 16*s*. per vol., and even less if the edition were of 2,000 copies. No doubt a fair sale would be obtained for such a publica-

tion both at home and abroad, for take it all in all, as Mr. Bullen says, "no catalogue in the world, whether in print or in manuscript, is equal to that of the British Museum." We hope, therefore, that the proposal of the Society will speedily meet with a favourable response from Government, and that should it be decided to print the British Museum Catalogue, some plan will be formed by which proofs may be revised not only by qualified bibliographers, but that the various departments of literature, science, and art will be represented on the staff of revisers.

A MIRROR BAROMETER

M. LÉON TEISSERENC DE BORT has invented an aneroid mirror barometer, which is described in a recent number of *La Nature*. It is based on a method analogous to that well-known since the researches of Gauss for the reading of small rotations. M. Teisserenc de Bort has sought to obtain an aneroid barometer which will give precise observations at sea, especially in rough weather, when it is impossible to read the mercury barometer. The principle of this barometer is very simple. The elastic tub or box B carries, as in most aneroids, a metallic point, which follows its movements. In the ordinary aneroid the transformation of the vertical movement into a rotating movement necessitates either a chain or a curb, or a sort of fork which works in a spiral furrow cut in the axis which supports the needle. These various systems have the inconvenience of producing frictions; some of them are liable to dust and rust. In the mirror barometer, the transformation of the movement is obtained by the simple contact of a small palette supported on the axis of the mirror and of the point spoken of above. As the angle which the plane of the mirror may describe does not exceed 12° on each side of the vertical, it follows that the contact of the point in the palette is always precise.



Teisserenc de Bort's mirror barometer.

As to the amplification of the movements necessary to enable us to appreciate millimetres and their fractions, this is obtained by reading with the aid of a small reticled telescope, L, the image of a graduated scale E which is reflected in the mirror M. By combining the enlargement of the telescope with the distance of the scale from the mirror, we succeed in giving to the apparatus a length of less than 20 cm. by 12, which renders it quite portable. It is important to remark that the amplification of the movements of the box, which, in ordinary barometers, is obtained by means of several levers, is obtained here by an optical process; it follows that the numerous frictions and the time lost in contacts are mostly eliminated. There remains only a single movement, that of the axis which bears the mirror; in the barometer figured the pivots are of steel and the cap of platinum, and in order to avoid rust, the whole is nickel-plated.

M. Teisserenc de Bort proposes to construct others, in which the axis will be mounted on rubies. This garniture will not sensibly increase the price of the apparatus. This instrument is too new to allow us to appreciate the full degree of precision which it can attain. In a trial in a captive balloon by Capt. Perrier of several aneroids as compared with the mirror, the latter showed a great sensibility, and it quickly resumed its original position on landing.

BUTTERFLIES WITH DISSIMILAR SEXES

NATURALISTS have long been familiar with the fact that the two sexes of certain species of lepidoptera often differed from each other in colour and marking, and sometimes in form and size to a very considerable extent. For this phenomenon the convenient term "Antigeny" has been proposed by Mr. S. H. Scudder.[1] In accordance with Darwin's theory of sexual selection we find that when the sexes of a butterfly differ to any marked extent in colour, it is generally the male which is the more gaudily coloured, although there are certain genera in which the reverse obtains; but, as I pointed out in NATURE (vol. iii. p. 508), there is reason to believe that in these exceptional cases the males may be the selecting sex. Mr. Charles Darwin having recently called my attention to a paper on this subject in *Kosmos*,[1] by that most philosophical entomologist, Fritz Müller, I have thought that an abstract might interest readers of NATURE.

The species of which the author treats, *Epicalia acontius*, has such very dissimilar sexes that Fabricius described them as distinct species, calling the male *Antiochus* and the female *Medea*, while in Doubleday and Westwood's "Genera of Diurnal Lepidoptera" the two sexes are placed in different genera, the male in *Epicalia* and the female in *Myscelia*. It is not known with certainty who first pointed out that *Antiochus* and *Medea* were the sexes of the same species; but this fact is now

[1] *Proc.* Amer. Acad., xii. 150.

[1] "Epicalia acontius. Ein ungleiches Ehepaar," *Kosmos*, January, 1879, p. 285.

established beyond doubt. Were this not the case *Antiochus* would be without a female and *Medea* without a male. Indeed Fritz Müller has reared from larvæ both sexes of an allied species, *Epicalia numilia*, which differ from one another to the same extent as do the sexes of *E. acontius*. In both sexes of this latter species the general ground colour of the wings is black, the male having a broad oblique bar of a bright orange colour extending from about the middle of the inner margin to about the middle of the fore-wing in the direction of the apex. There is a corresponding blotch near the middle of the hind-wing, so that when the wings are extended the bar on the fore-wing is continuous with the blotch on the hind-wing, the whole forming one oblique orange bar. The female (*Medea*) has two oblique rows of pale yellow spots across the fore-wings running nearly parallel with the costal margin, and two similar rows across the hind-wings; when the insect rests with outstretched wings, the fore- and hind-wings overlap so that the spots of all four wings form three straight parallel rows which are continued on the body by spots of the same colour. The sexes of *E. numilia* differ in a similar manner.

Further, in the female of *E. acontius* (as in both sexes of *E. numilia*), the inner margin of the fore-wing is nearly straight, while it is markedly curved in the male. Both wings in this latter sex are also much broader in proportion to their length than is the case with the female, and in consequence of this, the wings of *Antiochus* overlap each other to such an extent that nearly half the hind-wing is hidden beneath the fore-wing, the space thus concealed being fully twicc as broad as in *Medea*. The curvature of the inner margin of the fore-wing of a butterfly when exaggerated on the over-lapping portions of the two wings, is, according to the author, a never-failing indication of the presence of a scent-secreting organ at this spot. Thus, having read in Doubleday and Westwood's "Genera" that in the fore-wing of *Ageronia* "the inner margin in the male is occasionally dilated," Fritz Müller caught a male specimen of *A. arethusa*, and found a strong odour to be emitted by a scent organ concealed between the wings. Now in *Antiochus* a similar organ exists, while it is absent in the male of *E. numilia*, and in this latter the fore and hind wings overlap only to the same extent as in the female.

When in lepidoptera the sexes of a species differ from one another to any great extent in colour and marking, the female is generally inconspicuous or is coloured gaudily in imitation of some other species (mimicry). Thus in *Thecla hemon* the male is bright blue, while the female is dull brown, while in *Dyschema amphissa* the male is white, and the female is one of the numerous mimickers of *Acræa thalia*. This explanation, however, does not apply to the female of *E. acontius*, since there is no species marked in a similar manner which might serve as a model for mimicry. On the other hand, the *Medea* type of marking is to be found in a large number of species of the same and of allied genera (the female of *Myscelia orsis*, for example). Neither can the coloration of Medea be considered protective, since it is very conspicuous, and the insect has a habit of sitting with wings fully expanded.

According to Darwin's theory of sexual selection,[1] the ancestor of the present genus *Epicalia* was probably of the *Medea* type—the present form of the male having resulted from selection by the female. The author then asks whether *Medea* has preserved the form of marking common to both sexes of the progenitor, and whether this marking has any present significance; also: "Is the colour ornamental, or for offensive or defensive purposes, or both?—for the one does not exclude the other." In reply to the latter part of this question, dissent is expressed from Prof. Gustav Jaeger's view, that yellow is as a rule an offensive or defensive colour. It is next pointed out that in the female of *E. numilia*, the row of spots is replaced by a broad oblique yellow bar, this alteration of pattern being attributed to sexual selection by the males, which must have thus preserved but at the same time slightly modified, the taste of the common ancestor of the genera *Epicalia* and *Myscelia*, the females of a few species of which have been made to depart to a much greater extent from their congeners by a greater divergence of taste on the part of their mates. The females of most of the species of these genera had, however, "set the fashion" in a completely new direction, and thus brought about the dissimilarity of the males.

[1] "Descent of Man." i. 388.

In support of this view the author remarks, that although sexual selection is generally regarded as being exerted by the females, yet, as Haeckel has maintained,[1] the selection by the males must have an equal influence on the opposite sex. That such a choice is exerted by butterflies the author has already pointed out.[2] In the present case we must believe that the two sexes manifested completely different tastes,[3] just in the same manner as much that we consider physically or intellectually superior in woman would be considered unfitting for men.

The acquisition and modification of the *Medea* type of marking may have occurred at a time when both sexes of the ancestral form were alike. Such peculiar marking could not have been produced by the direct action of external conditions nor by any innate "laws of growth," neither can it be considered as a protective colouring produced by natural selection. Sexual selection is thus the only explanation left open.

It has been shown by Weismann that the colour and marking of butterflies' wings are undoubtedly affected by external conditions, and in the case of larvæ markings, which, through such conditions, make their appearance on one segment, not unfrequently extend to other segments (by correlation of growth?). The same appears to hold good for the wings of butterflies: markings which through any cause appear in any one wing cell tend to be repeated on corresponding places in the other wing-cells. When such markings serve as signs of distastefulness or for other protective purposes, they would be preserved, and even increased in brilliancy and size by the action of natural selection. Thus a striped butterfly might be produced from a simple grey or brown one, and the markings regularly repeated on the corresponding places of the wing-cells would not fail to give us a pleasing impression, although no selection with special regard to beauty had taken place. In such cases, however, it is obviously immaterial whether the markings of the fore- and hind-wings harmonise or not. When, however, we have an unbroken bar across both fore- and hind-wings so arranged that the pattern is only complete when the insect sits with outstretched wings, or is in an attitude of flight, while in every other position the bar is broken, it may be safely assumed that the ever-vigilant eye of selection had brought about this result.

The markings of *Medea* are then considered from this point of view. The two rows of yellow spots on each wing, as already described, form three straight rows when the wings are spread out as in flight; in any other position—if, for instance, the fore-wings are pushed too forward or too far backwards—the symmetry is broken. Special attention is called to the fact that the hindmost rows of spots on the hind-wings have been distorted so as to form a straight bar parallel with the other rows; this results from the displacement of the spots, each of which, although situated in one wing-cell, does not appear on the *corresponding place* in each cell; were this the case, the row would be curved instead of straight. That it was the sense of beauty of a critical eye which straight-

[1] "Generelle Morphologie," 1866, ii. 244. [2] *Kosmos*, ii. 42

[3] The term "reciprocal sexual selection" might be advantageously applied to such classes of cases.—R. M.

ened the original curved row of spots to a straight bar, is most strikingly shown by the two foremost spots of the row which are unsymmetrical with regard to the corresponding row on the front wings, and which really form the commencement of a curved bar, *but these are hidden by the overlapping of the front wings.*

Thus it was perhaps the selection of males by the females that first perfected the *Medea* type among the progenitors of the genus. Later on the males of some of the species may have been completely modified (as with *E. acontius*), while the females retained their peculiar pattern (by reciprocal selection or by sexually limited inheritance?) down to the present time.

In conclusion, attention is directed to the scent-secreting organ of *Epicalia acontius* as compared with that of another butterfly belonging to a quite different group, viz., *Antirrhæa archæa*, the organ being almost identical in these two widely-separated species, and thus affording a striking instance of what is well known to evolutionists as "analogy," in contradistinction to "homology."

R. MELDOLA

SUN-SPOTS AND COMMERCIAL CRISES

I HAVE been repeatedly told by men who have good opportunity of hearing current opinions, that they who theorise about the relations of sun-spots, rainfall, famines, and commercial crises are supposed to be jesting, or at the best romancing. I am, of course, responsible only for a small part of what has been put forth on this subject, but so far as I am concerned in the matter, I beg leave to affirm that I never was more in earnest, and that after some further careful inquiry, I am perfectly convinced that these decennial crises do depend upon meteorological variations of like period, which again depend, in all probability, upon cosmical variations of which we have evidence in the frequency of sun-spots, auroras, and magnetic perturbations. I believe that I have, in fact, found the missing link required to complete the first outline of the evidence.

About ten years ago it was carefully explained by Mr. J. C. Ollerenshaw, in a communication to the Manchester Statistical Society (*Transactions*, 1869-70, p. 109), that the secret of good trade in Lancashire is the low price of rice and other grain in India.[1] Here again some may jest at the folly of those who theorise about such incongruous things as the cotton-mills of Manchester and the paddy-fields of Hindostan. But to those who look a little below the surface the connection is obvious. Cheapness of food leaves the poor Hindoo ryot a small margin of earnings, which he can spend on new clothes; and a small margin multiplied by the vast population of British India, not to mention China, produces a marked change in the demand for Lancashire goods. Now, it has been lately argued by Dr. Hunter, the Government statist of India, that the famines of India do recur at intervals of about ten or eleven years. The idea of the periodicity of Indian famines is far from being a new one; it is discussed in various previous publications, as, for instance, "The Companion to the British Almanack for 1857," p. 76. The principal scarcities in the North-Western and Upper Provinces of Bengal are there assigned to the years 1782-3, 1792-3, 1802-3, 1812-13, 1819-20, 1826, 1832-3. Here we notice precise periodicity up to 1812-13, which, after being broken for a time, seems to recur in 1832-3.

Partly through the kind assistance of Mr. Garnett, the Superintendent of the British Museum Reading Room, I have now succeeded in finding the data so much wanted to confirm these views—namely, a long series of prices of grain in Bengal (Delhi). These data are found in a publication so accessible as the *Journal* of the London Statistical Society for 1843, vol. 6, pp. 246-8, where is printed a very brief but important paper by the Rev. Robert Everest, chaplain to the East India Company, "On the Famines that have devastated India, and on the Probability of their being Periodical."

[1] This view is confirmed by the opinion of Mr. E. Helm, as given in the *Transactions* of the same society for 1868–9, p. 76.

Efforts have, I believe, been made by Dr. Hunter, Mr. J. H. Twigg, and probably others, to obtain facts of this kind, which would confirm or controvert prevailing theories; but this little paper, which seems to contain almost the only available table of prices, has hitherto escaped the notice of all inquirers, except, indeed, Mr. Cornelius Walford. The last number of the *Journal* of the London Statistical Society contains the second portion of Mr. Walford's marvellously complete account of "The Famines of the World, Past and Present," a kind of digest of the facts and literature of the subject. At pp. 260-1 we find Everest's paper duly noticed. In this latter paper we have a list of prices of wheat at Delhi for seventy-three years, ending with 1835, stated in terms of the numbers of seers of wheat—a seer is equal to about 2lb. avoirdupois—to be purchased with one rupee. As this mode of quotation is confusing, I have calculated the prices in rupees per 1,000 seers of wheat, and have thus obtained the following remarkable table:—

Price of Wheat at Delhi

1763	50 M.C.	1800	22
1764	35	1801	23
1765	27	1802	25
1766	24	1803	65 M.
1767	23	1804	48 C.
1768	21	1805	33
1769	24	1806	31
1770	28	1807	28
1771	33	1808	36
1772	38 C.	1809	40
1773	100 M.C.	1810	25 C.
1774	53	1811	28
1775	40	1812	44
1776	25	1813	43
1777	17	1814	30
1778	25	1815	23 C
1779	33	1816	28
1780	45	1817	41
1781	55	1818	39
1782	91	1819	42
1783	167 M.C.	1820	46
1784	40	1821	38
1785	25	1822	35
1786	23	1823	33
1787	22	1824	39
1788	23	1825	39 C.
1789	24	1826	48 M.C
1790	26	1827	30
1791	33	1828	22
1792	81 M.	1829	21
1793	54 C.	1830	21
1794	32	1831	26
1795	14	1832	22
1796	14	1833	33
1797	15	1834	40 M.
1798	8	1835	25
1799	17	1836	— C.

The letter M indicates the maxima attained by the price, and we see that up to 1803, at least, the maxima occur with great regularity at intervals of ten years. Referring to Mr. Macleod's "Dictionary of Political Economy," pp. 627-8, we learn that commercial crises occurred in the years 1763, 1772-3, 1783, and 1793, in almost perfect coincidence with scarcity at Delhi. M. Clément Juglar, in his work, "Des Crises commerciales, et de leur Retour périodique," also assigns one to the year 1804. After this date the variation of prices becomes for a time much less marked and regular, and there also occurs a serious crisis about the year 1810, which appears to be exceptional; but in 1825 and 1836 the decennial periodicity again manifests itself, both in the prices of wheat at Delhi and in the state of English trade. The years of crisis are marked with the letter C.

When the above numbers are plotted out in the form of a curve, the earlier part of the series presents the appearance of a saw, with four or five high, sharp-pointed teeth at almost exactly equal distances of ten years. The first maximum, that of 1763, is perhaps imperfectly represented, and were the table extended backwards, the true maximum might fall in 1762. It is remarkable that after about the year 1807 the character of the curve suddenly and entirely changes, the oscillations becoming comparatively small, irregular, and rounded, although the periodicity, as already remarked, seems to recur in a less intense degree after 1823. This change in the curve may be due to some local causes, such as the opening of new roads and markets, and it is obviously important that we should learn whether this is the case, or whether some important meteorological variation is here manifested. This is not the only instance in which a well-marked decennial oscillation appears to be for a time suddenly arrested or thrown into confusion.

One difficulty which presents itself in connection with the above table is that the commercial crises in England occur *simultaneously* with the high prices in Delhi, or even in anticipation of the latter; now the effect cannot precede its cause, and in commercial matters we should expect an interval of a year or two to elapse before bad seasons in India make their effects felt here. The fact, however, is that the famines in Bengal appear to follow similar events in Madras. Thus it is well known that the great famine occurred in the year 1770, or even began in 1769, though it seems not to have made its mark at Delhi until 1773. This quite explains the fact that the English crisis was in 1772-3. Mr. F. C. Danvers, of the India Office (*Journal of Science*, N.S., vol. viii. p. 436), assigns famines in the Madras Presidency to the years 1781-3 and 1790-2. In fact Mr. Danvers explicitly points out this tendency of famines to travel northward, saying (p. 441): "It is a point worthy of remark that severe droughts in Northern India have, on several occasions, followed closely upon distress similarly caused in the Peninsula of India; thus the Madras famine of 1781 to 1783 was followed by one which affected Bengal, the north-western provinces, and the Punjab in 1783-4; the failure of rains which resulted in scarcity in many of the provinces of the Madras Presidency in 1824-5, was followed by a similar calamity in the North-western Provinces in the succeeding years. The "Guntoor" famine of 1833 preceded only by a few years one which affected the north-western and lower provinces of Bengal in 1837-8, and the Madras famine of 1866 was very closely followed by one in the North-western Provinces and the Punjab in 1868 to 1870." We see, then, that in looking for periodicity, we must confine each comparison to events of the same locality. It must also be allowed that the *commencement* of famine in India precedes by about two years the occurrence of commercial collapse in England.

It ought to be added that Everest refers to a journal published at Calcutta, called *Gleanings of Science*, which contains (vol. i. p. 368) a table of the prices of various kinds of grain at Chinsurah in Bengal, from 1700 to 1813. The volume is to be found in the British Museum; but on referring to it and plotting out the curve for the price of rice, it was very disappointing to find the series broken by gaps of several years every here and there, which renders it impossible to draw any safe inference, affirmative or negative. The table is said to have been drawn up by G. Herklots, the fiscal of Chinsurah, from authentic documents. Now, if such documents existed half a century ago, it is indispensable that minute inquiry should be made for any local records of the kind which may still exist.

Returning to the prices at Delhi, and taking the above table in connection with a mass of considerations of which I have given a mere outline at the last meeting of the British Association (see *Journal* of the Statistical and Social Inquiry Society of Ireland, August, 1878, pp 334-42; NATURE, vol. xix. pp. 33-37). I hold it to be established with a high degree of probability that the recurrence of manias and crises among the principal trading nations depends upon commerce with the east. This conclusion is confirmed by the fact that these fluctuations are but slightly felt by the non-trading nations, and that what these nations do feel is easily accounted for as an indirect effect.

It has been objected by the *Economist* that this explanation cannot be applied to the earlier crises in the years 1711,1721, and 1732, because trade with India was then of insignificant dimensions. But the reading of many old books and tracts of the seventeenth and eighteenth centuries has convinced me that trade with India was always looked upon as of the highest importance. A large part of the political literature of the time was devoted to the subject, and under the Mercantile Theory the financial system of the country was framed mainly with an eye to Indian trade. The published returns of exports and imports probably give us little idea of the real amount of trade, as smuggling was very common in those days, and much of the Indian trade went on secretly in private ships or indirectly through Holland.

Dr. George Birdwood has lately been studying the records of the India Office, and he gives as the result of his extensive reading "that the history of modern Europe, and emphatically of England, has been the quest of the aromatic gum-resins, and balsams and condiments, and spices of India and the Indian Archipelago" (*Journal* of the Society of Arts, February 7, 1879, vol. xxvii. p. 192). This closely corresponds with the view which I have been gradually led to adopt of the cause of decennial crises.

While India is, no doubt, together with China, the principal source of disturbance, there is no reason to suppose that it is the only source. A nearly exhaustive analysis which I have made of the trade of England with various parts of the world during the last century, as given in Whitworth's valuable tables, fails to disclose any clear periodicity as regards European trade. The investigation of various long series of prices of agricultural produce in Europe also leads me to believe that the decennial periodicity, if felt in Europe at all, is over-borne by disturbing causes, or involved in too great complication to admit of discovery. On the other hand, I have fallen upon the very interesting and significant fact that the export trade from Maryland and Virginia exhibits what seems to me an unquestionable periodicity, with maxima in the years 1701, 1711-13, 1720, 1742, 1753, 1764, and 1774. The same tendency is not apparent in the trade of New England. Thus it is likely that crises may have an independent meteorological origin in the semi-tropical States of the Union; and, if so, it is probable that there are other tropical parts of the world where the meteorological conditions allow the cycle to manifest itself. This subject, so far as it has yet been studied, is full of important and mysterious facts, which stimulate the interest of the inquirer in a high degree. At the same time it is plain that sound conclusions can be reached only by most extensive analyses and comparisons of large series of facts. The search for the facts, too, among the records of the last two centuries, the suitable part of which has in too many cases probably perished, is so tedious and disappointing that it taxes the patience of the inquirer very severely. It is no jest at all.

But whatever be the area of the tropical and semi-tropical regions from which the decennial impulse comes, mainly India and China, no doubt, it does not follow that the extent of the commercial mania or crisis here is bounded by the variation of the foreign trade. The impulse from abroad is like the match which fires the inflammable spirits of the speculative classes. The history of many bubbles shows that there is no proportion be-

tween the stimulating cause and the height of folly to which the inflation of credit and prices may be carried. A mania is, in short, a kind of explosion of commercial folly followed by the natural collapse. The difficulty is to explain why this collapse so often comes at intervals of ten or eleven years, and I feel sure the explanation will be found in the cessation of demand from India and China occasioned by the failure of harvests there, ultimately due to changes of solar activity. Certainly the events of the last few years, as too well known to many sufferers, entirely coincide with this view, which is, nevertheless, made the subject of inconsiderate ridicule.

Hampstead, April 23 W. STANLEY JEVONS

JAMES NICOL, F.R.S.E., F.G.S.

ANOTHER of the links connecting us with the early days of geology has been severed by the death of the Professor of Natural History in the University of Aberdeen. For some years past Prof. Nicol's failing health prevented him from undertaking more work than his college duties required, so that he had somewhat fallen behind the crowd of younger aspirants to scientific reputation. It is a pleasant duty to recall his early services to geology. As far back as the year 1843 we find him contributing to the series of prize essays of the Highland Society a memoir on the geology of his native county, Peebleshire. Devoting himself with energy to the prosecution of his favourite pursuits, he prepared a useful little Guide to the Geology of Scotland, illustrated with maps and sections, and giving, from his own observations and the researches of previous writers, a compendious account of Scottish geognosy, so far as then known. Many years afterwards he published another compilation of Scottish geology in the form of a Geological Map of that country. He specially took up the mineralogical and petrographical department of geology, and showed his capacity for these subjects by publishing a text-book of mineralogy, which has kept its place as a work of reference. Appointed Assistant Secretary of the Geological Society, he in that capacity edited the Society's Journal, and had an opportunity of coming personally in contact with the foremost geologists of his time. Among those whose friendship he formed, one of the kindest and most serviceable was Murchison. Through the assistance of that active and powerful friend Nicol was appointed to the Chair of Geology at Cork, and a few years afterwards to the more lucrative post at Aberdeen, which he resigned only last year. During these years of official work he found time for a number of original papers chiefly on the geology of different parts of Scotland. Thus he returned once more to the study of the rocks of his own Tweed Valley to which he had been the first definitely to apply the term silurian. In company with his friend and benefactor Murchison, he extended these observations into Ayrshire and the west of Scotland. With the same companion he visited the north-west of Scotland, and after a long journey through these regions produced an independent memoir, in which he suggested that much of the metamorphic rocks of the north-west Highlands consisted of altered Carboniferous formations. When the fossils found in the Assynt limestones proved to be unquestionably Lower Silurian he was of course compelled to retract his published suggestion. He then adopted a completely opposite view and endeavoured to prove that the rocks which he had thought might be altered Carboniferous were really the most ancient or fundamental masses of the west coast brought up everywhere to the surface again by a vast dislocation and inversion. In this view, no less than in that for which it was substituted, he was opposed by Murchison, who proved by many sections that the rocks in question really lay upon the fossiliferous limestones and could not therefore be older than the Lower Silurian period. From the time of this dispute the late professor devoted himself chiefly to his duties at Mareschal College, where his capacity for business made him a most useful colleague. From summer to summer, however, he could resume the hammer and renew his acquaintance with old haunts or make himself familiar with new ones. In these excursions he was sometimes accompanied by an old geological friend to whom he could communicate the views he no longer cared to publish. With a kindly nature he united a certain timidity which made him shrink from publicity and led to his being less widely known than his personal qualities deserved that he should be.

NOTES

THE International Meteorological Congress was opened at Rome on Tuesday last week, nearly all the Countries of Europe being represented, as well as the United States. Prof. H. P. S. Smith and Mr. Scott represented this country. Prof. Cantoni was elected president, M. Wild, of St. Petersburg, vice-president, Dr. Hoffmeyer, of Copenhagen, and Mr. Scott, secretaries. The introductory address was given by M. Depretis, who spoke of the great influence exercised by the physical sciences on the progress of the other sciences, and consequently on the moral and economical development of nations. He referred to the important place of meteorology among the physical sciences, and concluded by welcoming the strangers to Italy. Dr. Buys Ballot was unable to be present, but Prof. Mascart read an address sent by him, full of scientific data and statistics, passing in review all the discoveries recently made in America and Europe in meteorological science. The report on the work of the permanent committee was read by the secretary of the committee, Mr. Scott. The congress then divided into sections for work.

THE annual meeting of the French Sociétés Savantes commenced on April 16 at the Sorbonne. The general sessions of the Section of Sciences were held under the presidency of M. Milne Edwards, on April 16, 17, and 18. MM. Faye and Wurtz were vice-presidents, and M. Blanchard the secretary. M. Faye delivered a lecture on the 18th in the large hall, on the Great Movements of the Atmosphere. General Nansouty, the Director of the Pic du Midi Obsevatory, gave an address, in which he complained of the interruptions in the telegraphic communications with Toulouse, caused by the snows during winter, and insisted upon the necessity of placing the wire under ground. M. Ferry, the Minister of Public Instruction, who is president, said that he should take the measures which were asked for by the gallant observer, whose devotion to science was so widely admired in France and abroad. M. Alluard, Director of Pry de Dôme Observatory, presented a series of maps tabulating the readings taken at Clermont Ferrand and on the top of the mountain. An intermediate station has been established. The final meeting of the Congress took place in the large hall of the Sorbonne, under the presidency of M. Ferry, who was assisted by a large number of officials. Five reports were read on the works of the Sociétés Savantes. The Minister, as usual, delivered a speech stating the projects of his administration. The number of learned societies in France is now 360. He stated that the Government spent 11,000,000 frs. in 1870 for the Faculties; the sum was now 30,000,000 frs. The list of rewards granted was then read over. The four gold medalists in science are M. Combercure, of Montpellier, for mathematical disquisitions, M. Dieulafait, of Marseilles, for geology, M. Coquillon, for determining the quantity of inflammable gas contained in the air of coal-mines, and M. Schrader, for explorations in the Pyrenees.

THE French Physical Society held its annual meeting the other day at the Hotel of the Societé d'Encouragement, rue Bonaparte. The *façade* of the hotel was illuminated by a series of twenty-four lamps of the Reynier system fed by three large gramme machines, each of them consuming from three to four horse-power. The effect was regular for several hours, but the illuminating power was very low as compared with ordinary regulators. Among the apparatus exhibited we noticed a rotation machine exhibited by M. Antoine Breguet, to demonstrate that the Gramme machine may be considered as a form of the Barlow rotating wheel. M. Nodot, *preparateur* of the Dijon Faculty of Sciences, exhibited a Barlow apparatus, in which the rotating part is formed by a series of copper wires radially implanted in the centre. M. Deprez exhibited a new motor worked by six Bunsen elements, and which gives about five kilogrammetres per second. This apparatus is analogous to a Wilde electro-magnetic machine. All the principal opticians of Paris, Breguet, Ducretet, Carpentier (formerly Ruhmkorff), Dubosc, Dumontin, Froment, Deleuil, Sauter and Lemonnier, sent in an improved or enlarged form the instruments which have attracted the attention of physicists in recent years. The Faber speaking-machine, which has been attacked by one of the French scientific papers as being worked by a ventriloquist, was exhibited and explained by M. Garrel. The display was considered as one of the most successful that has been offered to the public since the Society was established. The large halls of the hotel were crowded up to a late hour.

SINCE the commencement of the present year, the well-known weekly German botanical journal, the *Botanische Zeitung*, has passed into the sole editorship of Prof. De Bary, of Strassburg.

THOSE interested in British botany will be glad to hear that the threatened extinction of the Botanical Exchange Club, to which we recently alluded, has been averted. Mr. Charles Bailey, of Manchester, has offered to undertake the main responsibility of the curatorship, although the scope of the Club will in future be somewhat restricted. There is a proposal for issuing, in connection with the Exchange Club, a small number of copies of a reference herbarium of British plants, the difficult and critical species being especially kept in view, on the plan of Reichenbach's "Flora Germanica Exsicata."

THE *Times* Paris correspondent telegraphs that at the sitting of the Academy of Sciences on Monday, it was announced that Lavoisier's chemical apparatus, still preserved by his heirs, but hitherto left unnoticed, had been minutely inspected by Prof. Truchot, of Claremont Ferrand. It is in excellent preservation, and the accompanying documents show that Lavoisier was the author of the work on sea-water distillation published anonymously in England.

AN exhibition of an interesting kind is to be held in Dresden in the summer of this year. This is a general exhibition of objects of art, science, and industry, connected with the education and training of youth. The following are the various classes into which the exhibition will be divided:—1. Teaching material for schools, home, Kindergärten, &c. 2. Printed works, as schoolbooks, children's books, illustrations. 3. Gymnastic and similar apparatus. 4. Musical instruments. 5. Toys. 6. Articles required for children in all departments of industry, as furniture, linen, clothes, orthopædic instruments, &c. A systematic exhibition of the development of various school materials will be connected with the above, and historical objects connected with training and education are therefore desired. A similar exhibition on a small scale in 1877 had a great success. The Committee of the Exhibition consists of one merchant and three teachers. Inquiries should be addressed to Herr Kaufmann C. Heinze, Dresden. The Exhibition will be open from July 1 to August 31.

SECONDARY Technical Education forms the subject of the address delivered before the American Institute of Mining Engineers by their president, Mr. Eckley B. Coxe, at their Baltimore meeting. Great stress is laid on the necessity of educating workmen, and the maxim, a little learning is a dangerous thing, is combated by the statement that false learning mingling with the truth causes the danger. If the truth of the maxim were admitted we fail to see that it provides a very strong argument against education. A little dynamite is a dangerous thing, but it is of great use in mining work. The author states that they have already five good schools at their works, and proposed to establish another to carry on the education of those boys who have left them to enter the works. While admitting that an average boy cannot work all day and study all the evening, and foreseeing the possibility of making Jack a dull boy, the programme of studies is sketched out "as far as we have been able to arrange it." It comprehends instruction in algebra, geometry, trigonometry, free-hand and mechanical drawing, with descriptive geometry, physics, chemistry, mineralogy, and geology, mechanics and the construction of machines, framing, mining, and mine surveying, English composition, book-keeping, and, last of all, writing. Our astonishment is that not only is arithmetic omitted but lunar and planetary theory have no place assigned to them.

The *Madras Times* writes:—The necessity of a scientific training for coffee planters is now being recognised. Men of intelligence, industry, and steady habits can alone hope to succeed as coffee planters. We would urge upon estate owners the expediency of insisting upon their superintendents and assistants possessing a knowledge of chemistry, sufficient at least for the purposes of coffee planting. They should be able to make analyses of the coffee tree, soil, manures, &c. Planters should also be able to take correct observations of the weather, gauge the rainfall, take notes of the nature and progress of the various diseases the coffee tree is subject to, and so forth. The paper of questions submitted by Mr. Harman to the various coffee planters in Coorg will put their capabilities to the test, and though we are aware that there are many educated and intelligent planters in that province, we fancy some of them will find it no easy task to answer the last of Mr. Harman's questions: Can you give analyses of your rock soil and sub-soil?

ON January 15, 1880, an International Exhibition of products of agriculture, industry, science, and fine arts will be opened at Mexico. The Exhibition will remain open for three months.

THE Anthropological Exhibition at Moscow was opened on the 16th inst. The International Anthropological Congress, connected with this exhibition, will however not meet until August 7 next.

SLIGHT shocks of earthquake were noticed at Montmarault and Chantelle, in the French Department of the Allier, on March 27th. A slight shock of earthquake, lasting about fifteen seconds, and travelling from east to west, was felt at Darjiling at 8.15 on the morning of the 11th ult.

THE death is announced of Mr. William Mudd, the curator of the Botanical Gardens, Cambridge, after a brief illness. The stipend attached to the office is about 100*l*. a year; it is in the gift of the Botanical Garden Syndicate.

MARK W. HARRINGTON, M.A., F.L.S., lately Professor of Astronomy at the Imperial University of Peking, and formerly assistant Professor of Botany at the University of Michigan, has just been appointed Professor of Astronomy and Director of the Observatory at the last-named institution, the chair rendered vacant by the resignation of Dr. James C. Watson, now Professor of Astronomy at the Wisconsin University.

A COURSE of three lectures will be delivered in the Galleries of Natural History and Antiquities, British Museum, on the 24th, 28th, and 30th inst., by Dr. Carter Blake, of Westminster Hospital. Some of the keepers of departments will also give *vivâ voce* explanations of the specimens under their care.

MR. ARTEMAS MARTIN, a well-known American mathematician, has lately commenced the publication of a serial work, entitled *The Mathematical Visitor*, appearing occasionally at intervals of several months. It is published by him at Erie, Pennsylvania, and shows a creditable spirit of enterprise in entering a field which is not generally considered remunerative.

WE have received the first number of the *American Chemical Journal*, which promises to take a high place in scientific literature. Its first object is to collect the good original papers written by American chemists, and to make them the basis of a purely chemical journal, while papers from other journals, and notes in all departments of chemistry will find a place. It is expected that six numbers will appear yearly. The principal articles in the first number are "On the Complex Inorganic Acids," by Dr. W. Gibbs, "On Nitrogen Iodide," by Mr. J. W. Mallet, a paper on Lockyer's hypothesis that the so-called elements are compound bodies, by Mr. C. S. Hastings, of Johns Hopkins University, and "On the Oxidation of Substitution Products of Aromatic Hydrocarbons," by Messrs. Remsen and Iles. There are, besides, several reviews and a number of notes.

THE scientific journals of Pennsylvania express much regret at the possibility of the failure of the Legislature of that State to make appropriations for the continuance of the work of the Geological Survey. This work has been carried on for several years past under Prof. Lesley with great success, and it is so near completion that its cessation now might be considered almost a national calamity.

THE War Department is on the point of at length adopting war balloons into the land and sea services. Movable apparatus for inflating and manipulating military balloons in the field has just been completed in the Royal Arsenal, Woolwich, and been tried with two new balloons, specially constructed for military purposes. The appliances consist of a portable tank, weighing 400 lb., containing iron shavings, together with a portable boiler and furnace. These appliances can be moved about with troops on the field or on vessels at sea. Hydrogen is generated by passing steam through the iron turnings. As soon as the necessary arrangements can be made it is in contemplation to send a few war balloons out to Zululand.

THE boring of an artesian well for the purpose of investigating the nature of the chalk layers through which the submarine tunnel between England and France is to pass was resumed on the French coast at Sandgatte on March 1 last. The depth of the well, which at the end of last year was at 34·35 metres, was extended to 38·50 m.—that is, to a depth corresponding to 8·67 m. below the low-water level. At this depth the flow into the well amounted to 1,300 litres per minute, and the exhaust machines became insufficient. They are to be replaced by more powerful ones.

WE are glad to see that Messrs. Kegan Paul and Co. have published in a handy form a complete translation of Prof. Haeckel's "Freedom in Science and Teaching," first reproduced in this country in our own columns. There is an interesting prefatory note by Prof. Huxley.

A NEW monthly electrical paper has been started in Paris, the *Lumière electrique*, intended as a general organ of electricity.

WE have received from Messrs. Cole and Sons, of Notting Hill, several specimens of pathological, physiological, and educational preparations for the microscope, which for cutting and mounting surpass anything we have seen. They are really beautiful preparations, and deserve to be widely used.

THE Report of the Marlborough College Natural History Society for the past year is an unusually satisfactory one. Several modifications in the rules have been attended with good results, and the Society seems in a fair way to become a real working one. The papers by the boys and others are highly creditable; perhaps the most generally interesting is that by Mr. Rodwell, on Iceland. The Report of the Winchester and Hampshire Scientific and Literary Society is not quite so satisfactory as could be wished; the *dilettante* and absolutely idle elements seem large, and the Report complains of the indifference to the less popular subjects. We trust that the next Report will be more satisfactory.

Apropos of electric perforation of glass, Prof Waltenhofen, of Prague, has recently described the following experiments:—A thin glass plate, having on it a small drop of stearine, is introduced into the spark-path of an electric machine. It is perforated at the part where the drop is, and more easily so when the drop-side is turned to the positive electrode. A glass plate, hung bifilarly between the electrodes of a Holtz machine, is driven by the discharge towards the negative electrode, and more strongly, if the side turned towards the positive electrode be partly covered with stearine. Prof. Waltenhofen considers that the rapidly-moving air-molecules in the spark-path are ruled by a component of velocity directed from the positive to the negative electrode.

THE following subjects in natural science have been proposed by the Society of Arts and Sciences of Utrecht, for prize competition:—1. Researches on the development of one or several species of invertebrates whose history is not yet known. 2. Researches on the influence of small variations in exterior circumstances on the evolution of the embryo of one or several species of vertebrates. 3. Exact anatomical description of the larva and nymph of the common cockchafer (*Melolontha vulgaris*). 4. By what means may the water of rivers which traverse Holland be purified so as to become potable, without any injury to health? What would be the expense of applying them on a large scale? 5. A memoir on the results of experiments made in recent times on the motion of liquids and the resistance they offer to moving bodies; with an exposition (*a*) of the general or special laws which may be deduced; (*b*) of the principal points on which some data are still wanting, and the nature of the experiments necessary to obtain them. 6. Critical and experimental study of the functions of the semicircular canals of the ear. 7. Critical and historical study of the theories of electric phenomena observed in muscles and nerves. 8. Critical *aperçu* of the methods employed to determine the place which substituted atoms and groups of atoms occupy in bodies of the aromatic series, according to the theory of the constitution of benzol given by Kekulé and Ladenburg. 9. Determine rigorously the quantities of heat liberated or absorbed in the allotropic change of two or several simple substances. Each prize consists of an honorary diploma and about 25*l*. Papers must be sent in to the Secretary before December 1, 1879.

THE additions to the Zoological Society's Gardens during the past week include three Red Brockets (*Cervus rufus*) from Brazil, presented by Mr. W. H. Lacy; a Blue-faced Green Amazon (*Chrysotis bouqueti*) from St. Lucia, West Indies, a Yellow-fronted Amazon (*Chrysotis ochrocephala*) from Guiana, presented by Mr. Neville Holland; a Black-faced Kangaroo (*Macropus melanops*) from South Australia, three White-eared Conures (*Conuras leucotis*) from Brazil, an Upland Goose (*Bernicla magellanica*) from the Falkland Islands, deposited; a Reeve's Muntjac (*Cervulus reevesi*) born in the Gardens.

ON THE DEVELOPMENT OF THE SKULL AND ITS NERVES IN THE GREEN TURTLE (CHELONE MIDAS), WITH REMARKS ON THE SEGMENTATION SEEN IN THE SKULL OF VARIOUS TYPES[1]

FOR these embryos the author is indebted to Sir Wyville Thomson and Mr. H. N. Moseley, the latter having sent him the smaller specimens, and the former the ripe and nearly ripe young. There are in all five stages.

1st Stage, ½-in. long.—The embryo is already fairly formed, for there are rudiments of all the principal organs. About fifty-two somatomes may be counted behind the head, and there are evidently seven clefts—four post-oral, two pre-oral, and one oral. The body of the embryo is tolerably distinct from the yolk-sac, the mesocephalic flexure is well marked, and the tail is coiled upon itself.

The regions of the body, viz., cervical, dorsal, and caudal, are plain. A fold lying between the fore and hind limbs shows the commencing carapace, which is at present the only mark to distinguish it from any other Sauropsidan embryo.

Half the ventral region is now taken up by the heart and its pericardium, and behind it the ventral laminæ have not closed below, thus showing the Wolffian bodies within. Posteriorly the umbilical vessels are seen emerging

The limb-buds grow out from a continuous ridge, due to a thickening of the mesoblast at the upper part of the somatopleure.

The body-cavity extends into the head, thus corroborating

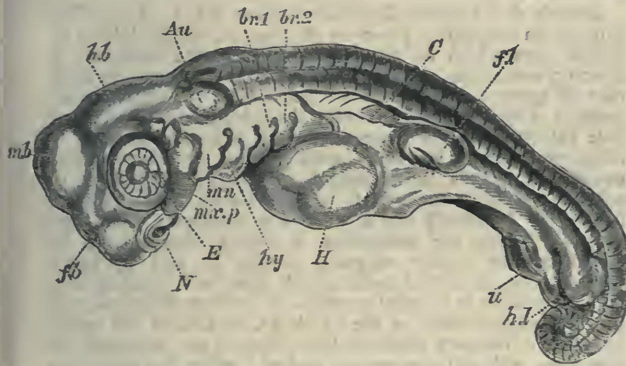


FIG. 1.—*Chelone midas*, 1st stage. *Au*, auditory capsule; *br.* 1 and 2, branchial arches; C, carapace; E, eye; *f.b*, fore-brain; *f.l*, fore-limb; H, heart; *h.b*, hind brain; *h.l*, hind limb; *hy*, hyoid; *m.b*, mid brain; *mn*, mandible; *mx.p*, maxillo-palatine; N, nostril; *u*, umbilicus.

Mr. Balfour's account of the same thing taking place in the Selachians.[2]

As far as possible, the head has formed a coil similar to that of the tail, from which it never more than partially recovers. This bending of the head, which imprisons the elements of the face, sets the dorsal region free, and the neural canal expands to form the three vesicles of the brain. Buds are already seen on the forebrain which give rise to the hemispheres.

The axial tissues, below the nervous structures, are thickening into embryonic cartilage.

A sectional view shows the mid-brain to be bent like a horseshoe, forming the "middle trabecula" of Rathke, which is occupied by the apex of the notochord, its investing structures, and the third nerves.

Three pairs of chambers, for the organs of special sense, are built in the sides of the cranium.

The mouth is formed as in other types, by the extension of the third pair of clefts into one another; the fourth or mandibulohyoid cleft, being what is usually known as the first cleft.

The first post-oral visceral arch, forms most of the framework and machinery of the mouth, but as a rule, rudiments of pre-oral arches, supplemented by sub-cutaneous bones, finish the upper jaw.

On the whole, the series of clefts and folds along the face of the embryo are at this stage very regular, and the sense capsules are intimately connected with those which lie below them.

[1] Abstract of a paper by Prof. Parker, F.R.S., read at the Royal Society on Februnry 13.

[2] This extension of the body-cavity is also seen in the lizard.

The slit-like opening of the nasal sac and the space between the eyeball and maxillo-palatine fold are very probably openings of the same nature as those behind them.

The tubular cartilage that forms round the external nostril is homologous with the "labial" that serves the same purpose in the Icthyopsida.

The floor of the skull is open under the fore-brain, and the double maxillo-palatine fold is sharply severed from the nasal fold. The fronto-nasal process is but little freed from the inferior cranial wall and the nasal folds.

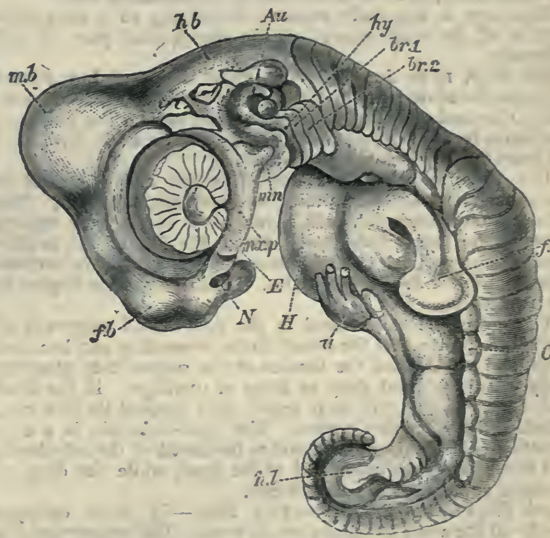

FIG. 2.—*Chelone midas*, 2nd stage. Letters as before.

2nd Stage, ¾-in. long.—The proximal part of each limb now lies adherent to the infero-lateral region of the body in a manner very similar to what is seen in the osseous fishes. The edge above the deep sulcus between the marginal row of cutaneous folds and the ingrowing abdominal part of the body-wall is ultimately somewhat bevelled down, but it shows well that the structure in which the plastron is formed is not originally flat but trough-shaped.

The upper region of the mandible is already assuming the very image of the quadrate with its tympanic cavity and its

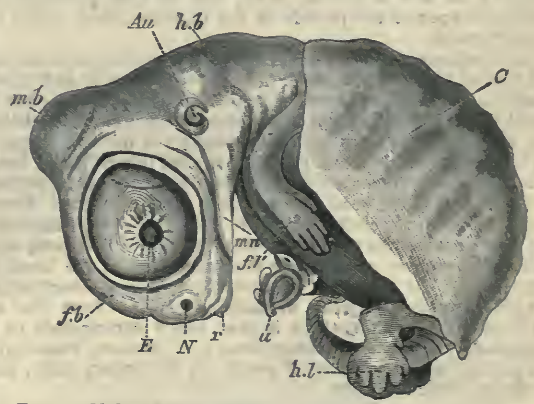

FIG. 3.—*Chelone midas*, 3rd stage. Letters as before. *r*, rostrum.

condyles. In the cavity a discoid body—the "extra-stapedial" has developed. Between the second post-oral (hyoid) fold and the hollow of the quadrate elevation, the beginning of the membrana tympani is seen.

The eyeball is now at its relatively largest size, exceeding the mid-brain in bulk.

The maxillo-palatine fold is somewhat hour-glass shaped, and has a head-cavity in its fore part.

In the middle of the palate an open space appears into which the oral lining has grown. This diverticulum is the rudiment of the pituitary body. It lies where the hypoblast and epiblast

meet, but is probably formed from the latter. The infundibulum is beginning to grow towards the pituitary body, and close in front of it are seen the optic nerves which are still hollow. Rudimentary olfactory lobes are seen where the solid olfactory nerves are given off.

Cartilage is forming in the base and sides of the skull, as well as in the ear-capsules. The notochord ascends high into the head and is slightly curved over at the end. The azygous prochordal element, or inter-trabecular bar, is of equal size to the trabeculæ, which are now articulated with the hind part of the basis cranii, in front of the base of the ascending wall.

This stage is especially valuable in helping to a clear conception of the true nature of the prochordal part of the trabeculæ.

3rd Stage, 1¼-in. long.—In this stage the head has almost acquired the adult form, and the carapace is well marked out. The abdominal region is flattened to give rise to the plastron. The limbs have also practically acquired their adult form, and the heart is fairly inclosed in the thorax.

The post-oral clefts are now filled in, and the skull is thoroughly chondrified, forming a cartilaginous trough. The trabeculæ and inter-trabecula have grown into a high septum between the eyes and nose. From the former, the orbito-sphenoids grow, and the alisphenoids extend from the orbito-sphenoids to the auditory capsules. Ossification now begins in the palate.

The notochord turns round in the post-clinoid upgrowth of of the basal plate, and the sheath in its descending part becomes solid, and ends behind the lobules of the rudimentary pituitary body as a tear-shaped drop or lump of cartilage. If the head had been straight, this drop *might* have reached its fore end, directly below the first nerves. The inter-trabecula is a continuation of the same skeletal tract as the sheath of the notochord, and it reaches to the *actual* end of the head, while the drop of cartilage approaches the *organic* end.

4th Stage—two-thirds ripe—3-in. long.—In these embryos nearly all the adult structures can be seen. The epipterygoid is still, however, a cartilaginous hook hanging down from the quadrate. The columella is well developed, and its shaft is ossified.

The parietals have grown down the sides of the skull causing the alisphenoids to be absorbed to a great extent. The investing bones are now rapidly developed, but much of the endocranium is still soft.

5th Stage—ripe—4in. long.—The processes of development and ossification have now gone so far that little can be remarked upon as differing from the adult. The epipterygoid, however, which is wedged in between the descending parietal and the pterygoid, is now a distinct bone, but its apex permanently touches the apex of the pedicle of the quadrate, from which it was segmented.

The development of *Chelone midas* corresponds in all essentials with that of the common snake (*Tropidonotus natrix*) and lizard (*Lacerta agilis*) which the author has recently worked out; but it is well worth remarking that that which distinguishes the chelonian from other reptiles is already manifest in the first stage.

The author considers that there are several things in the head of the vertebrate embryo which are evidently of a segmental nature. Firstly, nerves in the head corresponding to spinal nerves. These constantly fork over clefts, which are also signs of segmentation. The number of inferior arches, whether pre-cral or post-oral, also indicate the number of segments that may exist in the head of a vertebrate. At any rate, wherever there is any diverticulum of a pleuro-peritoneal cavity, although divided off from that of the body by the clefts, there is that which corresponds to a somatome. By this last evidence there is at least one homologue of a pre-oral somatome, and if we go by the nerves, clefts, and cartilages, there are more.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

THE Council of King's College have decided to give the name "Wheatstone Laboratory" to the physical laboratory of the College, in honour of Sir Charles Wheatstone, who was for some years Professor of Experimental Philosophy in the College, to which he also bequeathed his valuable collection of physical apparatus. The report of the laboratory work shows that the physical laboratory was established in the year 1868, and that during the eleven years of its existence about 250 students have been trained in it in the various branches of practical physics. The average number of occasional students—*i.e.*, students who are engaged in research and do not attend with any special class, has been nine a year during the last five years. Among these are graduates of the older universities, who come to reside in London after they have completed their term of residence at the University. Engineering students in their third year's course have the privilege of working in the laboratory free of charge. There are also special practical classes which have been well attended, for the Bachelor of Science and the Preliminary Scientific M.B. Examinations of the University of London, and also special classes for evening class students who are engaged in business during the day-time. In all there are not less than forty students now engaged in practical work in physics in "the Wheatstone Laboratory" in King's College. The Laboratory is greatly in need of endowment, in order that an additional Demonstrator may be appointed, and the usefulness of the laboratory still further extended.

SCIENTIFIC SERIALS

Journal of the Franklin Institute, March.—We note the following papers in this number:—Concerning $\frac{T_1 - T_0}{T_1}$, or the limit of efficacy of steam-engines, by Mr. Klein.—Gauging- and measuring-implements, by Mr. Richards.—A new engine-governor, by Prof. d'Auria.—Conical arches at South Street Bridge, Philadelphia, Pa., by Mr. Stauffer.—Graphic freight diagrams, by Mr. Dudley.

Bulletin de l'Académie Royale de Belgique, No. 1, 1879.—This contains an interesting paper by M. Niesten, on the colours of double stars, which he was led to study by the variations in intensity and colour of planets in relation to the sun. He finds that in systems which allow of connecting the colours with position of the satellite in its orbit, the principal star is white or pale yellow when the companion is at periaster, whereas in other positions it is yellow, gold yellow, or orange. The companion follows the principal star in its fluctuations of colour, and often exceeds it as it removes from periaster (where it is mostly white, like the principal). In perspective groups, the companion is nearly always blue, by an effect (the author suggests) similar to that by which mountains on the distant horizon look blue (and pointing to a gaseous medium in celestial space).—M. Delarge describes some instructive experiments on the telephone, applied in the neighbourhood of ordinary telegraph lines. Secrecy can be insured for telegrams, with dial-apparatus or that of Hughes, but the former is objectionable as leaving no trace, and the latter is very expensive and delicate. Hence recourse should generally be had to cipher.—M. Marchal contributes a revision of American Hederaceæ, describing eighteen new species and a genus.—M. Chevron is led to deny the inalterability of tricalcic phosphate by citrate of ammonia; but the use of this solvent for separation of the phosphate may give sufficiently exact results if a too great excess of the citrate solution be avoided.—We further note an analysis of, and reports on, the second part of M. Lagrange's work on the origin and establishment of astronomical movements, wherein is assumed that the material atoms were originally diffused through space in a state of rest and at the absolute zero of temperature, and endowed simply with reciprocal attraction.—M. Malaise writes on arsenopyrite, or mispickel, and on the arsenical water of Court Saint-Etienne.

No. 2. We have here a paper by M. Saltel on a mathematical paradox, and on a new character of decomposition due to the presence of multiple lines.—M. van Beneden records the receipt of some interesting fossils of cetacea from marls of the tertiary epoch in Croatia.

THE *Revue Internationale des Sciences* (January-March, 1879), contains the following papers of interest: On the cell soul and soul cells, by Ernst Haeckel.—On the nutrition of plants, by J. L. de Lanessan.—Analysis of two memoirs on *Noctilucæ*, by G. Carlet.—On a monstrous skeleton of a batrachian, by F. Lataste.—Researches on *Bacteria*, by Dr. Koch.—On vascular innervation, by MM. Grutzner and Heidenhain.—On the action of light and heat upon moving spores, by E. Strassburger and E. Stahl.—On contagious diseases and disinfecting agents, by Prof. Naegeli.—General observations on fertilisation, by E. Strassburger.—On a technical process for the study of fish embryos, by F. Henneguy.—On the retina red and its relation to vision, by

W. S. S.—On the movements of diatoms and *Oscillatoria*, by Th. W. Engelmann.—On the preparation and conservation of inferior organisms, by R. Blanchard.—On the influence of motion and rest upon life, by Dr. A. Horwath.

SOCIETIES AND ACADEMIES

London

Chemical Society, April 17.—Dr. Roscoe in the chair.—The following communications were made:—On heptane, from *Pinus sabiniana*, by T. E. Thorpe. Wenzell, in 1872, described, under the name of abietene a hydrocarbon obtained by distilling the exudation of the Californian "nut pine." The author has subjected the crude oil (which occurs in commerce in San Francisco) to an exhaustive chemical and physical examination, and finds that it consists of nearly pure heptane. This discovery, that a paraffin is playing the part of oil of turpentine in a tree now living is exceedingly interesting, as our only natural sources of this hydrocarbon are petroleum and fossil fish oil.—On the determination of tartaric acid in lees and inferior argol, by B. J. Grosjean. The author suggests several improvements in the well-known oxalate process of Warington. The employment of the method of filtration suggested by Casamajor, the addition of potassium chloride to render the precipitation of the potassium bitartrate complete, precipitation of the latter salt by stirring, &c. By these improvements the author has shortened the time required for an estimation to four hours.—Conditions affecting the equilibrium of certain chemical systems, by M. M. P. Muir. The author has carefully studied the influence of time, temperature, and mass on certain reactions: 1. Bismuthous chloride, hydrochloric acid, and water. 2. Calcium chloride and potassium or sodium carbonate.—On the action of oxides on salts, Part II., by E. J. Mills and J. W. Pratt. The authors have examined the actions of aluminic, ferric, and stannic oxides on potassic carbonate at a temperature of 735°.—Examination of substances by the time method, by J. B. Hannay. The author has arrived at the following conclusion:—Two hydrated salts, in forming a double salt containing the normal amount of water, expend one-half of the affinity of the anhydrous salt for its water of crystallisation, in combining with each other, showing that the formation of double salts is comparable with other forms of chemical action.—Preliminary note on certain compounds of naphthalene and benzene with antimony chloride, &c., by Watson Smith. The author has obtained white needles, which he believes to be trinaphthylstibine or naphthyloxystibine. He has obtained other crystalline compounds, which have not yet been examined.

Anthropological Institute, April 8.—Mr. Hyde Clarke, vice-president, in the chair.—Mr. Coutts Trotter, of the Bengal Civil Service, was announced a Member.—Prof. W. H. Flower, LL.D., F.R.S., read a paper entitled "Illustrations of the Method of Preserving the Dead in Darnley Island and South Australia." A mummy from Erroob or Darnley Island, in Torres Strait, inhabited by a Papuan race, was first described. It was fastened in an extended position upon a framework made of pieces of wood, joined together with native cords, and kept in an upright position in the house of the relatives. The surface was covered with red ochre, and a piece of the large Indian volute shell (*Melo indica*), fashioned into the shape of a shield, was suspended in front of the body, as worn by the warriors in battle. The whole of the viscera had been removed through an aperture in the right flank, which had been carefully closed by an interrupted suture. Pieces of light wood filled the abdominal and thoracic cavities. The tongue, larynx, &c., had been removed through the mouth; the lips were not closed, but the jaw was kept from falling by a piece of cord passing close to the bone, through the nostril, and round the ramus of the mandible. The orbits were filled with a resinous substance, and imitation eyes of mother-of-pearl introduced. The second specimen described was a dried mummy from near Adelaide, in South Australia, presented in 1845 to the museum of the Royal College of Surgeons by Sir George Grey. In this case the limbs were bent jointly, and fixed by a band of native netting close to the side of the body, the knees being behind the shoulders, and the feet close to the hips. The internal organs had not been removed, but the mouth had been filled with emu's feathers, and carefully sewn up, a tassel of feathers hanging from one corner. Both cases showed a considerable amount of care and trouble bestowed in what was considered the decent and proper care of the body after death; but, as might be expected, a more elaborate development of art was attained in the Papuan than in the Australian.—A paper by Mr. M. J. Walhouse was read, on rag-bushes and kindred observances. The author, referring to the custom of tying pieces of rag to the bushes near springs of healing repute and by the tombs of holy men, once common in England, and still observed on the Continent, adduced evidence of its antiquity, and instances of its occurrence in Europe, Africa, throughout Asia, and all over America from the north to Patagonia. He also described some apparent varieties of custom, when other objects than rags were used, but with the same motive, and thought that they, as well as the rags, were offered as symbols of sacrifice or gifts, sometimes to deities, sometimes to ghosts, and often as thank-offerings for cures of sickness and other benefits. The worthless form of such offerings might be owing to the sacred spots being frequently in remote and desert regions, where travellers and pilgrims were not likely to have things of value to spare, and would leave trivial scraps and shreds ready at hand rather than nothing at all. Or they might be substitutes for more valuable offerings, once generally made, but which have a tendency to decrease in value, and at last exist only nominally as survivals. The Chinese custom of offering mock food and gilt-paper ornaments at tombs, where costly gifts were anciently made, was referred to in illustration of this. It was further suggested that the *ex voto* offerings, so commonly hung in Roman Catholic churches, are a form and development of the rags and shreds tied to bushes, and that may-poles and even Christmas-trees may have had a similar origin.—A number of antiquities from the United States of Colombia were exhibited by Mr. W. D. Powles.

Meteorological Society, April 16.—Mr. C. Greaves, F.G.S., president, in the chair.—The following were elected Fellows of the Society:—R. W. Abbotts, Rev. S. Allen, D.D., E. H. Banks, F. J. Bramwell, F.R.S., J. A. Caird, E. H. Cardwell, the Earl of Durham, J. Farquharson, W. Garnett, Rev. C. W. Harvey, W. Inskip, the Earl of Powis, and D. Robie. The papers read were: On the results of comparisons of Goldschmid's aneroids, by G. M. Whipple, F.R.A.S.—Observations on the temperature of the Atlantic during the month of March, by P. F. Reinsch.

Entomological Society, April 2.—J. W. Dunning, M.A., F.L.S., vice-president, in the chair.—Mr. McLachlan exhibited the cases of a number of species of Brazilian caddis-flies with the insects bred from the larvæ that manufactured some of them, sent to him by Dr. Fritz Müller from Santa Catharina, and read extracts (with notes) from Dr. Müller's letters on the subject. In reference to the habits of Mantidæ, which had been recently brought under the notice of the Society, Mr. Stainton referred to a larval form of probably *Mantis religiosa*, which had been forwarded to him in 1866 by Mr. Moggridge, jun., and which, from its saltatorial habits, that gentleman had described as a "curious grasshopper." De Geer had also drawn attention to the apparent similarity between these insects belonging to different orders, and Mr. Stainton considered that the peculiar motion of the young Mantis was an illustration of the remark of Mr. Darwin, that the relationships and affinities of animals are often more expressed in the embryonic than in the adult form.—Sir Sydney Saunders exhibited a bag-like fabrication, said to be the production of a large species of spider inhabiting the Fiji Islands.—The Secretary read a note from Mr. J. W. Sclater, on insects destroyed by flowers.—Miss E. A. Ormerod communicated a paper entitled "Observations on the Effects of Low Temperature on Larvæ." From an examination of many species belonging to different orders, during the severe frosts of the past winter, none were found materially injured by the low temperature to which they were subjected.—Mr. Distant communicated a paper containing descriptions of new species of hemiptera collected by Dr. Stoliczka during the Forsyth expedition to Kashgar in 1873–74, to form portion of the general work on the scientific results of the expedition now in course of publication at Calcutta.

Geological Society, April 9.—Henry Clifton Sorby, F.R.S., president, in the chair.—Rev. Joseph Finnemore, Thomas James Slatter, William H. Twelvetrees, Arthur Pendarves Vivian, and Ernest Westlake, were elected Fellows; Prof. Bernhard von Cotta, Freiberg, Dr. Nicolai von Kokscharow, St. Petersburg, and Dr. J. J. S. Steenstrup, Copenhagen, were elected Foreign Members; and Prof. P. J. van Beneden, Louvain, Prof. Guglielmo Guiscardi, Naples, and Prof. Gerhard von Rath, Bonn, Foreign Correspondents of the Society.—The following communications were read:—On the geological age of the rocks of the southern highlands of Ireland, generally known as "the

Dingle Beds" and "Glengariff Grits," by Prof. E. Hull, F.R.S. The author has arrived at the following results:—First, that "the Dingle Beds" are perfectly conformable to, and continuous with, the upper silurian beds of the Dingle promontory. Secondly, that they are the representatives of "the Mweelrea Beds and Salrock Slates," of West Galway and Mayo, the age of which, as shown by the fossils, is upper silurian, and that "the Dingle Beds" may therefore be regarded as of the age of the Ludlow Rocks, but unusually developed—the view adopted as far back as 1839 by Sir Richard Griffiths. Thirdly, that throughout the south of Ireland "the Dingle and Glengariff Beds" are disconnected from the succeeding conformable series, consisting of (*c*) lower carboniferous slate; (*b*) the upper old red sandstone with *Anadonta jukesii*; (*a*) the lower old red sandstones and conglomerate, as these three conformable formations are found resting upon, and against, the Glengariff beds successively in a direction either from south to north, or from south-west to north-east, owing to a conformable overlap against the flanks of an old shelving shore formed of the Glengariff beds. Fourthly, that at the close of the upper silurian period, and after the deposition of "the Dingle and Glengariff Beds," these strata were disturbed, upraised, and denuded, and were not again submerged till the commencement of the old red sandstone (*a*), when they were successively overlain by the beds of that formation with the succeeding ones of the lower carboniferous period, probably including the carboniferous limestone in some places. Lastly, that it was during this period of upheaval that, as the author believes, the marine Devonian beds (Ilfracombe and Morte series) were deposited, which accounts for their absence in the Irish area, which was either a land surface or only partially submerged. To this part of the subject the author hoped to call the attention of the Society on a future occasion.—On some three-toed footprints from the triassic conglomerate of South Wales, by W. J. Sollas, F.G.S.—On the silurian district of Rhymney and Pen-y-lan, Cardiff, by W. J. Sollas, F.G.S.

Statistical Society, April 15.—Sir R. W. Rawson, vice-president, in the chair.—Mr. E. G. Ravenstein, F.R.G.S., read a paper on the geographical distribution of the Celtic speaking population of the British Isles. He stated that four Celtic languages are at present spoken in the British Isles, three of which belonged to the northern Gaelic or Gadhelic, and one to the southern or Cymraig branch. The former are Irish Gaelic, Scotch Gaelic, and Manx; the Cymraig branch, since the extinction of Cornish, being now represented only by the Welsh. *Ireland*.—The localities where Irish Gaelic is the language of the majority, are comparatively limited and remote areas, where the population is less dense than in the more fertile and English speaking districts of the island. In 1851, 23·3 per cent. of the population spoke Irish, and in 1871 15·3 per cent. The success of the labours of the "Society for the Preservation of the Irish Language" was referred to, although it cannot be doubted that Irish is on the decrease. Opinions differ as to the agencies to which this decrease must be ascribed. The census on the whole presented a very fair picture of the linguistic condition of Ireland. *Scotland*.—Mr. Ravenstein said that not quite 9 per cent. of the population could speak Scotch Gaelic, and that there was no doubt it was dying out, although in the more remote parts of the Highlands, and in the Hebrides, it still maintains its ground. In the Isle of Man 25·6 per cent. of the population still understood Manx. *Wales* (Cymraig).—Of all the Celtic speaking races in the United Kingdom, the Welsh were the most important, and in the maintenance of their own language they showed by far the greatest amount of vitality. Including 60,000 Welsh in England, there are 1,006,100 Welsh speaking people in Great Britain. The total number of persons in the United Kingdom still speaking a Celtic tongue was:—

Irish Gaelic ...	867,600
Scotch ,, ...	309,250
Manx ...	12,500
Welsh ...	1,006,100
Total ...	2,195,450

or nearly 7 per cent. of the population of the British Isles.

PARIS

Academy of Sciences, April 14.—M. Daubrée in the chair.—The following papers were read:—Law of propagation of expressive nervous affections and phenomena, by M. Rambosson. A movement purely physical may be transformed into one physiological, and into one psychic or cerebral, being transmitted to these different media; and reciprocally, a psychical movement may be transformed with a physiological and a physical; and that without altering in nature, the same phenomena being reproduced after all these transmissions and transformations, on repassing into the same medium.—Studies on Collioure and its environs, by M. Seriziat.—On the curve-place of positions of centres of curvature of a left curve after its development on a straight line, by M. Aoust.—On various experiments with an oscillating pendulum having large amplitudes, by M. Dejean de Fonroque. The pendulum being free to oscillate in all directions, the plane of oscillation becomes rapidly oriented in a particular direction; which the author thinks is nothing but the horizontal projection of the earth's trajectory, or the resultant of the two great motions of translation of the earth, towards Hercules and round the sun. The trajectory in question does not change sensibly in direction, in the course of a day; but in this time the inclination of the horizontal plane (passing through the point of suspension) to this trajectory varies incessantly according to a law easily determined, consequently its projection on this plane must vary, also the direction of the pendulum. M. Cornu, while not accepting the causes assigned, thought the phenomena worthy of attention.—Anomaly of magnetic observations of Paris, by M. Flammarion. He does not allow M. Marié-Davy's explanation.—Fossil fauna of the environs of Castres, by M. Caraven-Cochin. He has discovered several carapaces of tortoises in the eocene sandstone of the place, also jaws and teeth of Lophiodon, scales and teeth of crocodiles (apparently three new species), remains of various mammalia, &c.—On an alteration of the cells of renal epithelium, at the commencement of Bright's disease, by M. Cornil. He describes vacuoles in the cells of the uriniferous tubes, filled with a ball or drop of granular albuminoid matter.—Researches on the Pyrenomycetes of St. Paul and Amsterdam Islands, by M. Crié.—Considerations on the Echinida of the Cenomanian formation in Algeria, by M. Cotteau. He finds remarkable relations of the system in Algeria to that in France.

GÖTTINGEN

Royal Society of Sciences, February 12.—On the constant batteries of Grove and Bunsen, by Herr Fromme.—Report on ear diseases, by Dr. Burkner.

March 1.—On the reduction of Abel integrals to elliptical and hyper-elliptical, by Herr Königsberger.

NATURE

A WEEKLY ILLUSTRATED JOURNAL OF SCIENCE

"To the solid ground
Of Nature trusts the mind which builds for aye."—WORDSWORTH

No. 471, Vol. 19] THURSDAY, NOVEMBER 7, 1878 [Price Sixpence

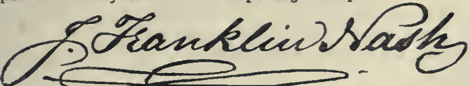
Registered as a Newspaper at the General Post Office.]

ENGRAVINGS AND ELECTROTYPES

FOR SALE, at prices ranging from 1s. to 10s., in good condition, ready for printing. Small, medium size, and large engravings, comprising a great variety of subjects, suitable for Publishers, Advertisers, and Amateurs. Specimen of any subject required sent post free on application.

FACSIMILE OF SIGNATURE for 3*s*. An exact copy of any name guaranteed. These signatures being engraved in bold relief, are useful for Stamping Books, Circulars, and Documents, or Marking Linen, and made type-high for ordinary Letterpress Printing.

Sent post free to any address on receipt of 36 stamps.



75, FLEET STREET, LONDON, E.C.

ARTISTIC.—To Ladies and Gentlemen with

some leisure time, desiring to supplement their incomes, an opportunity is offered of acquiring the ART of DRAWING and ENGRAVING on WOOD in a thoroughly satisfactory and perfect style. The terms are moderate, and the hours can be made to suit the convenience of pupils. Persons residing in the country can receive full instruction by correspondence. For further particulars call or address Mr. J. FRANKLIN NASH, Artist and Engraver, 75, Fleet Street, London, E.C.

PRICE 4*d*.

THE TELEGRAPHIC JOURNAL AND ELECTRICAL REVIEW

For November 1, 1878, contains:—

1.—The Gas Companies.
2.—Wallace Farmer Machine and Lamp. (Illustrated.)
3.—Rapieff's Electric Lamp. (Illustrated.)
4.—Phonic Wheel of Paul le Cour.
5.—Cost of Electric Light.
6.—Progress of Electric Light.
7.—Notes.
8.—Reviews.
10.—Patents.
11.—Correspondence.
12.—General Science Columns.
13.—City Notes.

London: HAUGHTON & CO., 10. Paternoster Row.

Now ready, price 3*s*. 6*d*. No. III. of

BRAIN:

A QUARTERLY JOURNAL OF NEUROLOGY

EDITED BY

Drs. BUCKNILL, CRICHTON-BROWNE, FERRIER, and HUGHLINGS-JACKSON.

CONTENTS.

ORIGINAL ARTICLES.
Some of the Lessons of Neurotomy. By S. Weir Mitchell, M.D.
Metalloscopy and Metallotherapy. By A. Hughes Bennett, M.D.
A Study of Four Hundred and Fifteen Cases of Tetanus. By David W. Yandell, M.D.
Application of Freezing Methods to the Microscopic Examination of the Brain. By Bevan Lewis, M.D.
Is there a Sympathetic Centre in the Medulla Oblongata? By W. H. Kesteven, M.R.C.S.
Critical Digests and Notices of Books; Clinical Cases; Abstracts of British and Foreign Journals, &c.

MACMILLAN & CO., LONDON.

Now ready, price 6*s*.

THE JOURNAL OF ANATOMY AND PHYSIOLOGY

NORMAL AND PATHOLOGICAL.

CONDUCTED BY

Profs. HUMPHRY, TURNER, M'KENDRICK, & Dr. CREIGHTON.

Vol. XIII., Part I. October, 1878.

Contents:—

Intrinsic Muscles of Mammalian Foot. By Dr. Cunningham. (Plate I.)
Anatomy of Indian Elephant. By Prof. Miall and F. Greenwood. (Plates II. to V.)
Theory of the Homology of the Suprarenals. By Dr. Creighton. (Plates VI. and VII.)
Anatomy of Genu Valgum. By Edmund Owen.
Growth of Bone from the Articular Cartilages. By Prof. Humphry.
Tumour of Ovary in Common Pheasant. By H. H. Slater. (Plate VIII.)
Placenta of the Hog-Deer (*Cervus porcinus*). By Prof. Turner.
Development of Organ of Corti. By Dr. Pritchard. (Plate IX.)
Case of Hemiplegia from an Injury involving Loss of Brain. By Dr. Coats.
Experiments on Physiological Effects of Inhalation of Phosphuretted Hydrogen. By Dr. Henderson.
Anatomical Notes and Queries. Prof. Rolleston.
Ovum and Placenta of Dugong. By Paul Harting, Utrecht.
Notice of New Book.
Abstract of Physiological Papers.

MACMILLAN & CO., LONDON.

"That excellent periodical THE GARDEN."—Professor Owen.

THE GARDEN: A Weekly Illustrated

Journal of Gardening in all its Branches. Founded and Conducted by W. ROBINSON, F.L.S., Author of "Alpine Flowers for English Gardens," &c.

A Coloured Plate is now issued with every number of *The Garden*.

"Mr. Robinson's valuable and elegant weekly."—*Saturday Review*, Aug. 10th, 1872.

The following are some of the subjects regularly treated of in its pages —

The Flower Garden.	Hardy Flowers.
Landscape Gardening.	Town Gardens.
The Fruit Garden.	The Conservatory.
Garden Structures.	Public Gardens.
Room and Window Gardens.	The Greenhouse and Stove.
Notes and Questions.	The Household.
Market Gardening.	The Wild Garden.
Trees and Shrubs.	The Kitchen Garden.

Professor ASA GRAY says: "It seems admirably adapted to the wants and tastes of gentlemen who are interested in rural affairs By such we hear it highly spoken of; and we think we do a favour to those of that class who know it not as yet, by calling attention to it."

Price 6*d*. Weekly. Specimen Copy, Post-free, 6½*d*.

Terms of Subscription.—Sent direct from the Office in London, post free, payable in advance—For One Year, 26*s*.; Half a Year, 14*s*.; Quarter of a Year, 7*s*. Address all letters concerning Subscriptions to—The Publisher of *The Garden*, 37, Southampton Street, Covent Garden, London, W.C.

NORTH BRITISH AGRICULTURIST,

Is the only Agricultural Journal in Scotland, and circulates extensively amongst landed proprietors, factors, farmers, farm-bailiffs, and others interested in the management of landed property throughout Scotland and the Northern Counties of England.

The AGRICULTURIST has also a very considerable circulation on the Continent of Europe, America, Australia, and the Colonies.

The AGRICULTURIST is published every Wednesday afternoon in time for the evening mails, and contains Reports of all the principal British and Irish Markets of the week, besides telegraphic reports of those held on the day of publication.

The Veterinary Department is edited by one of the leading Veterinarians in the country, and is invaluable to the breeder and feeder as a guide to the rearing of animals, and their treatment when labouring under disease.

Full Reports are given of the Meetings of the Royal Agricultural Society of England, the Royal Agricultural Society of Ireland, the Highland and Agricultural Society of Scotland, the Scottish Chamber of Agriculture, and all the principal Agricultural Associations throughout Great Britain and Ireland.

For Advertisers addressing themselves to Farmers a better medium does not exist.

Price 3*d*. By post, 3½*d*. Annual Subscription, payable in advance, 14*s*.
Office.—377, High Street, Edinburgh.
Post-Office Orders payable to Charles Anderson, Jun., Edinburgh.

ESTABLISHED 1843.

THE BEST FARMERS' NEWSPAPER.

THE CHAMBER OF AGRICULTURE JOURNAL AND FARMERS' CHRONICLE,

Edited by JOHN ALGERNON CLARKE, Secretary to the Central Chamber of Agriculture,

Devotes special attention to the discussions and proceedings of the Chambers of Agriculture of Great Britain (which now number upwards of 18,000 members), besides giving original papers on practical farming, and a mass of intelligence of particular value to the agriculturist.

The London Corn, Seed, Hop, Cattle, and other Markets of Monday are specially reported in this Journal, which is despatched the same evening so as to ensure delivery to country subscribers by the first post on Tuesday morning. Price 3*d*., or prepaid, 15*s*. a year post free.

Published by W. PICKERING, 21, Arundel Street, Strand, W.C.

THE ENTOMOLOGIST'S MONTHLY MAGAZINE.

Price Sixpence, Monthly, 24 pages 8vo, with occasional Illustrations.
Conducted by J. W. DOUGLAS, R. MCLACHLAN, F.R.S., E. C. RYE, F.Z.S., and H. T. STAINTON, F.R.S.

This Magazine, commenced in 1864, contains standard articles and notes on all subjects connected with Entomology, and especially on the Insects of the British Isles.

Subscription—Six Shillings per Volume, post free. The volumes commence with the June number in each year.

Vols. I. to V. (strongly bound in cloth) may be obtained by purchasers of the entire set to date, at the increased price of 10*s*. each; the succeeding vols. may be had separately or together, at 7*s*. each.

London: JOHN VAN VOORST, 1, Paternoster Row.

N.B.—Communications, &c., should be sent to the Editors at the above address.

THE BREWERS' GUARDIAN:

A Fortnightly Paper devoted to the Protection of Brewers' Interests Licensing, Legal, and Parliamentary Matters.

REVIEW OF THE MALT AND HOP TRADES; AND WINE AND SPIRIT TRADE RECORD.

The Organ of the Country Brewers.

"The Brewers' Guardian" is published on the evenings of every alternate Tuesday, and is the only journal officially connected with brewing interests.

Subscription, 16*s*. 6*d*. per annum, post free, dating from any quarter-day. Single Copies, 1*s*. each. Registered for transmission abroad.

Offices—5, Bond Court Walbrook, London, E.C.

WANTED, Clean Copies of NATURE,

No. 433.—Address Office of NATURE, 29, Bedford Street, Strand.

DIARY OF SOCIETIES.

London

THURSDAY, November 7.

Linnean Society, at 8.—On the Existence of *Carpesium* (*C. cernuum*?) in Queensland: Lewis A. Bernays.—Notes on Cleistogamic Flowers, chiefly of *Viola, Oxalis*, and *Impatiens*: Alfred W. Bennett.—Descriptions of New Hemiptera: Dr. F. Buchanan White.—On the Absorption of Rain and Dew by the Green Parts of Plants: Rev. George Henslow.

Chemical Society, at 8.—On the Red Colouring Matter of the Lithospermum Erythrorhizon: M. Kahara.—On the Occurrence of Certain Nitrogen Acids amongst the Products of Combustion of Coal Gas and Hydrogen Flames: L. T. Wright.—Second Report on Researches on some points in Chemical Dynamics; Dr. Wright and Mr. Luff.—On the Constitution of the Olefine produced by the Action of Zinc on Ethylic Iodide: Dr. Frankland.

SATURDAY, November 9.

Physical Society, at 3.

SUNDAY, November 10.

Sunday Lecture Society, at 4.—Voltaire: Moncure D. Conway.

MONDAY, November 11.

Royal Geographical Society, at 8.30.

TUESDAY, November 12.

Anthropological Institute, at 8.—Report on Anthropological Proceedings at the Oriental Congress: R. Cust.—On some Characters Tattooed on a Motu Woman: J. Park Harrison, M.A.—On some American Illustrations of the Evolution of New Varieties of Men: Dr. Daniel Wilson.

West London Scientific Association, at 8.

WEDNESDAY, November 13.

Royal Microscopical Society, at 8.—Further Inquiry into the Limits of Microscopic Vision and the Delusive Application of Fraunhofer's Optical Law of Vision: Dr. R. Pigott.—On the Measurement of the Angle of Aperture of Objectives: F. H. Wenham.

THURSDAY, November 14.

Mathematical Society, at 8.—Anniversary.—Instability of Jets: Lord Rayleigh, F.R.S.—Self-strained Frames of Six Joints: Prof. M. W. Crofton, F.R.S.

SUBSCRIPTIONS TO NATURE

Subscribers are asked to note that the subscriptions to NATURE are as follows:—

Yearly	28*s.*
Half-yearly	14*s.* 6*d.*
Quarterly	7*s.* 6*d.*

To the Colonies, United States, the Continent, and all places within the Postal Union:—

Yearly	30*s.* 6*d.*
Half-yearly	15*s.* 6*d.*
Quarterly	8*s.*

Office: 29, Bedford Street, Strand.

E. DENT & Co.,

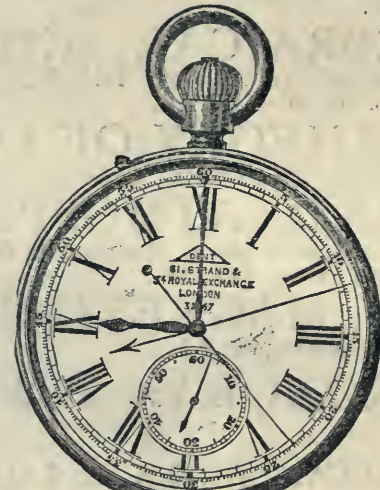
MANUFACTURERS OF

WATCHES, CHRONOMETERS, ASTRONOMICAL, TURRET, AND OTHER CLOCKS.

TO HER MAJESTY THE QUEEN.

To Foreign Sovereigns.

Catalogues on Application.



TO H.R.H. THE PRINCE OF WALES.

To Foreign Republics.

Catalogues on Application.

Makers of the Great Westminster Clock (Big Ben); of the Standard Clock and Standard Galvanic Chronograph of the Royal Observatory, Greenwich; and of Standard Clocks in most principal Home and Foreign Observatories.

MAKERS OF ADMIRALTY STANDARD COMPASSES.

Only Places of Business—

61, STRAND, AND 34, ROYAL EXCHANGE, LONDON.

THE TELEPHONE COMPANY, LIMITED,

36, COLEMAN STREET, LONDON, E.C.

SOLE PROPRIETORS OF BELL'S AND OTHER PATENTS.

TELEPHONES and all necessary Instruments Supplied for DOMESTIC or BUSINESS Purposes, on SALE or RENTAL.

ESTIMATES can be obtained for fitting up Telephonic Communication in MINES, FACTORIES, WORKSHOPS, or PRIVATE DWELLINGS; also for Lines of Wire Communicating between LIGHTHOUSES and the SHORE; SHIPPING OFFICES and VESSELS in PORT; NOBLEMEN'S MANSIONS and their LODGES, STABLES, or GAMEKEEPERS' RESIDENCES, &c., &c.

AGENTS WANTED.—A Liberal Discount allowed to the Trade.

PROCEEDINGS will be taken against ALL PERSONS selling or using any Telephones, or otherwise infringing the Company's Patents.

APPLICATION for Price Lists or further information to be made to the MANAGER.

MICROSCOPIC SPECIALITIES.

Series I.—24 Pathological Preparations, in Case	£2	2	0
,, II.—24 Physiological ,, ,,	2	2	0
,, III.—24 Educational ,, ,,	2	2	0
,, IV.—48 Physiological ,, ,,	4	4	0
Series V.—24 Preparations from the Frog, in Case	£2	2	0
,, A.—48 Diatomaceæ (selected)	2	10	0
,, B.—24 ,, (very rare)	1	11	6

Whole Insects and Parts of Insects and Pathological and Physiological Preparations in great and constantly increasing variety, and of most valuable descriptions. 15*s.* to 30*s.* per doz.

Descriptive Lists and full particulars on application to

ARTHUR C. COLE & SON,

ST. DOMINGO HOUSE, OXFORD GARDENS, NOTTING HILL, LONDON, W.

Late of 62, St. Domingo Vale, Everton, Liverpool.

MICROSCOPIC OBJECTS

Of superlative perfection, illustrating Histology and every branch of Microscopy. Catalogue post free and gratis on application.

PARIS UNIVERSAL EXHIBITION, 1878.

E. WHEELER'S OBJECTS ARE IN THE BRITISH SECTION, GROUP 2, CLASS VIII.
EDMUND WHEELER, 48N, Tollington Road, Holloway, London, N.

UNIVERSITY COLLEGE (LONDON) MEDICAL SOCIETY.

An ADDRESS on "The Use of Physiology to Medical Students" will be delivered by Dr. MICHAEL FOSTER, M.A., F.R.S., Prælector in Physiology, and Fellow of Trinity College, Cambridge, in the Botanical Theatre of University College, Gower Street, on TUESDAY, December 3, at 8 P.M. Admission (Gentlemen only) by Ticket, to be obtained on application to the Secretaries of the Society.

H. M. MURRAY, W. R. PARKER, } Hon. Secs.

SUNDAY LECTURE SOCIETY.—LECTURES at ST. GEORGE'S HALL, Langham Place, each SUNDAY AFTERNOON, commencing at Four o'clock precisely. Sunday, November 24, 1878:—Dr. G. G. ZERFFI, F.R.Hist.S., F.R.S.L., on "Long and Short Chronologists."—Members' Annual Subscription, £1. Payment at the Door—One Penny, Sixpence, and (reserved seats) One Shilling.

WANTED, for the INSTITUTION of NAVAL ARCHITECTS, a SECRETARY. His Salary will be £250 a year, and he will be required to give security to the extent of £500. His duties will involve attendance from Ten to Four daily, with occasional extra attendance at Meetings.—Apply, by letter only, to C. W. MERRIFIELD, at the Offices of the Institution, 5, Adelphi Terrace, W.C. Applications must be sent in not later than November 30.

DUNHEVED COLLEGE (LIMITED),

LAUNCESTON, CORNWALL.

Seven hours from London. SEPARATE BEDROOMS. Systematic Teaching in SCIENCE, FOREIGN LANGUAGES, and UNIVERSITY COURSES.
Calendar post free from
THE PRINCIPAL—BENJAMIN RALPH, LL.B. Dub.

LIBRARY OF HARVARD UNIVERSITY, CAMBRIDGE, MASS., U.S.A.

Packages for the General Library, or for any of the Departmental Libraries (Astronomical Observatory, Botanic Garden, Bussey Institution, Divinity School, Law School, Museum of Comparative Zoology, Scientific School), may be sent to the Agents, Messrs. TRÜBNER & Co., 57 and 59, Ludgate Hill, London.

JUSTIN WINSOR, Librarian.

ROYAL POLYTECHNIC.—CLASSES for the preparation of Students for University Examinations, under the direction of EDWARD B. AVELING, D.Sc., F.L.S. London University Matriculation, 1st and 2nd B.Sc., Preliminary Scientific M.B., Botany, Physiology, Chemistry. All the work practical.

BERNERS COLLEGE.—The Laboratory and Class Rooms are open for Private and Class Study, morning and evening. ANALYSES performed. Especial arrangements for Gentlemen and Ladies preparing for the various Examining Boards. Fees moderate.—Apply to Prof. GARDNER, at Berners College, 44, Berners Street, W.

WITHERNDEN SCHOOL, CATERHAM VALLEY, SURREY.—Principal, Mr. C. H. LAKE, B.A. Lond. (in Honours). Education on Natural Principles. A limited number of Pupils.

THE LONDON ATHENÆUM,

26, SUFFOLK STREET, PALL MALL.

This Institution being now established (500 Members having been admitted), an Admission Fee of Two Guineas will now be payable by new Members.

Annual Subscription:—Town Members, Two Guineas; Country Members, One Guinea.

Members admitted in November do not pay the subscription for the current year.

J. LOGAN LOBLEY, Secretary.

SHELLS AND MINERALS.—A very choice Collection of Shells, named according to H. and A. Adams's work on Recent Shells, suitable for a Public or Private Scientific Museum. Price 100 Guineas. Also a Collection of Minerals (about 700), labelled ready for display. Price 80 Guineas.—Address MEEK, THOMAS, & Co., Advertising Agents, 4, Cable Street, Liverpool.

FOR SALE.—A Splendid Collection of Falkland Island BUZZARDS, HARRIERS, and FALCONS, set up by GARDNER. Also a King Penguin and two King Shags.—Address L., Post Office, Wimborne.

AIR-PUMP.—A Bargain.—A Griffin Air-Pump, quite new, double barrels 7 inches long, $1\frac{3}{4}$-inch bore, $5\frac{1}{2}$-inch stroke, with a 10-inch ground plate. Original cost, complete, £16. Price 9 Guineas. P. NOLST, Cooper's Hill College, Staines.

LIVING SPECIMENS FOR THE MICROSCOPE.

THOMAS BOLTON, MICROSCOPIST'S and NATURALIST'S STUDIO, 17, ANN STREET BIRMINGHAM.

RAPHIDIOPHRYS PALLIDA,

The Freshwater Rhizopoda of F. Schulze figured in *Archiv für mikroskop. Anatomie*, vol. x. Plate xxvi. fig. 1.

Also Floscules, some fine *Melicerta ringens*, and *Volvox globator*, &c.

Price List of Specimens on Application, with Stamped Addressed Envelope. Weekly Announcements will be made in this place of Organisms ready for sale.

LANTERN SLIDES.—Size, $3\frac{1}{4}$ in. square; 18s. per dozen. Skeletons, Skulls, &c., of Mammalia; Pond-life, Insects, &c., enlarged from Microscope. List for stamp.—JOHN BURTON, F.R.M.S., 50, Portland Road, Nottingham.

SHEPPEY FOSSILS.

W. H. SHRUBSOLE, SHEERNESS-ON-SEA, respectfully intimates that the appeal recently made by him has been so heartily responded to, that he cannot receive any more orders for "extra selected" specimens at present.

Orders for 10s. Collections of 100 "good" specimens can be executed without delay.

"NOTES ON THE GEOLOGY OF SHEPPEY" post free on application.

MINERALS, FOSSILS, AND ROCKS.

COLLECTIONS IN CABINETS.

50 characteristic Specimens, 10s.; 100 do., 20s.; 150 do., 30s.; 200 do., 40s.; 300 do., £3; 400 do., £4; 500 do., £5. Size of Specimens, about 2 square inches. "Guaranteed superior Collections."

N.B.—Carriage prepaid to any part of Great Britain.

Catalogues free.

"THE POPULAR SCIENTIFIC POCKET CABINET SERIES,"

25 Specimens, 2s. 6d.

THOMAS J. DOWNING (MINERALOGIST),
38, WHISKIN STREET, LONDON, E.C.

NATURAL HISTORY AGENCY.

Collections of Insects, Bird and Mammal Skins, Eggs, Shells, Skeletons &c., bought or sold on Commission.

N.B.—Wanted Good Specimens of Native Implements of War.

A. H. JAMRACH, 218, East India Road, London, E.

THIN GLASS FOR MICROSCOPIC MOUNTING, of best quality. Circles, 3s. 6d. per ounce; Squares, 2s. 9d.; post free 1d. extra; Ground-edged Slips, 5s. per gross: also other Mounting Materials and Objects prepared for mounting.—CHAS. PETIT, 151, High Street, Stoke Newington, N.

GEOLOGY.—In the Preface to the Student's ELEMENTS of GEOLOGY, by Sir Charles Lyell, price 9s., he says:—"As it is impossible to enable the reader to recognise rocks and minerals at sight by aid of verbal descriptions or figures, he will do well to obtain a well arranged collection of specimens, such as may be procured from Mr. TENNANT (149, Strand), Teacher of Mineralogy at King's College, London." These Collections are supplied on the following terms, in plain Mahogany Cabinets:—

100 Specimens, in Cabinet, with 3 Trays	£2	2	0
200 Specimens, in Cabinet, with 5 Trays	5	5	0
300 Specimens, in Cabinet, with 9 Drawers	10	10	0
400 Specimens, in Cabinet, with 13 Drawers	21	0	0

More extensive Collections at 50 to 5,000 Guineas each.

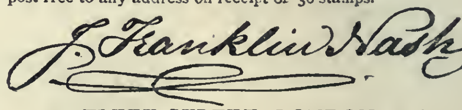
ELECTRICAL and SCIENTIFIC APPARATUS.—BEST WORKMANSHIP at LOWEST PRICES.—Induction Coils and Electric Machines. New Electric Lamp, 21s. Bells with Automatic Switches and Batteries for Telephones, complete, 50s. Microphones, most sensitive, 3s. 6d.; Battery for ditto, per cell, 1s. 6d. Electric Bells, Fire and Thief Alarms, Telephonic Materials, Wires, Carbons, Batteries, &c. Catalogues one stamp.—DALE & CRAMPTON, Electricians, 4, Little Britain, London, E.C.

ENGRAVINGS AND ELECTROTYPES

FOR SALE, at prices ranging from 1s. to 10s., in good condition, ready for printing. Small, medium size, and large engravings, comprising a great variety of subjects, suitable for Publishers, Advertisers, and Amateurs. Specimen of any subject required sent post free on application.

FACSIMILE OF SIGNATURE for 3s. An exact copy of any name guaranteed. These signatures being engraved in bold relief, are useful for Stamping Books, Circulars, and Documents, or Marking Linen, and made type-high for ordinary Letterpress Printing.

Sent post free to any address on receipt of 36 stamps.



75, FLEET STREET, LONDON, E.C.

ARTISTIC.—To Ladies and Gentlemen with some leisure time, desiring to supplement their incomes, an opportunity is offered of acquiring the ART of DRAWING and ENGRAVING on WOOD in a thoroughly satisfactory and perfect style. The terms are moderate, and the hours can be made to suit the convenience of pupils. Persons residing in the country can receive full instruction by correspondence. For further particulars call or address Mr. J. FRANKLIN NASH, Artist and Engraver, 75, Fleet Street, London, E.C.

DIARY OF SOCIETIES.

LONDON

THURSDAY, NOVEMBER 21.

ROYAL SOCIETY, at 8.30.—On a Method of Using the Balance with great Delicacy, and on its Employment to Determine the Mean Density of the Earth: J. H. Poynting.—On Repulsion Resulting from Radiation, Part VI.: W. Crookes, F.R.S.

CHEMICAL SOCIETY, at 8.—The Processes and their Comparative Value for Determining the Quantity of Organic Matter in Potable Waters: Dr. C. M. Tidy.—A Chemical Study of Vegetable Albinism: Prof. A. H. Church.—Researches on the Action of the Copper-Zinc Couple on Organic Compounds: Dr. Gladstone and Mr. Tribe.—On a New Gravimetric Method for the Estimation of Minute Quantities of Carbon: Dr. Dupré and Dr. Hake.

LINNEAN SOCIETY, at 8.—Preliminary Report on the Mollusca of the *Challenger* Expedition (viz., the Genera Dentalium, Siphodentalium, and Cadulus): Rev. R. Boog Watson.—On the Symplocaceæ: John Miers.—On Tuberous Branch Terminations in *Vitis gongylodes*: R. Irwin Lynch

ELEMENTARY CLASS-BOOKS OF SCIENCE.

ASTRONOMY, by the Astronomer-Royal.

POPULAR ASTRONOMY. With Illustrations. By Sir G. B. AIRY, K.C.B., Astronomer-Royal. New Edition. 18mo. 4*s.* 6*d.*

Six lectures, intended "to explain to intelligent persons the principles on which the instruments of an Observatory are constructed, and the principles on which the observations made with these instruments are treated for deduction of the distances and weights of the bodies of the Solar System."

ASTRONOMY.

ELEMENTARY LESSONS IN ASTRONOMY. With Coloured Diagram of the Spectra of the Sun, Stars, and Nebulæ, and numerous Illustrations. By J. NORMAN LOCKYER, F.R.S. New Edition. 18mo. 5*s.* 6*d.*

"Full, clear, sound, and worthy of attention, not only as a popular exposition, but as a scientific 'Index.'"—*Athenæum.*

QUESTIONS ON LOCKYER'S ELEMENTARY LESSONS IN ASTRONOMY. For the Use of Schools. By JOHN FORBES-ROBERTSON. 18mo, cloth limp. 1*s.* 6*d.*

PHYSIOLOGY.

LESSONS IN ELEMENTARY PHYSIOLOGY. With numerous Illustrations. By T. H. HUXLEY, F.R.S., Professor of Natural History in the Royal School of Mines. New Edition. 18mo. 4*s.* 6*d.*

"Pure gold throughout."—*Guardian.*

"Unquestionably the clearest and most complete elementary treatise on this subject that we possess in any language."—*Westminster Review.*

QUESTIONS ON HUXLEY'S PHYSIOLOGY FOR SCHOOLS. By T. ALCOCK, M.D. 18mo. 1*s.* 6*d.*

BOTANY.

LESSONS IN ELEMENTARY BOTANY. By D. OLIVER, F.R.S., F.L.S., Professor of Botany in University College, London. With nearly Two Hundred Illustrations. New Edition. 18mo. 4*s.* 6*d.*

CHEMISTRY.

LESSONS IN ELEMENTARY CHEMISTRY, INORGANIC AND ORGANIC. By HENRY E. ROSCOE, F.R.S., Professor of Chemistry in Owens College, Manchester. With numerous Illustrations and Chromo-Litho of the Solar Spectrum, and of the Alkalies and Alkaline Earths. New Edition. 18mo. 4*s.* 6*d.*

"As a standard general text-book it deserves to take a leading place."—*Spectator.*

"We unhesitatingly pronounce it the best of all our elementary treatises on Chemistry."—*Medical Times.*

A SERIES OF CHEMICAL PROBLEMS, prepared with Special Reference to the above, by T. E. THORPE, Ph.D., Professor of Chemistry in the Yorkshire College of Science, Leeds. Adapted for the preparation of Students for the Government, Science, and Society of Arts Examinations. With a Preface by Professor ROSCOE. New Edition, with Key, 18mo. 2*s.*

POLITICAL ECONOMY.

POLITICAL ECONOMY FOR BEGINNERS. By MILLICENT G. FAWCETT. New Edition. 18mo. 2*s.* 6*d.*

"Clear, compact, and comprehensive."—*Daily News.*

"The relations of capital and labour have never been more simply or more clearly expounded."—*Contemporary Review.*

LOGIC.

ELEMENTARY LESSONS IN LOGIC; Deductive and Inductive, with copious Questions and Examples, and a Vocabulary of Logical Terms. By W. STANLEY JEVONS, M.A. Professor of Logic in University College, London. New Edition. 18mo. 3*s.* 6*d.*

"Nothing can be better for a school-book."—*Guardian.*

"A manual alike simple, interesting, and scientific."—*Athenæum.*

PHYSICS.

LESSONS IN ELEMENTARY PHYSICS. By BALFOUR STEWART, F.R.S., Professor of Natural Philosophy in Owens College, Manchester. With numerous Illustrations and Chromo-litho of the Spectra of the Sun, Stars, and Nebulæ. New Edition. 18mo. 4*s.* 6*d.*

"The beau-ideal of a scientific text-book, clear, accurate, and thorough."—*Educational Times.*

PRACTICAL CHEMISTRY.

THE OWENS COLLEGE JUNIOR COURSE OF PRACTICAL CHEMISTRY. By FRANCIS JONES, Chemical Master in the Grammar School, Manchester. With Preface by Professor ROSCOE, and Illustrations. New Edition. 18mo. 2*s.* 6*d.*

ANATOMY.

LESSONS IN ELEMENTARY ANATOMY. By ST. GEORGE MIVART, F.R.S., Lecturer in Comparative Anatomy at St. Mary's Hospital. With upwards of 400 Illustrations. 18mo. 6*s.* 6*d.*

"It may be questioned whether any other work on anatomy contains in like compass so proportionately great a mass of information."—*Lancet.*

"The work is excellent, and should be in the hands of every student of human anatomy."—*Medical Times.*

STEAM.

AN ELEMENTARY TREATISE. By JOHN PERRY, Bachelor of Engineering, Whitworth Scholar, &c., late Lecturer in Physics at Clifton College. With numerous Woodcuts and Numerical Examples and Exercises. 18mo. 4*s.* 6*d.*

"The young engineer and those seeking for a comprehensive knowledge of the use, power, and economy of steam, could not have a more useful work, as it is very intelligible, well arranged, and practical throughout."—*Ironmonger.*

PHYSICAL GEOGRAPHY.

Office : 29, Bedford Street, Strand.

DIARY OF SOCIETIES.

LONDON

THURSDAY, DECEMBER 5.

ROYAL SOCIETY, at 8.30.—On the Illumination of Lines of Molecular Pressure, and the Trajectory of Molecules: W. Crookes, F.R.S.—On a Machine for the Solution of Simultaneous Linear Equations: Sir W. Thomson, F.R.S.

SOCIETY OF ANTIQUARIES, at 8.30.—Portrait of Charles Brandon, Duke of Suffolk: Everard Green, F.S.A.—Hoard of Bronze Objects from Yattendon, Berks: John Evans, D.C.L., F.S.A.

LINNEAN SOCIETY, at 8.—Note on *Gardenia turgida*, Roxb.: Chas. B. Clarke.—Geographical Distribution of Indian Freshwater Fishes. Part III. Conclusion: Dr. Francis Day.—Memorandum respecting the Growth of *Melocactus communis?* Dr. W. B. Kesteven.—On some Coleoptera Collected by Chas. Darwin, of Interest as regards Insular Fauna: F. H. Waterhouse.—Remarks on a New British Moss: Ed. Morell Holmes.—Mollusca of *Challenger* Expedition. No. II. (the Genera Seguinzia, Bassillissa, and Gaza): Rev. R. Boog Watson.

CHEMICAL SOCIETY, at 8.—The Processes and their Comparative Value for Determining the Quantity of Organic Matter in Potable Waters: Dr. Tidy.—Researches on the Action of the Copper-Zinc Couple on Organic Compounds: Dr. Gladstone and Mr. Tribe.—On a New Gravimetric Method for the Estimation of Minute Quantities of Carbon: Dr. Dupré and Dr. Hake.

LONDON INSTITUTION, at 7.—Present Tendencies of English Art: J. Comyns Carr.

FRIDAY, DECEMBER 6.

GEOLOGISTS' ASSOCIATION, at 8.—On the so-called "Crater Necks" and "Volcanic Bombs" of Ireland: Mattieu Williams.—On the Volcanic Region of Auvergne, Illustrated by Specimens of Minerals and Diagrams: W. F. Black, F.G.S.Ed.

SUNDAY, DECEMBER 8.

SUNDAY LECTURE SOCIETY, at 4.—Discoveries by the Spectroscope: Channel Law.

MONDAY, DECEMBER 9.

LONDON INSTITUTION, at 5.—Self-defence among Plants: Francis Darwin.

SOCIETY OF ARTS, at 8.—Mathematical Instruments: W. M. Williams.

MEDICAL SOCIETY, at 8.30.

ROYAL GEOGRAPHICAL SOCIETY, at 8.30.—The Swedish Expedition; the Dutch Arctic Expedition; the Route for Future Polar Discovery: C. R. Markham, C.B., F.R.S.

TUESDAY, DECEMBER 10.

WEST LONDON SCIENTIFIC ASSOCIATION, at 8.

ANTHROPOLOGICAL INSTITUTE, at 8.—Finds in Midian: Capt. Richard F. Burton.—Notes on Skulls from Midian: Prof. R. Owen, and C. Carter Blake.—On Left-Handedness: Dr. Henry Muirhead.

WEDNESDAY, DECEMBER 11.

ROYAL MICROSCOPICAL SOCIETY, at 8.—On *Oecistes sphagni* (a New Species) and other Rotifers: Dr. Hudson.—On a New Microspectroscope without a Slit: F. H. Ward.—On Hoffman's New Form of Camera Lucida: F. Crisp, LL.B., &c.

SOCIETY OF ARTS, at 8.

THURSDAY, DECEMBER 12.

ROYAL SOCIETY, at 8.30.

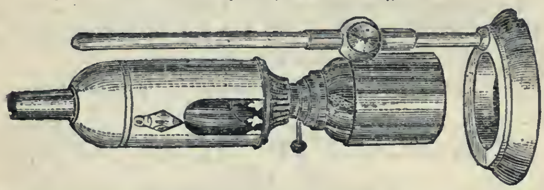
LONDON INSTITUTION, at 7.—Wingless Birds, Fossil and Living: Prof. Flower.

SOCIETY OF ARTS, at 8.—Chemical Section.

MATHEMATICAL SOCIETY, at 8.—On Motion: H. Perigal.—On Forms of Numbers determined by Continued Fractions: S. Roberts, F.R.S.—On a Graphic Construction of the Powers of a Linear Substitution: Prince Camilla de Polignac.

SATURDAY, DECEMBER 14.

PHYSICAL SOCIETY, at 3.—On a Condenser of Variable Capacity: C. Boys.—On a Differential Air Thermometer: Dr. O. J. Lodge.



Printed by R. CLAY, SONS, and TAYLOR, at 7 and 8, Bread Street Hill, Queen Victoria Street, in the City of London, and published by MACMILLAN AND CO., at the Office, 29 and 30, Bedford Street, Covent Garden.—THURSDAY, December 5, 1878.

Registered as a Newspaper at the General Post Office.]

DIARY OF SOCIETIES.

LONDON

THURSDAY, DECEMBER 12.

ROYAL SOCIETY, at 8.30.—On the Flow of Water in Uniform *régime* in Rivers and other Open Channels: Prof. James Thomson, F.R.S.—On the Magic Mirror of Japan: Professors Ayrton and Perry.—On the Torsional Strain which remains in a Glass Fibre after release from Twisting Stress: Dr. Hopkinson, F.R.S.—Note, in Correction of an Error in his Paper, Notes on Physical Geology, No. V.: Rev. Dr. Haughton, F.R.S.—Measurements of Electrical Constants, No. II.: J. E. H. Gordon.—Preliminary Note on the Compound Nature of the Chemical Elements: J. N. Lockyer, F.R.S.

SOCIETY OF ANTIQUARIES, at 8.30.—Discoveries in the Church of Ste. Marie du Castel, Guernsey: Edgar MacCulloch, F.S.A.—A Mithræum at Spoleto: H. C. Coote, F.S.A.

LONDON INSTITUTION, at 7.—Wingless Birds, Fossil and Living: Prof. Flower.

SOCIETY OF ARTS, at 8.—Chemical Section.

MATHEMATICAL SOCIETY, at 8.—On Motion: H. Perigal.—On Forms of Numbers determined by Continued Fractions: S. Roberts, F.R.S.—On a Graphic Construction of the Powers of a Linear Substitution: Prince Camilla de Polignac.

SATURDAY, DECEMBER 14.

PHYSICAL SOCIETY, at 3.—On a Condenser of Variable Capacity: C. Boys.—On a Differential Air Thermometer: Dr. O. J. Lodge.

SUNDAY, DECEMBER 15.

SUNDAY LECTURE SOCIETY, at 4.—Socialism: Miss Helen Taylor.

MONDAY, DECEMBER 16.

LONDON INSTITUTION, at 5.—The Formation of the Alps: Prof. J. W. Judd.
SOCIETY OF ARTS, at 8.—Mathematical Instruments: W. M. Williams.
MEDICAL SOCIETY, at 8.30.

TUESDAY, DECEMBER 17.

STATISTICAL SOCIETY, at 7.45.—Reports on the Demographic Congress, the International Statistical Congress, and the International Penitentiary Congress: Dr. Mouat.—Discussion on the Best Form of Statistical Annual for International Purposes.

WEDNESDAY, DECEMBER 18.

METEOROLOGICAL SOCIETY, at 7.—Abstract of the Meteorology of the Bombay Presidency: C. Chambers, F.R.S. Communicated by Sir G. B. Airy, K.C.B., F.R.S., Astronomer-Royal.—Experiments with Lowne's Anemometer: Capt. William Watson, F.M.S.—Meteorology of Bangkok, Siam: J. Campbell, Staff-Surgeon, R.N.—Results of Meteorological Observations, taken at Calvinia, South Africa: Kaufmann I. Marks, F.M.S.

GEOLOGICAL SOCIETY, at 8.—On Remains of Mastodon and other Vertebrata of the Miocene Beds of the Maltese Islands: Prof. A. Leith Adams, F.R.S.—Dinosauria of the Cambridge Greensand, Parts 1-6: Prof. H. G. Seeley, F.L.S.

SOCIETY OF ARTS, at 8.—Science Teaching in Elementary Schools: Dr. J. H. Gladstone.

ROYAL SOCIETY OF LITERATURE, at 8.—On the Ogham and Mushiggar Character: Capt. R. F. Burton.

CROYDON MICROSCOPICAL CLUB, at 8.30.

THURSDAY, DECEMBER 19.

ROYAL SOCIETY, at 8.30.
LONDON INSTITUTION, at 7.—The Abuse of Books: Frederick Harrison.
LINNEAN SOCIETY, at 8.—Note on South African Orchids: W. Mansell Weale.

CHEMICAL SOCIETY, at 8.—Researches on the Action of the Copper-Zinc Couple on Organic Compounds: Dr. Gladstone and Mr. Tribe.—On the Formula of Glyoxylic Acid: Dr. Debus.—On the Production of Oxides of Nitrogen by the Electric Arc in Air: T. Wills.—On Baric Periodate: S. Siguira and C. F. Cross.—On Erbium and Yttrium.—Dr. Humpidge and Mr. Burney.

Printed by R. CLAY, SONS, and TAYLOR, at 7 and 8, Bread Street Hill, Queen Victoria Street, in the City of London, and published by MACMILLAN AND CO., at the Office, 29 and 30, Bedford Street, Covent Garden.—THURSDAY, December 12, 1878.

EDMUND WHEELER, 48N, Tollington Road, Holloway, London, N.

LIBRARY OF HARVARD UNIVERSITY, CAMBRIDGE, MASS., U.S.A.

Packages for the General Library, or for any of the Departmental Libraries (Astronomical Observatory, Botanic Garden, Bussey Institution, Divinity School, Law School, Museum of Comparative Zoology, Scientific School), may be sent to the Agents, Messrs. TRÜBNER & Co., 57 and 59, Ludgate Hill, London.

JUSTIN WINSOR, Librarian.

BERNERS COLLEGE.—The Laboratory

and Class Rooms are open for Private and Class Study, morning and evening. ANALYSES performed. Especial arrangements for Gentlemen and Ladies preparing for the various Examining Boards. Fees moderate.—Apply to Prof. GARDNER, at Berners College, 44, Berners Street, W

PRELIMINARY SCIENTIFIC EXAMINATION.

UNIVERSITY OF LONDON.

A Class in all the subjects for this Examination is held at St. Bartholomew's Hospital and College from January to July, commencing on January 20.

The Class is open to others than Students of the Hospital. Fee for the entire Course (including practical instruction and materials)—To Students of the Hospital, £8 8*s*.; to others, £10 10*s*.

For particulars, application may be made personally or by letter to the Warden of the College, St. Bartholomew's Hospital, E C.

ROYAL SCHOOL OF MINES.

Dr. FRANKLAND, D.C.L., F.R.S., will commence a Course of Thirty Lectures on "Organic Chemistry," at South Kensington, on Friday, JANUARY 17, at 10 o'clock, to be continued on each succeeding Monday, Wednesday, and Friday, at the same hour. Fee, £3; to those who have attended the previous Course, £2.

TRENHAM REEKS, Registrar.

MATRICULATION.—LONDON UNIVERSITY.

Six months' Course. Fee, £10 10*s*.

1ST BACHELOR OF SCIENCE and PRELIMINARY SCIENTIFIC M.B. Six months' Course. Fee, £10 10*s*.

The above Classes will commence at the Royal Polytechnic, Regent Street, in January next, under the direction of Edward B. Aveling, D.Sc., F.L.S. All work practical.

The REV. LEWIS HENSLEY, Vicar of

Hitchin, Herts, and Rural Dean, formerly Fellow and Assistant-Tutor of Trinity College, Cambridge, receives several Pupils, to prepare for Cambridge, and has now a VACANCY.

SUNDAY LECTURE SOCIETY.—LEC-

TURES at ST. GEORGE'S HALL, Langham Place, each SUNDAY AFTERNOON, commencing at Four o'clock precisely. Sunday, January 5.—BENJAMIN W. RICHARDSON, Esq., M.D., LL.D., F.R.S., on "Anæsthetic Sleep, and the Temporary Abolition of Pain." Second Lecture. With Oxyhydrogen Lantern Illustrations.—Members' Annual Subscription, £1. Payment at the Door—One Penny, Sixpence, and (reserved seats) One Shilling.

ROYAL INSTITUTION OF GREAT BRITAIN,

ALBEMARLE STREET, PICCADILLY, W.

Lecture Arrangements, Three o'Clock.

PROFESSOR E. A. SCHÄFER, F.R.S.—Twelve Lectures on Animal Development; Tuesday next, January 14 to April 1.—One Guinea the Course.

J. H. GORDON, Esq.—Four Lectures on Electric Induction; Thursday next, January 16 to February 6.—Half-a-Guinea.

PROFESSOR H. G. SEELEY, F.L.S., F.G.S.—Three Lectures on Reptilian Life; Saturday, January 18, 25, February 1.—Half-a-Guinea.

Subscription to all the Courses in the Season, Two Guineas.

Friday, January 17th, at 9 P.M., PROFESSOR TYNDALL on the Electric Light.

Members and Friends only admitted.

SHEPPEY FOSSILS.

W. H. SHRUBSOLE, SHEERNESS-ON-SEA, respectfully intimates that the appeal recently made by him has been so heartily responded to, that he cannot receive any more orders for "extra selected" specimens at present.

Orders for 10*s*. Collections of 100 "good" specimens can be executed without delay.

"NOTES ON THE GEOLOGY OF SHEPPEY" post free on application.

LIVING SPECIMENS FOR THE MICROSCOPE.

THOMAS BOLTON, MICROSCOPIST'S and NATURALIST'S STUDIO, 17, ANN STREET BIRMINGHAM.

RAPHIDIOPHRYS PALLIDA,

The Freshwater Rhizopoda of F. Schulze figured in *Archiv für mikroskop. Anatomie*, vol. x. Plate xxvi. fig. 1.

An interesting marine organism which Prof. E. Ray Lankester has recognised as an *embryo* of the Polyzoa, *Alcyonidium*.

Also Floscules, some fine *Melicerta ringens*, and *Volvox globator*, &c.

Price List of Specimens on Application, with Stamped Addressed Envelope.

Weekly Announcements will be made in this place of Organisms ready for sale.

"HALL MARK" FOR THERMOMETERS.

The Kew Committee of the Royal Society hereby give Notice that after this date all Thermometers verified at the Kew Observatory will be marked, free of expense, with their monogram, "K.O.," interlaced, and a register number, in addition to the maker's number.

The Table of Errors will be furnished as usual.

By order,

G. M. WHIPPLE, Superintendent.

Kew Observatory, December 13, 1878.

Scale of Charges for Verification, &c., post free on application.

WITHERNDEN SCHOOL, CATERHAM

VALLEY, SURREY.—Principal, Mr. C. H. LAKE, B.A. Lond. (in Honours). Education on Natural Principles. A limited number of Pupils.

ROYAL POLYTECHNIC.—CLASSES for

the preparation of Students for University Examinations, under the direction of EDWARD B. AVELING, D.Sc., F.L.S. London University Matriculation, 1st and 2nd B.Sc., Preliminary Scientific M.B., Botany, Physiology, Chemistry. All the work practical.

DUNHEVED COLLEGE (LIMITED),

LAUNCESTON, CORNWALL.

Seven hours from London. SEPARATE BEDROOMS. Systematic Teaching in SCIENCE, FOREIGN LANGUAGES, and UNIVERSITY COURSES.

Calendar post free from

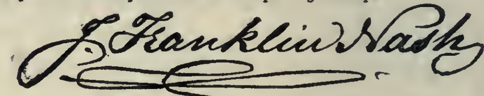
THE PRINCIPAL—BENJAMIN RALPH, LL.B. Dub.

ENGRAVINGS AND ELECTROTYPES

FOR SALE, at prices ranging from 1*s*. to 10*s*., in good condition, ready for printing. Small, medium size, and large engravings, comprising a great variety of subjects, suitable for Publishers, Advertisers, and Amateurs. Specimen of any subject required sent post free on application.

FACSIMILE OF SIGNATURE for 3*s*. An exact copy of any name guaranteed. These signatures being engraved in bold relief, are useful for Stamping Books, Circulars, and Documents, or Marking Linen, and made type-high for ordinary Letterpress Printing.

Sent post free to any address on receipt of 36 stamps.



75, FLEET STREET, LONDON, E.C.

ARTISTIC.—To Ladies and Gentlemen with

some leisure time, desiring to supplement their incomes, an opportunity is offered of acquiring the ART of DRAWING and ENGRAVING on WOOD in a thoroughly satisfactory and perfect style. The terms are moderate, and the hours can be made to suit the convenience of pupils. Persons residing in the country can receive full instruction by correspondence. For further particulars call or address Mr. J. FRANKLIN NASH, Artist and Engraver, 75, Fleet Street, London, E.C.

GEOLOGY.—In the Preface to the Student's

ELEMENTS of GEOLOGY, by Sir Charles Lyell, price 9*s*., he says:—"As it is impossible to enable the reader to recognise rocks and minerals at sight by aid of verbal descriptions or figures, he will do well to obtain a well arranged collection of specimens, such as may be procured from Mr. TENNANT (149, Strand), Teacher of Mineralogy at King's College, London." These Collections are supplied on the following terms, in plain Mahogany Cabinets:—

	£	s.	d.
100 Specimens, in Cabinet, with 3 Trays	2	2	0
200 Specimens, in Cabinet, with 5 Trays	5	5	0
300 Specimens, in Cabinet, with 9 Drawers	10	10	0
400 Specimens, in Cabinet, with 13 Drawers	21	0	0

More extensive Collections at 50 to 5,000 Guineas each.

EOZÖON CANADENSE.

JAMES R. GREGORY has just received a large number of very fine Specimens of the above, at all prices; also Sections of the same, cut for the microscope. Price of Specimens polished, 5*s*., 10*s*., and upwards. Microscopic Sections, post free, 2*s*. 2*d*. each, of

JAMES R. GREGORY,

Dodgson.—Some Experiments on Metallic Reflection: Sir John Conroy.

MATHEMATICAL SOCIETY, at 8.—On a Theorem in Elliptic Functions: Prof. Cayley, F.R.S.—On a New Modular Equation: Prof. H. J. S. Smith, F.R.S.

LONDON INSTITUTION, at 7.—The English Stage: Prof. H. Morley.

ROYAL INSTITUTION, at 3.—Juvenile Lecture; A Soap Bubble: Prof. Dewar.

FRIDAY, JANUARY 10.

QUEKETT MICROSCOPICAL CLUB, at 8.

SUNDAY, JANUARY 12.

SUNDAY LECTURE SOCIETY, at 4.—Anæsthetic Sleep (Second Lecture): Dr. B. W. Richardson.

MONDAY, JANUARY 13.

LONDON INSTITUTION, at 5.—Good and Bad Etymology: E. B. Tylor.

MEDICAL SOCIETY, at 8.30

TUESDAY, JANUARY 14.

ROYAL INSTITUTION, at 3.—Animal Development: Prof. Schäfer.

ZOOLOGICAL SOCIETY, at 8.30.—On the Habits and Changes of Plumage of Humboldt's Penguin: A. D. Bartlett.—On the Anatomy of *Hyæna crocuta*: Dr. Morrison Watson and Dr. Alfred H. Young.—On a Collection of Birds made by Mr. Huebner, on Duke of York Island and New Britain: Dr. O. Finsch, C.M.Z.S.

WEST LONDON SCIENTIFIC ASSOCIATION, at 8.

WEDNESDAY, JANUARY 15.

SOCIETY OF ARTS, at 8.—Automatic Couplings: T. A. Brocklebank.

METEOROLOGICAL SOCIETY, at 7.—Annual Meeting.

CROYDON MICROSCOPICAL CLUB, at 8.30.—Annual Meeting.

THURSDAY, JANUARY 16.

ROYAL SOCIETY, at 8.30.

LINNEAN SOCIETY, at 8.—On the Colchicaceæ and Aberrant Tribes of Liliaceæ: J. G. Baker.

LONDON INSTITUTION, at 7.—Man's Power of Modifying External Nature: Prof. Rolleston.

ROYAL INSTITUTION, at 3.—Electric Induction: J. E. H. Gordon.

FRIDAY, JANUARY 17.

ROYAL INSTITUTION, at 9.—Electric Light: Prof. Tyndall.

SATURDAY, JANUARY 18.

ROYAL INSTITUTION, at 3.—Reptilian Life: Prof. Seeley.

Printed by R. CLAY, SONS, and TAYLOR, at 7 and 8, Bread Street Hill, Queen Victoria Street, in the City of London, and published by MACMILLAN AND CO., at the Office, 29 and 30, Bedford Street, Covent Garden.—THURSDAY, January 9, 1879.

NATURE

A WEEKLY ILLUSTRATED JOURNAL OF SCIENCE

*"To the solid ground
Of Nature trusts the mind which builds for aye."*—WORDSWORTH

No. 481, Vol. 19] THURSDAY, JANUARY 16, 1879 [Price Sixpence

Registered as a Newspaper at the General Post Office.]

DIARY OF SOCIETIES.

London

THURSDAY, January 16.

Royal Society, at 8.30.—On some Points connected with the Anatomy of the Skin; and, On Hyaline Cartilage and Deceptive Appearances Produced by Reagents, as Observed in the Examination of a Cartilaginous Tumour of the Lower Jaw: Dr. G. Thin.—Volumetric Estimation of Sugar by an Ammoniated Cupric Test giving Reduction without Precipitation: Dr. Pavy, F.R.S.—On the Effect of Strong Induction Currents upon the Structure of the Spinal Cord: Dr. W. M. Ord.—Concluding Observations on the Locomotor System of Medusæ: G. J. Romanes.

Society of Antiquaries, at 8.30.—Sepulchral Remains on the Coast of Algeria: Major Heales.—Office of King's Advocate-General: E. W. Brabrook.

Linnean Society, at 8.—On the Colchicaceæ and Aberrant Tribes of Liliaceæ: J. G. Baker.

London Institution, at 7.—Man's Power of Modifying External Nature: Prof. Rolleston.

Royal Institution, at 3.—Electric Induction: J. E. H. Gordon.

FRIDAY, January 17.

Royal Institution, at 9.—Electric Light: Prof. Tyndall.

SATURDAY, January 18.

Royal Institution, at 3—Reptilian Life: Prof. Seeley.

SUNDAY, January 19.

Sunday Lecture Society, at 4.—Is Life Worth Having? T. W. Rhys Davids.

MONDAY, January 20.

London Institution, at 5.—Health and Recreation: Dr. B. W. Richardson.

Society of Arts, at 8.—Mathematical Instruments: W. M. Williams.

Medical Society, at 8.30.—Second Lettsomian Lecture.

Victoria Institute, at 8.—The Argument from Design: Dr. I. P. Thompson.—Genesis and Geology: Rev. E. Duke.

TUESDAY, January 21.

Royal Institution, at 3.—Animal Development: Prof. Schäfer.

Anthropological Institute, at 8.—On Circumcision, its Significance, its Origin, and its Kindred Rites: Elie Reclus.

Society of Arts, at 8.—Retrospect and Prospect in Egypt: B. F. Cobb.

WEDNESDAY, January 22.

Geological Society, at 8.—On Community of Structure in Rocks of Dissimilar Origin: Frank Rutley.—Distribution of the Serpentine and Associated Rocks with their Metallic Ores in Newfoundland: A. Murray, C.M.G.—The Gold Leads of Nova Scotia: H. S. Poole, M.A.

Royal Society of Literature, at 8.—On the Ogham Inscriptions and on the Mushajjar Characters: Capt. R. F. Burton.

Society of Arts, at 8.—Modern Science of Economics: H. D. Macleod.

THURSDAY, January 23.

Royal Society, at 8.30.—Researches on Chemical Equivalence, Part 1: Dr. Mills and T. W. Walton; Part 2: Dr. Mills and J. Hogarth.—Researches on Lactin: Dr. Mills and J. Hogarth.—On the Microrheometer: J. B. Hannay.—Limestone as an Index of Geological Time: T. M. Reade.—Preliminary Note on the Substances which produce Chromospheric Lines: J. N. Lockyer.

Royal Institution, at 3.—Electric Induction: J. E. H. Gordon.

London Institution, at 7.—Fauna and Flora of Prehistoric Periods: Prof. Rolleston.

FRIDAY, January 24.

Royal Institution, at 9.—The Mirror of Japan: Prof. Ayrton.

Quekett Microscopical Club, at 8.—On the Urticating Threads of *Actinia parasitica*: F. A. Bedwell, M.A., F.R.M.S.—On a New Method of Preparing a Dissected Model of an Insect's Brain, from Microscopic Sections: E. T. Newton, F.G.S.

SATURDAY, January 25.

Royal Institution, at 3.—Reptilian Life: Prof. Seeley.

Physical Society, at 3.

Printed by R. CLAY, SONS, and TAYLOR, at 7 and 8, Bread Street Hill, Queen Victoria Street, in the City of London, and published by MACMILLAN AND Co., at the Office, 29 and 30, Bedford Street, Covent Garden.—THURSDAY, January 16, 1879

PHOTOGRAPHED SPECTRA. One

Hundred and Thirty-six Photographs of Metallic, Gaseous, and other Spectra printed by the Permanent Autotype Process, with Introduction, Description of Plates, and Index, and with an extra Plate of the Solar Spectrum (showing bright lines), compared with the Air Spectrum. By J. RAND CAPRON, F.R.A.S.

". . . . Mr. Capron has earned the thanks of spectroscopists for the large amount of useful work which he has performed for them in the way of preliminary investigation. No exact scale or measurement accompany the photographs, and they will be chiefly useful in indicating by comparison with each other the lines which belong to particular metals, and the conditions under which particular lines are produced. . . . . But although no exact measurements are given, and although the photographs vary very perceptibly in length, nearly all show lines which can be used as reference lines, by measurement from which the wave-lengths of the metal lines can be determined. . . . . The advantages of the photographic method are noticed by the author as follows :—' Absolute truth is everything in spectroscopic work, and the very best draughtsman working with the most perfect micrometer cannot, even at the expense of a vast amount of labour, equal in accuracy a good photograph of a set of spectral lines.' . . . . The photographs obtained from the electric light are particularly interesting. This is, as far as we know, the first extensive series of measurements of spectra obtained by the ignition of substances in the electric arc."—*Philosophical Magazine.*

London : E. & F. N. SPON, 46, Charing Cross.

CHEAPER EDITION, REVISED AND ENLARGED.

This day is published, price 7*s.* 6*d.*

PROFESSOR JOHNSTON'S

CHEMISTRY OF COMMON LIFE.

NEW EDITION.

Revised and brought down to the Present Time.

BY ARTHUR HERBERT CHURCH, M.A. OXON.,

Author of "Food, its Sources, Constituents, and Uses," &c., &c.

Illustrated with Maps and numerous Engravings on Wood.

One Volume, crown 8vo, pp. 618.

SUMMARY OF CONTENTS.

The Air we Breathe—The Water we Drink—The Soil we Cultivate—The Plant we Rear—The Bread we Eat—The Beef we Cook—the Beverages we Infuse—The Sweets we Extract—The Liquors we Ferment—The Narcotics we Indulge in—The Poisons we Select—The Odours we Enjoy—The Smells we Dislike—The Colours we Admire—What we Breathe and Breathe for—What, How, and Why we Digest—The Body we Cherish—The Circulation of Matter.

WILLIAM BLACKWOOD & SONS, Edinburgh and London.

Price 7*s.* 6*d.*

DESCRIPTION OF THE CHEMICAL

LABORATORIES AT THE OWENS COLLEGE. By Prof. H. E. ROSCOE, F.R.S. From the Plans of ALFRED WATERHOUSE, A.R.A.

J. E. CORNISH, 33, Piccadilly, Manchester.

THE ENTOMOLOGIST'S MONTHLY MAGAZINE.

Price Sixpence, Monthly, 24 pages 8vo, with occasional Illustrations. Conducted by J. W. DOUGLAS, R. MCLACHLAN, F.R.S., E. C. RYE, F.Z.S. and H. T. STAINTON, F.R.S.

This Magazine, commenced in 1864, contains standard articles and note on all subjects connected with Entomology and especially on the Insects of the British Isles.

Subscription—Six Shillings per Volume, post free. The volumes commence with the June number in each year.

Vols. I. to V. (strongly bound in cloth) may be obtained by purchasers of the entire set to date, at the increased price of 10*s.* each ; the succeeding vols. may be had separately or together, at 7*s.* each.

London : JOHN VAN VOORST, 1, Paternoster Row.

N.B.—Communications, &c., should be sent to the Editors at the above address.

THE JOURNAL OF BOTANY,

BRITISH AND FOREIGN.

Edited by HENRY TRIMEN, M.B., F.L.S., British Museum ; assisted by S. le M. MOORE, F.L.S., Royal Herbarium, Kew.

On and after January 1, 1878, the JOURNAL OF BOTANY will be printed and published by T. P. NEWMAN, 32, Botolph Lane, E.C., to whom Subscriptions for 1878 should be sent. The volume for 1877 (price 16*s.* 6*d.*, bound in cloth), covers for the volume (price 1*s.*), and back Numbers, can also be obtained of Mr. NEWMAN. The Annual Subscription, payable in advance, is 12*s.*, post free in the United Kingdom. Post-Office Orders payable at EASTCHEAP.

On the 1st of every Month, price Sixpence.

THE ENTOMOLOGIST:

AN ILLUSTRATED JOURNAL OF BRITISH ENTOMOLOGY.

Edited by JOHN T. CARRINGTON,

With the Assistance of

FREDERICK BOND, F.Z.S.	FREDERICK SMITH, F.L.S.
EDWARD A. FITCH.	J. JENNER WEIR, F.L.S.
JOHN A. POWER, M.D.	F. BUCHANAN WHITE, M.D.

The *Entomologist* was founded for the purpose of diffusing information with regard to the science generally, and especially respecting Insects injurious to Farm or Garden ; for Recording the Capture of Rarities ; and for Figuring Varieties. Monthly Lists of Duplicates and Desiderata are published.

Interesting articles on all branches of the science are promised by leading entomologists. Especial attention is given to the printing of the WOODCUT ILLUSTRATIONS, which are numerous. There are occasionally COLOURED PLATES.

SIMPKIN, MARSHALL, and CO., Stationers' Hall Court.

JOURNAL OF PHYSIOLOGY.

THE

CLASSIFIED LIST OF TITLES OF BOOKS AND PAPERS

On subjects of Physiological Interest published during the year 1878, has been issued to all subscribers.

Any subscriber not having received his copy is requested to communicate with Messrs. MACMILLAN.

LA SEMAINE FRANÇAISE.—For General and Family Reading.

LA SEMAINE FRANÇAISE.—"Tel est le titre d'un journal hebdomadaire, nous pourrions dire d'une revue de tous les journaux français accrédités. Ce journal réunit, sous le même couvert, 24 ou 32 pages grand format, et dans ces pages sont publiés, en français, les meilleurs articles, politiques, critiques, et littéraires, qui ont paru pendant la semaine dans les journaux de Paris. Assurément le numéro que nous avons sous les yeux est un excellent spécimen de ce que peut faire un heureux choix, guidé par une intelligence parfaite de ce qui peut intéresser les lecteurs."—*Nouvelle Chronique de Jersey.*

LA SEMAINE FRANÇAISE.—"The numbers before us are full of good things. . . . . It will be far better for most than any one of the best papers published in Paris itself. We are much pleased with the character of it, and believe it will be highly valued in all those many households where French is cultivated. The printing is very well done."—*Queen.*

THE MONTHLY JOURNAL OF SCIENCE

AND ANNALS OF
BIOLOGY, ASTRONOMY, GEOLOGY, INDUSTRIAL ARTS, MANUFACTURES, AND TECHNOLOGY.

Edited by WILLIAM CROOKES, F.R.S., &c.

On Monday next, No. LXIV., April, 1879.
Price ONE SHILLING and SIXPENCE.

CONTENTS:—

I. Is Nature Perfect?
II. Thoughts on our Conceptions of Physical Law. By Prof. Francis E. Nipher.
III. The Old Stannaries of the West of England. By James Quick.
IV. A New Theory of Terrestrial Magnetism. By Profs. Perry and Ayrton.
V. The Jablochkoff Candle: its Practical Results in London. By Charles W. Quin.
VI. The Tornado in Wisconsin in 1878.
VII. The Electric Light for India.
VIII. Painless Death.
Correspondence.—The Sea Serpent.—Spider's Web for Micrometers.—The Senses of the Lower Animals.—Optical Illusions.
Reviews of Books—Science Notes, &c., &c.

London: 3, Horse-Shoe Court, Ludgate Hill, E.C.

Just published, price 1*s.* post free.

IS NATURE CRUEL?

By Rev. H. H. HIGGINS, M.A.
Liverpool: GILBERT G. WALMSLEY, 50, Lord Street.

GARDENING ILLUSTRATED: a new

Weekly Journal for all interested in Gardening in Town or Country. Price 1*d.* weekly. Profusely Illustrated. Flowers, Fruits, Vegetables, Town and Suburban Gardening, Villa Gardening, the Cottage Garden, Window Gardening, Work in the Garden for every week. May be had of all Newsagents and at the Book-stalls, 1*d.* every Saturday. Post free for twelve months for 6*s* 6*d.* Specimen copy, 1½*d.* in stamps. Office, 37, Southampton Street, Covent Garden, London, W.C.

NOW READY, PART XV., Price 4*s.* 6*d.*,

THE JOURNAL OF PHILOLOGY.

EDITED BY
WILLIAM ALDIS WRIGHT, M.A.,
Fellow of Trinity College, Cambridge.
INGRAM BYWATER, M.A.,
Fellow of Exeter College, Oxford.
AND
HENRY JACKSON, M.A.,
Fellow of Trinity College, Cambridge.

CONTENTS:—

How were the Bodies of Criminals at Athens Disposed of after Death? Herman Hager.
Upon Notices of Army Surgeons in Ancient Greek Warfare. H. Hager.
"Shall" and "Should" in Protasis, and their Greek Equivalents. W. W. Goodwin.
Lucretius Prœmium and Epicurean Theology. John Masson.
Notes on the Æneid. H. Nettleship.
An Interpretation of יזה גוים. C. Taylor.
A Word of Lucilius. R. Ellis.
On the Dirae. R. Ellis.
On some Passages in the Medea of Euripides. W. C. Green.
On some Peculiarities in the Use of the Future Participles of Greek Verbs. F. A. Paley.
On Choephoroe 472—3 (481—2 Dind.). F. A. Paley.
On the MS. of Sophocles in the Library of Trinity College, Cambridge. L. Campbell.
The Antigone of Sophocles. Two Criticisms. Evelyn Abbott.
Note on Odyssey v. 368. Henry Molden.
Note on Xenophon's Hellenics. I. c. vii. § 2. Henry Malden.
On the word βουγαιος and the Prefix βου-. J. P. Postgate
Some New Latin Fragments R. Ellis.
Judges and Litigants. Perceval M. Laurence.
On Early Greek Written Literature. Henry Hayman.
Some Further Observations on Ancient Theories of Causation. D. D. Heath.
William George Clark. H. A. J. Munro.

MACMILLAN & CO., London.

THE BEST FARMERS' NEWSPAPER.

THE CHAMBER OF AGRICULTURE JOURNAL AND FARMERS' CHRONICLE,

Edited by JOHN ALGERNON CLARKE, Secretary to the Central Chamber of Agriculture,

Devotes special attention to the discussions and proceedings of the Chamber of Agriculture of Great Britain (which now number upwards of 18,000 members), besides giving original papers on practical farming, and a mass of intelligence of particular value to the agriculturist.

The London Corn, Seed, Hop, Cattle, and other Markets of Monday are specially reported in this Journal, which is despatched the same evening so as to ensure delivery to country subscribers by the first post on Tuesday morning. Price 3*d.*, or prepaid, 15*s.* a year post free.

Published by W. PICKERING 21, Arundel Street, Strand, W.C.

On the 1st of every Month, price Sixpence.

THE ENTOMOLOGIST:

AN ILLUSTRATED JOURNAL OF BRITISH ENTOMOLOGY.
Edited by JOHN T. CARRINGTON,
With the Assistance of

FREDERICK BOND, F.Z.S.	FREDERICK SMITH, F.L.S.
EDWARD A. FITCH.	J. JENNER WEIR, F.L.S.
JOHN A. POWER, M.D.	F. BUCHANAN WHITE, M.D.

The *Entomologist* was founded for the purpose of diffusing information with regard to the science generally, and especially respecting Insects injurious to Farm or Garden; for Recording the Capture of Rarities; and for Figuring Varieties. Monthly Lists of Duplicates and Desiderata are published.

Interesting articles on all branches of the science are promised by leading entomologists. Especial attention is given to the printing of the WOODCUT ILLUSTRATIONS, which are numerous. There are occasionally COLOURED PLATES.

SIMPKIN, MARSHALL, and CO., Stationers' Hall Court.

THE BREWERS' GUARDIAN:

A Fortnightly Paper devoted to the Protection of Brewers' Interests, Licensing, Legal, and Parliamentary Matters.
REVIEW OF THE MALT AND HOP TRADES; AND WINE AND SPIRIT TRADE RECORD.
The Organ of the Country Brewers.

"The Brewers' Guardian" is published on the evenings of every alternate Tuesday, and is the only journal officially connected with brewing interests.

Subscription, 16*s.* 6*d.* per annum, post free, dating from any quarter-day. Single Copies, 1*s.* each. Registered for transmission abroad.

Offices—5, Bond Court, Walbrook, London E.C.

DIARY OF SOCIETIES.

LONDON

THURSDAY, MARCH 27.

ROYAL SOCIETY, at 8.30.—On the Organisation of the Fossil Plants of the Coal-measures, Part X.: Prof. W. C. Williamson.—Observations on the Physiology and Histology of *Convoluta Schultzii*: P. Geddes.
ROYAL INSTITUTION, at 3.—Sound: Prof. Tyndall.
SOCIETY OF ARTS, at 8.—Dodé's Process of Inoxidating Iron: L. M. Stoffel.
LONDON INSTITUTION, at 7.—The Harmonium: Ebenezer Prout.

FRIDAY, MARCH 28.

ROYAL INSTITUTION, at 9.—Etching: Seymour Haden.
QUEKETT MICROSCOPICAL CLUB, at 8.—On the "Dual-Lichen" Hypothesis: Dr. M. C. Cooke, M.A.—On a Successf l Method of Examining the Anatomy of *Actinia mesembryanthemum*: F. A. Bedwell, M.A.
SOCIETY OF ARTS, at 8.—Ship Canal through Ramiseran Island: S. McBean.

SATURDAY, MARCH 29.

GEOLOGISTS' ASSOCIATION.—Visit to the British Museum at 2.30.

SUNDAY, MARCH 30.

SUNDAY LECTURE SOCIETY, at 4.—Joseph Mazzini: Wm. Clarke.

MONDAY, MARCH 31.

MEDICAL SOCIETY, at 8.30.
INSTITUTE OF ACTUARIES, at 7.—On the Construction of a Combined Marriage and Mortality Table: T. B. Sprague.

TUESDAY, APRIL 1.

ZOOLOGICAL SOCIETY, at 8.30.—To exhibit and make Remarks on a Drawing of the Dolphin (*Delphinus delphis*): Prof. Flower.—Remarks on the Bird's Eggs Collected during the *Challenger* Expedition: Mr. Sclater.—A Contribution to the Avi-fauna of the Zooloo Archipelago: R. Bowdler Sharpe, F.Z.S.
ROYAL INSTITUTION, at 3.—Animal Development: Prof. Schäfer.
STATISTICAL SOCIETY, at 7.45.—The Silver Question: Stephen Bourne.
SOCIETY OF ARTS, at 8.—African Section; Remarks upon an Old Map of Africa contained in Janson's Atlas, published in Paris in 1612, and exhibited by R. Ward.—The Submarine Telegraph to South Africa: J. Sivewright.

WEDNESDAY, APRIL 2.

ENTOMOLOGICAL SOCIETY, at 7.
SOCIETY OF ARTS, at 8.—Some Causes of the Recent Depression in Trade: B. Francis Cobb.

THURSDAY, APRIL 3.

ROYAL SOCIETY, at 8.30.—On the Thermal Conductivity of Water: J. T. Bottomley.—The Preparation in a State of Purity of the Group of Metals known as the Platinum Series, and Notes upon Iridio-Platinum: Geo. Matthey.—On the Reversal of the Lines of Metallic Vapours, No. VI.: Profs. Liveing and Dewar.
ROYAL INSTITUTION, at 3.—Sound: Prof. Tyndall.
CHEMICAL SOCIETY, at 8.—On the Transformation of Aurin into Trimethylpararosaniline: R. S. Dale and C. Schorlemmer.—On a Gold Nugget from South America: Mr. Attwood.—On the Solution of Aluminium Hydrate by Ammonia and a Physical Isomeride of Alumina: G. C. F. Cross.
LINNEAN SOCIETY, at 8.—Notes on *Moquilea*, &c.: John Miers.

FRIDAY, APRIL 4.

GEOLOGISTS' ASSOCIATION, at 8.
ROYAL INSTITUTION, at 9.—Molecular Physics: Mr. Crookes.

SATURDAY, APRIL 5.

ROYAL INSTITUTION, at 3.—Etching: Seymour Haden.

Office: 29, Bedford Street, Strand.

NOW READY,
SECOND EDITION,

GRIFFIN'S CHEMICAL HANDICRAFT.

PRICE 4s. 7d. POST FREE.

A CATALOGUE OF CHEMICAL APPARATUS:

ILLUSTRATED, CLASSIFIED DESCRIPTIVE.

Demy 8vo, 480 pp., Illustrated with 1,600 Woodcuts.

Most Complete and Cheapest List of Apparatus.

JOHN J. GRIFFIN AND SONS, 22, GARRICK STREET, LONDON, W.C.

EDWARD PATERSON,

Electrical Engineer and Scientific Apparatus Manufacturer,

3, BEDFORD COURT, COVENT GARDEN, LONDON.

STEAM WORKS, GRAY'S INN ROAD.

Experiments in Electric Lighting carried out.

Electrical Apparatus of all descriptions for Lecture Purposes Loaned out.

APPARATUS FOR CLASS DEMONSTRATION and for SCIENCE SCHOOLS.
ELECTRIC LIGHT APPARATUS.
SIEMEN'S and GRAMME'S DYNAMO MACHINES and LAMPS for Hire and Purchase.
LARGE ASSORTMENT of RUHMKORFF COILS and VACUUM TUBES.
PROFESSOR HUGHES' MICROPHONE.
ELECTRIC BELLS and INDICATORS.
TELEPHONES and TELEPHONE CALL BELLS, WIRE, &c., for Fixing.
PROF. S. P. THOMPSON'S LANTERN SLIDE GALVANOMETER, 20s.
EDISON'S ELECTRIC PEN £8 8s.
ELECTRIC and MAGNETIC APPARATUS of all Descriptions.

New Illustrated Catalogue of 60 pages post free 6 stamps.

Orders over £2 carriage paid to any part of the United Kingdom.

THE ENTOMOLOGIST'S MONTHLY MAGAZINE.

Price Sixpence, Monthly, 24 pages 8vo, with occasional Illustrations. Conducted by J. W. DOUGLAS, R. MCLACHLAN, F.R.S., E. C. RYE, F.Z.S. and H. T. STAINTON, F.R.S.

This Magazine, commenced in 1864, contains standard articles and note on all subjects connected with Entomology and especially on the Insects of the British Isles.

Subscription—Six Shillings per Volume, post free. The volumes commence with the June number in each year.

Vols. I. to V. (strongly bound in cloth) may be obtained by purchasers of the entire set to date, at the increased price of 10s. each; the succeeding vols. may be had separately or together, at 7s. each.

London: JOHN VAN VOORST, 1, Paternoster Row.

N.B.—Communications, &c., should be sent to the Editors at the above address.

THE MINIATURE MICROSCOPE LAMP

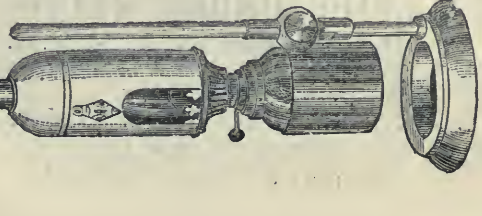
(REGISTERED)

PRICE 14s. PORTABLE TIN CASE FOR DITTO, 2s. 6d.

JAMES HOW & Co.,

SCIENTIFIC INSTRUMENT MAKERS,

5, *ST. BRIDE ST. (late 2, Foster Lane), LONDON.*



S. C. TISLEY & Co., OPTICIANS,

172, BROMPTON ROAD, S.W.
(Close to South Kensington Museum).

THE PHONEIDOSCOPE

An Instrument for Observing the Colour-Figures of Liquid Films under the action of Sonorous Vibrations.

Being a visible demonstration of the Vibratory and Molecular Motion of a Telephone Plate.

The PHONEIDOSCOPE, with 3 Discs, Bottle of Solution, Descriptive Pamphlet, &c., in Cardboard Box, 10s. 6d.

MANUFACTURED AND SOLD WHOLESALE AND RETAIL BY
S. C. TISLEY & CO., 172, BROMPTON ROAD, LONDON, S.W.

TELEPHONIC ELECTRICITY. All Materials supplied for experimental purposes

Price Lists of Electrical and Acoustic Apparatus, with Drawings and Description of the Harmonograph, Post Free, 2d.

ENGRAVINGS AND ELECTROTYPES

FOR SALE, at prices ranging from 1s. to 10s., in good condition, ready for printing. Small, medium size, and large engravings, comprising a great variety of subjects, suitable for Publishers, Advertisers, and Amateurs. Specimen of any subject required sent post free on application.

FACSIMILE OF SIGNATURE for 3s. An exact copy of any name guaranteed. These signatures being engraved in bold relief, are useful for Stamping Books, Circulars, and Documents, or Marking Linen, and made type-high for ordinary Letterpress Printing.

Sent post free to any address on receipt of 36 stamps.

J. Franklin Nash

75, FLEET STREET, LONDON, E.C.

ARTISTIC.—To Ladies and Gentlemen with

some leisure time, desiring to supplement their incomes, an opportunity is offered of acquiring the ART of DRAWING and ENGRAVING on WOOD in a thoroughly satisfactory and perfect style. The terms are moderate, and the hours can be made to suit the convenience of pupils. Persons residing in the country can receive full instruction by correspondence. For further particulars call or address Mr. J. FRANKLIN NASH, Artist and Engraver, 75, Fleet Street, London, E.C.

THE JOURNAL OF BOTANY,

BRITISH AND FOREIGN.

Edited by HENRY TRIMEN, M.B., F.L.S., British Museum; assisted by S. le M. MOORE, F.L.S., Royal Herbarium, Kew.

On and after January 1, 1878, the JOURNAL OF BOTANY will be printed and published by T. P. NEWMAN, 32, Botolph Lane, E.C., to whom Subscriptions for 1878 should be sent. The volume for 1877 (price 16s. 6d., bound in cloth), covers for the volume (price 1s.), and back Numbers, can also be obtained of Mr. NEWMAN. The Annual Subscription, payable in advance, is 12s., post free in the United Kingdom. Post-Office Orders payable at EASTCHEAP.

Walker, Henry Herbert, 344, Glossop-road, Sheffield.
Williams, P. Caradoc, 6, Parliament-place, Liverpool.

Fellows and Associates are requested to give notice of Change of Address to the Secretary.

LIBRARY OF HARVARD UNIVERSITY, CAMBRIDGE, MASS., U.S.A.

Packages for the General Library, or for any of the Departmental Libraries (Astronomical Observatory, Botanic Garden, Bussey Institution, Divinity School, Law School, Museum of Comparative Zoology, Scientific School), may be sent to the Agents, Messrs. TRÜBNER & Co., 57 and 59, Ludgate Hill, London.

JUSTIN WINSOR, Librarian.

WITHERNDEN SCHOOL, CATERHAM VALLEY, SURREY.—Principal, Mr. C. H. LAKE, B.A. Lond. (in Honours). Education on Natural Principles. A limited number of Pupils.

LABORATORY, 38, GRACECHURCH STREET, LONDON, E.C.

A. ANTHONY NESBIT, F.C.S.,

WATER ANALYST,

Performs every description of Water Analysis on moderate terms.

Properly cleansed bottles for the reception of samples sent to any part of the Kingdom.

MINERALOGY AND GEOLOGY.

A New List of Collections of Fossils, Minerals, and Rocks now ready, including Special Collections to illustrate the various Text-books, in Cabinets. List of Sections of Rocks for the Microscope. Blowpipe Apparatus and Materials of all kinds in Cases or separately. New Patterns of Geological Hammers, with prices. List of New and Second-hand Books of

JAMES R. GREGORY,

MUSEUM OF GEOLOGY,

88, CHARLOTTE STREET, FITZROY SQUARE.

THIN GLASS FOR MICROSCOPIC MOUNTING, of best quality. Circles, 3*s.* 6*d.* per ounce; Squares, 2*s.* 9*d.*; post free 2*d.* extra; Ground edged Slips, 5*s.* per gross; also other Mounting Materials and Objects prepared for mounting.—CHAS. PETIT, 151, High Street, Stoke Newington, N.

GEOLOGY.—In the Preface to the Student's ELEMENTS of GEOLOGY, by Sir Charles Lyell, price 9*s.*, he says: —"As it is impossible to enable the reader to recognise rocks and minerals at sight by aid of verbal descriptions or figures, he will do well to obtain a well arranged collection of specimens, such as may be procured from Mr. TENNANT (149, Strand), Teacher of Mineralogy at King's College, London." These Collections are supplied on the following terms, in plain Mahogany Cabinets:—

100 Specimens, in Cabinet, with 3 Trays	£2	2	0
200 Specimens, in Cabinet, with 5 Trays	5	5	0
300 Specimens, in Cabinet, with 9 Drawers	10	10	0
400 Specimens, in Cabinet, with 13 Drawers	21	0	0

More extensive Collections at 50 to 5,000 Guineas each.

SHEPPEY FOSSILS.

W. H. SHRUBSOLE, SHEERNESS-ON-SEA, respectfully intimates that the appeal recently made by him has been so heartily responded to, that he cannot receive any more orders for "extra selected" specimens at present.

Orders for 10*s.* Collections of 100 "good" specimens can be executed without delay.

"NOTES ON THE GEOLOGY OF SHEPPEY" post free on application.

ELECTRICAL & SCIENTIFIC APPARA-TUS for AMATEURS and the TRADE.—Microphones of every form, from 1*s.* 6*d.* New cheap Electric Lamps and Batteries. Induction Coils and Frictional Machines are specialties. Electrical Bells, Fire and Thief Alarms, and Automatic Switch-boards. Magnets, Covered Wires, Screws, and all Materials. Apparatus for Science Teachers. Illustrated Catalogue, one stamp. Repairs and Alterations. Apparatus made to sketch.—DALE & CRAMPTON, Manufacturing Electricians, 4, Little Britain, E.C.

DIAMONDS IN MATRIX.

R. C. NOCKOLD, Diamond and Oriental Stone Cutter and Dealer, has for sale specimens of the above; also Cut Precious Stones in all Colours. 12, FRITH STREET, SOHO, W.

MINERALOGY AND GEOLOGY.

24 assorted Minerals for Blowpipe Experiments, with printed List, in Pocket Case, 2*s.*; 24 ditto (second series), 2*s.*; Moh's Scale of Hardness of Minerals, 9 Specimens with File and streak tablet in a convenient Case, 4*s.*; von Kohbell's Scale of Fusibility of Minerals, 6 Specimens in Pocket Case, 2*s.*; Geological Collecting Bag complete, 4*s.*; Ditto Hammer Holder and Strap, 2*s.* Geological Charts, Books, Hammers, Chisels, Lenses, Acid Bottles, Glass-capped Boxes, Cement for Mounting and Repairing Fossils, Tablets, Card Trays, &c., &c. Minerals, Fossils, and Rocks, sent on approval and for selection to all parts of the world.

THOMAS J. DOWNING,

38, WHISKIN STREET, LONDON, E.C.

CATALOGUES FREE.

MINERALOGY AND GEOLOGY.

COLLECTIONS ILLUSTRATING ABOVE SCIENCES FROM 4*s.*

ALSO SINGLE SPECIMENS AT VERY REASONABLE PRICES.

POLISHED STALAGMITE AND FLUOR SPAR.

SCRAPS FOR BLOWPIPES 1*s.* per doz. boxes.

TABLE OF HARDNESS, 2*s.* 6*d.*

GEOLOGICAL CHISELS AND HAMMERS.

PRIVATE LESSONS AND EVENING CLASSES.

SAMUEL HENSON,

277 (*Late* 113*a*), STRAND, LONDON, W.C.

"To the solid ground
Of Nature trusts the mind which builds for aye."—WORDSWORTH

No. 495, Vol. 19] THURSDAY, APRIL 24, 1879 [Price Sixpence

CLIFFORD TESTIMONIAL FUND.

The friends of PROFESSOR CLIFFORD, who was compelled by ill health to relinquish active work and reside in Madeira, were anxious to present him with a substantial Testimonial in public recognition of his great scientific and literary attainments.

At a meeting held at the Royal Institution, Albemarle Street, on Friday, January 31st, WILLIAM SPOTTISWOODE, Esq., President of the Royal Society, in the Chair, it was resolved that a Fund should be raised for the above-mentioned purpose, and that the sums received should be placed in the hands of Trustees, for the benefit of PROFESSOR CLIFFORD and his family.

PROFESSOR CLIFFORD *died at Madeira on March 3rd. The Executive Committee have now to announce that it is intended to proceed with the raising of the Fund for the benefit of his Widow and Children, who have no other provision.*

Contributions may be paid to the account of the "Clifford Testimonial Fund," with Messrs. Robarts, Lubbock, and Co., or to either of the Honorary Secretaries.

GENERAL COMMITTEE.

WILLIAM SPOTTISWOODE, Esq., President of the Royal Society, Chairman.

DIARY OF SOCIETIES.

LONDON

THURSDAY, APRIL 24.

ROYAL SOCIETY, at 8.30.—On the Nature of the Fur on the Tongue: H. T. Butlin.—Note on the Supplementary Forces concerned in the Abdominal Circulation in Man; and, Note on the Auxiliary Forces concerned in the Circulation of the Pregnant Uterus, and its Contents in Woman: Dr. J. B. Hicks, F.R.S.—Summary of an Inquiry into the Functions of Respiration at various Altitudes on the Island and Peak of Teneriffe: Dr. W. Marcet, F.R.S.—Further Researches on the Physiology of Sugar in Relation to the Blood: Dr. Pavy, F.R.S.

ROYAL INSTITUTION, at 3.—Dissociation: Prof. Dewar.

FRIDAY, APRIL 25.

ROYAL INSTITUTION, at 9.—Generic Images: Fr. Galton.

QUEKETT MICROSCOPICAL CLUB, at 8.—On a Method of Resolving the Finest-lined Diatomaceous Tests: Adolf Schulze.—On the Reproductive System of Certain of the Acarina: A. D. Michael, F.R.M.S.

SATURDAY, APRIL 26.

ROYAL INSTITUTION, at 3.—Architecture: H. H. Statham.

PHYSICAL SOCIETY, at 3.—On Selective Reflection: Capt. Abney.—On some Phenomena connected with Magneto-Electric Induction: C. Boys.—Notes from the Physical Laboratory of University College, Bristol: Dr. S. P. Thompson.

MONDAY, APRIL 28.

SOCIETY OF ARTS, at 8.—Recent Advances in Telegraphy: W. H. Preece.

MEDICAL SOCIETY, at 8.30.

INSTITUTE OF ACTUARIES, at 7.—A Suggestion towards adding a New Feature of Usefulness to the Institute of Actuaries of Great Britain and Ireland: Cornelius Walford.

TUESDAY, APRIL 29.

ANTHROPOLOGICAL INSTITUTE, at 8.—Notes on Analogies of Manners between the Indo-Chinese Races and the Races of the Indian Archipelago: Col. Henry Yule, C B.—Relationships, and the names used for them, among the Peoples of Madagascar, chiefly the Hovas; together with Observations upon Marriage Customs and Morals among the Malagasy: Rev. James Sibree, Jun.

ROYAL INSTITUTION, at 3.—Mendelssohn: Ernest Pauer.

SOCIETY OF ARTS, at 8.—Railways in Africa: J. F. Bell and J. C. Morrell.

WEDNESDAY, APRIL 30.

SOCIETY OF ARTS, at 8.—Discussion on Mr. Hollway's Paper on a New Process in Metallurgy.

GEOLOGICAL SOCIETY, at 8.—A Contribution to the History of Mineral Veins: J. Arthur Phillips.—*Vectisaurus valdensis*, a New Wealden Dinosaur: J. W. Hulke, F.R.S.—The Cudgegong Diamond-field, New South Wales: Norman Taylor. Communicated by R. Etheridge, Jun.—On the Occurrence of the Genus *Dithyrocaris* in the Lower Carboniferous, or Calciferous Sandstone Series of Scotland; and on that of a Second Species of *Anthrapalæmon* in these Beds: R. Etheridge, Jun.

THURSDAY, MAY 1.

ROYAL SOCIETY, at 8.30.—A Magnetic Survey of the Fortieth Parallel in North America between the Atlantic Ocean and the Great Salt Lake, Utah: Prof. Thorpe.—On Certain Definite Integrals occurring in Spherical Harmonic Analysis, and on the Expansion in Series of the Potentials of the Ellipsoid and the Ellipse: W. D. Niven.—On the Origin of the Parallel Roads of Lochaber, and their Bearing on other Phenomena of the Glacial Period: Prof. Prestwich.

CHEMICAL SOCIETY, at 8.—On the Volumes of Liquids at their Boiling Points obtainable from Unit Volumes of Gases: Dr. W. Ramsay.—On a Method of Precipitating Manganese entirely as Dioxide, and its Application to the Volumetric Determination of Manganese: S. Pattinson.—On the Determination of Nitric Acid as Nitric Oxide by Means of its Action on Mercury: R. Warrington.

ROYAL INSTITUTION, at 2.—Annual Meeting.

LINNEAN SOCIETY, at 8.—Note on the Occurrence of a Restiaceous Plant in Cochin China: Dr. Maxwell Masters.—On the Structure of the Pouched Rats of the Genus *Heteromys*: Dr. J. Murie.—Nutrition in its Relation to the Fertilisation of Flowers: Thos. Meehan.

FRIDAY, MAY 2.

ROYAL INSTITUTION, at 9.—Action of Anæsthetics: Prof. McKendrick.

SOCIETY OF ARTS, at 8.—The Wild Silks of India: Thos. Wardle.

GEOLOGISTS' ASSOCIATION, at 7.30.

SATURDAY, MAY 3.

ROYAL INSTITUTION, at 3.—Architecture: H. H. Statham.
